With increasing globalization, the impacts of climate change outside the European region are likely to have implications for countries within the region. For example, the Mediterranean region (Southern Europe and non-European Mediterranean countries) has been considered high vulnerable to climate change (Navarra, 2013). Eastern European countries have, in general, lower adaptive capacity than Western or Northern European countries. The high volume of international travel increases Europe’s vulnerability to invasive species, including the vectors of human and animal infectious diseases. The transport of animals and animal products has facilitated the spread of animal diseases (Conraths and Mettenleiter, 2011). Important “exotic” vectors that have become established in Europe include the vector *Aedes albopictus* (Becker, 2009) (23.5.1).

Another inter-regional implication concerns the changes in the location of commercial fish stocks shared between countries. Such changes may render existing international agreements regarding the sharing of yield from these stocks obsolete giving rise to international disputes (Arnason, 2012). For instance, the North Sea mackerel stock has recently been extending westwards beyond the EU jurisdiction into the Exclusive Economic Zones of Iceland and the Faroe Islands, which unilaterally claimed quota for mackerel Territorial disagreements of this type could increase in the future with climate change.

Although several studies have proposed a role of climate change to increase migration pressures in low and middle income countries in the future, there is little robust information regarding the role of climate change, environmental resource depletion and weather disasters in future inter-continental population movements. The effect of climate change on external migration flows into Europe is highly uncertain (see chapter 12.4.1 for a more complete discussion). Modelling future migration patterns is complex and so far no robust approaches have been developed.

23.9.3. Effects of Observed Climate Change in Europe

Table 23-6 summarises the evidence with respect to key indicators in Europe for the detection of a trend and the attribution of that trend to observed changes in climate factors. The attribution of local warming to anthropogenic climate change is less certain (see Chapter 18 for a full discussion). Further and better quality evidence since 2007 supports the conclusion of AR4 (Europe chapter, Alcamo et al., 2007) that climate change is affecting land, freshwater and marine ecosystems in Europe. Observed warming has caused advancement in the life cycles of many animal groups, including frogs spawning, birds nesting and the arrival of migrant birds and butterflies (see WGII chapter 4 and review by (Feehan *et al.*, 2009). There is further evidence that observed climate change is already affecting agricultural, forest and fisheries productivity (see 23.4).

The frequency of river flood events, and annual flood and windstorm damages in Europe have increased over recent decades, but this increase is mainly due to increased exposure and the contribution of observed climate change is unclear (high confidence – based on robust evidence and high agreement)(SREX 4.5.3, (Barredo, 2010).

The observed increase in the frequency of hot days and hot nights (high confidence, WGI) is likely to have increased heat-related health effects in Europe (medium confidence), and well as a decrease in cold related health effects (medium confidence) (Christidis *et al.*, 2010). Multiple impacts on health, welfare and economic sectors were observed due to the major heat wave events of 2003 and 2010 in Europe (Table 23-5) (see Chapter 18 for discussion on attribution of events).

[INSERT TABLE 23-6 HERE
Table 23-6: Observed changes in key indicators in ecological and human systems attributable to climate factors.]

23.9.4. Key Knowledge Gaps and Research Needs

There is a clear mismatch between the volume of scientific work on climate change since the AR4 and the insights and understanding required for policy needs, as many categories of impacts are still understudied. Some specific research needs have been identified:

- Little information is available on integrated and cross-sectoral climate change impacts in Europe, as the impact studies typically describe a single sector [see sections 23.3 to 23.6]. This also includes a lack of information on cross-sector vulnerabilities, and the indirect effects of climate change impacts and adaptation responses. This is a major barrier in developing successful evidence-based adaptation strategies that are cost-effective.
- Climate change impact models are difficult to validate [sections 23.3 to 23.6]; proper testing of the characteristics of baseline impact estimates against baseline information and data would improve their reliability, or the development of alternative methods where baseline data are not available.
- There is little knowledge on the co-benefits and unintended consequences of adaptation options across a range of sectors [section 23.3 to 23.6].
- There is a need to better monitor and evaluate local and national adaptation and mitigation responses to climate change, in both public and private sectors [23.7; Box 23-3]. This includes policies and strategies– as well as the effectiveness of individual adaptation measures. Evaluation of adaptation strategies, over a range of time-scales, would better support decision-making. While some means for reporting of national

actions exist in Europe (e.g. EU Climate-ADAPT), there is no consistent method of monitoring or a mechanism for information exchange [23.7].
- There are now more economic methods and tools available for the costing and valuation of specific adaptation options, in particular for flood defences, water, energy, and agriculture sectors [23.7.6]. However, for other sectors, such as biodiversity, business and industry, and population health costs, cost estimates are still lacking or incomplete. The usefulness of this costing information in decision making need to be evaluated and research can be undertaken to make economic evaluation more relevant to decision making.
- The need for local climate information to inform decision making also needs to be evaluated.
- Further research is needed on the effects of climate change on critical infrastructure (including transport, and water and energy supplies, health services) [23.5.2].
- Further research is needed on the role of governance in adaptation (including local and national institutions) with respect to implementation of measures in the urban environment, including flood defences, over-heating, and urban planning.
- The impacts for Europe from high end scenarios of climate change (above 4°C global average warming, with higher temperature change in Europe) are yet unknown. This is because such scenarios have only recently become available, and related impact studies still need to be undertaken for Europe.
- More study of the implications of climate change for rural development would inform policy in this area [23.7.5]. There is also a lack of information on the resilience of cultural landscapes and communities, and how to manage adaptation, particularly in low technology (productively marginal) landscapes.
- More research is needed for the medium and long- term monitoring of forest responses and adaptation to climate change and on the predictive modelling of wildfire distribution to better address adaptation and planning policies. There is also a lack of information on the impact of climate changes and climate extremes on carbon sequestration potential of agricultural and forestry systems [23.4.4].
- More research on the impacts of climate change on transport, especially on the vulnerability of road and rail infrastructure, and on the contribution of climatic and non-climatic parameters in the vulnerability of air transport (e.g. changes in air traffic volumes, airport capacities, air traffic demand, weather at the airports of origin, intermediate and final destination) [23.3.3].
- Improved monitoring of droughts is needed to support the management of crop production [23.4]. Remote sensing could be complemented by field experiments that assess the combined effects of elevated CO_2 and extreme heat and drought on crops and pastures.
- Research is needed on the resilience of human populations to extreme events (factors which increase resilience), including responses to flood and heat wave risks. Inequalities – and how adaptation policies may increase or reduce social inequalities [23.5].
- Development of improved risk models for vector borne disease (human and animal diseases) in order to support health planning and surveillance [23.4.2, 23.5.1].

A major barrier to research is lack of access to data, which is variable across regions and countries (especially with respect to socio-economic data, climate data, forestry, and routine health data). There is a need for long term monitoring of environmental and social indicators and to ensure open access to data for long-term and sustainable research programmes. Cross-regional cooperation could also ensure compatibility and consistency of parameters across the European region.

Frequently Asked Questions

FAQ 23.1: Will I still be able to live on the coast in Europe? *[to remain at the end of the chapter]*
Coastal areas affected by storm surges will face increased risk both because of the increasing frequency and of storms and because of higher sea level. Most of this increase in risk will occur after the middle of this century. Models of the coast line suggest that populations in the north western region of Europe are most affected and many countries, including the Netherlands, Germany, France, Belgium, Denmark, Spain and Italy, will need to strengthen their coastal defences. Some countries have already raised their coastal defence standards. The combination of raised sea defences and coastal erosion may lead to narrower coastal zones in the North Sea, the Iberian coast, and Bay of Biscay. Adapting dwellings and commercial buildings to occasional flooding is another response to climate change.

But while adapting buildings in coastal communities and upgrading coastal defences can significantly reduce adverse impacts of sea level rise and storm surges, they cannot eliminate these risks, especially as sea levels will continue to rise over time. In some locations, 'managed retreat' is likely to become a necessary response.

FAQ 23.2: Will climate change introduce new infectious diseases into Europe?
[to remain at the end of the chapter]
Many factors play a role in the introduction of infectious diseases into new areas. Factors that determine whether a disease changes distribution include: importation from international travel of people, vectors or hosts (insects, agricultural products), changes in vector or host susceptibility, drug resistance, and environmental changes, such as land use change or climate change. One area of concern that has gained attention is the potential for climate change to facilitate the spread tropical diseases, such as malaria, into Europe. Malaria was once endemic in Europe. Even though its mosquito vectors are still present and international travel introduces fresh cases, malaria has not become established in Europe because infected people are quickly detected and treated. Maintaining good health surveillance and good health systems are therefore essential to prevent diseases from spreading. When an outbreak has occurred (i.e. the introduction of a new disease) determining the causes is often difficult. It is likely that a combination of factors will be important. A suitable climate is a necessary but not a sufficient factor for the introduction of new infectious diseases.

FAQ 23.3: Will Europe need to import more food because of climate change?
[to remain at the end of the chapter]
Europe is one of the world's largest and most productive suppliers of food, but also imports large amounts of some agricultural commodities. A reduction in crop yields, particularly wheat in southern Europe, is expected under future climate scenarios. A shift in cultivation areas of high value crops, such as grapes for wine, may also occur. Loss of food production may be compensated by increases in other European sub-regions. However, if the capacity of the European food production system to sustain climate shock events is exceeded, the region would require exceptional food importation.

Table 23-1: Impacts of climate extremes in the last decade in Europe.

Year	**Region**	**Meteorological Characteristics**	**Production Systems and Physical Infrastructure, settlements**	**Agriculture, Fisheries, Forestry, Bioenergy**	**Health and Social Welfare**	**Environmental Quality and Biological Conservation**	**Mega-fire**
2003	Western and Central Europe	Hottest summer in at least 500 years (Luterbacher *et al.*, 2004)	Damage to road and rail transport systems. Reduced/ interrupted operation of nuclear power plants (mostly in France). High transport prices in Rhine due to low water levels.	Grain harvest losses of 20% (Ciais, et al. 2005)	35,000 deaths in August in Central and Western Europe, (Robine *et al.* 2008)	Decline in water quality (Daufresne et al. 2007). High outdoor pollution levels (EEA 2012)	Yes
2004/ 2005	Iberian Peninsula - Portugal	Hydrological drought	-	Grain harvest losses of 40% (EEA, 2010c)	-	-	
2007	Southern Europe	Hottest summer on record in Greece since 1891 (Founda & Giannakopoulos 2009)	1710 buildings burned down or rendered uninhabitable in Greece (JRC, 2008)	Approx. 575,500 hectares burnt area (JRC, 2008)	Significant mortality impact: 6 deaths in Portugal, 80 deaths in Greece.	Several protected conservation sites (Natura 2000) were destroyed (JRC, 2008)	Yes, - Greece
2007	England and Wales	May–July wettest since records began in 1766.	Estimated total losses £4 billion (£3 billion insured losses) (Chatterton et al. 2010). Failure of pumping station led to 20,000 people without water for 2 weeks	78 farms flooded. Impacts on agriculture £50 million (Chatterton et al. 2010)	13 deaths and 48,000 flooded homes (Pitt, 2008). Damage costs for health effects, incl. loss of access to education £ 287 million (Chatterton et al. 2010)		
2010	Western Russia	Hottest summer since 1500 (Barriopedro *et al.*, 2011)		Fire damage to forests (Shvidenko et al., 2011). Reduction in crop yields (Coumou and Rahmstorf, 2012)	Estimated 10,000 excess deaths due to heatwave in Moscow in July and August (Revich and Shaposhnikov, 2012)	High outdoor pollution levels in Moscow (Bondur, 2011, Revich and Shaposhnikov, 2012)	Yes
2011	France	Hottest and driest spring in France since 1880	Reduction in snow cover for skiing	8% decline in wheat yield (AGRESTE, 2011)			

* Extreme events derived from Coumou and Rahmstorf, 2012.

Table 23-2: Selected published cost estimates for planned adaptation in European countries.

Region	**Cost estimate**	**Time period**	**Sectors/Outcomes**	**Reference**
Europe	€2.6-3.5 billion/a	In 2100	Coastal adaptation costs	Hinkel et al. 2010
Europe	€1.7 billion/a €3.4 billion/a €7.9 billion/a	By 2020s By 2050s By 2080s	Protection from river flood risk for EU27	Rojas et al., in press
Netherlands	€1.2–1.6 billion/a €0.9–1.5 billion/a	up to 2050 2050–2100	Protection from coastal and river flooding	Delta Committee, 2008
Sweden	total of up to €10 billion	2010-2100	Multi sector	Swedish Commission on Climate and Vulnerability, 2007
Italy	€0.4-2 billion Up to € 44 billion	By 2080s	Coastal protection Hydrogeological protection	Bosello et al. 2012, Medri et al. 2013.
Greece	€0.4-3.3 billion	Up to 2100	Coastal protection	Bank of Greece, 2011
UK	€1.8 billion €2.2 billion €7-8 billion	Until 2035 2035-2050 At 2100	Maintain and improve Thames flood protection Renew and improve Thames flood protection New Thames barrier for London	EA, 2011

Table 23-3: Limits to adaptation to climate change.

Area/Location	**System**	**Adaptation measures**	**Limits to adaptation measure(s)**	**References**
Low altitude/ small-size ski resorts	Ski tourism	Artificial snowmaking	Climatic, technological and environmental constraints Economic viability Social acceptability of charging for previously free skiing. Social acceptability of alternatives for winter sport/leisure.	Landauer et al, 2012 ; Steiger, 2010; Steiger, 2011; Steiger and Mayer, 2008, Unbehaun et al., 2008
Thermal power plants/ cooling through river intake and discharge	Once-through cooling systems	Closed- circuit cooling	High investment cost for retrofitting existing plants	van Vliet et al., 2012, Koch and Vögele, 2009, Hoffman et al., 2013
Rivers used for freight transport	Inland transport	Reduced load factor of inland ships	Increased transport prices (Rhine and Moselle market)	Jonkeren, 2009, Jonkeren et al., 2007
		Use of smaller ships	Existing barges below optimal size (Rhine)	Demirel, 2011
Agriculture, Northern and Continental Europe.	Arable crops	Sowing date as agricultural adaptation	Other constraints (e.g. frost) limit farmer behaviour	Oort, 2012
Agriculture, Northern and Continental Europe.	Arable crops	Irrigation	Groundwater availability, competition with other users.	Olesen *et al.*, 2011
Agriculture, Viticulture	High value crops	Change distribution	Legislation on cultivar and geographical region	Box 23-1
Conservation Cultural landscapes	Alpine meadow/	Extend habitat	No technological adaptation option.	Engler *et al.*, 2011, Dullinger *et al.*, 2012
Conservation of species richness	Movement of species	Extend habitat	Landscape barriers and absence of climate projections in selection of conservation areas.	Butchart et al., 2010, Araújo *et al.*, 2011; Filz *et al.*, 2012; Virkkala *et al.*, 2013
Forests	Movement of species and productivity reduction	Introduce new species	Not socially acceptable, Legal barriers to non-native species	Giuggiola *et al.*, 2010; Hemery *et al.*, 2010; García-López J.M. and Alluéa, 2011, Casalegno *et al.*, 2007

Table 23-4: Assessment of climate change impacts by sub-region by 2050, assuming a medium emissions scenario, and no planned adaptation. Impacts assume economic development, including land use change. Impacts are assessed for the whole sub-region, although differences in impact within sub-regions are estimated for some impacts.

Water quality	→	↘ (red)	→	→	↘ (red)	23.6.3

Key:
Green means a "beneficial" change
Red means a "harmful" change
? means no relevant literature found

Confidence levels:
Risks were identified based on assessment of the literature and expert judgment.

Footnotes:
[1] Simulations have been performed, but mostly for the period after 2070.
[2] The increasing trend is for Norway.
[3] The decreasing trend refers mainly to the number of severe accidents.
[4] Impacts have been studied and quantified for UK only. The increasing trend stands for summer delays and the decreasing trend for winter delays.
[5] In both seasons, no significant impacts are expected by 2020, while more substantial changes are expected by 2080. For 2050 impacts are assumed to vary linearly (although this may not be the case).
[6] The constant trend stands for the Mediterranean, where some studies estimate no changes due to climate change at least until 2030 or even 2060.

Table 23-5: Key risks from climate change in Europe and the potential for reducing risk through mitigation and adaptation. Risk levels are presented in three timeframes: the present, near-term (2030-2040), and longer-term (2080-2100). For each timeframe, risk levels are estimated for a continuation of current adaptation and for a hypothetical highly adapted state. For a given key risk, change in risk level through time and across magnitudes of climate change is illustrated, but because the assessment considers potential impacts on different physical, biological, and human systems, risk levels should not necessarily be used to evaluate relative risk across key risks, sectors, or regions. Key risks were identified based on assessment of the literature and expert judgment.

Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe / Risk for current and high adaptation
Increased economic losses and people affected by flooding in river basins and coasts, driven by increasing urbanisation and by increasing sea-levels and increasing peak river discharges (*high confidence*)	Adaptation can prevent most of the projected damages (high confidence). The experience in hard flood protection technologies is significant. Main issues include the high costs for increasing flood protection demand for land in Europe, and environmental and landscape concerns.		23.2.3, 23.3.1, 23.7	Increased water restrictions. Significant reduction in water availability from river abstraction and from groundwater resources, combined to increased demands from a range of sectors (irrigation, energy and industry, domestic use) and to reduced water drainage and run-off (as a result of increased evaporative demand) (*high confidence*)	Proven adaptation potential from changes in technologies and adoption of more water efficient technologies and of water saving strategies (irrigation, crop species, land cover, industries, domestic use). Further adaptation possible through solar desalinization (to limit fossil fuel demand).		23.4.3, 23.4.4, 23.7.2	Increased economic losses and people affected by extreme heat events: impacts on health, welfare (overheating in buildings), labour productivity, crop production, reduced air quality (*medium confidence*)	Implementation of warning systems, adaptation of dwellings and work places, and transport and energy infratructure. Reductions in emissions to improve air quality. Improved wild fire management.		23.3.2, 23.3.4, 23.3.3, 23.5, 23.6.1, 23.6.3, 23.7.4	
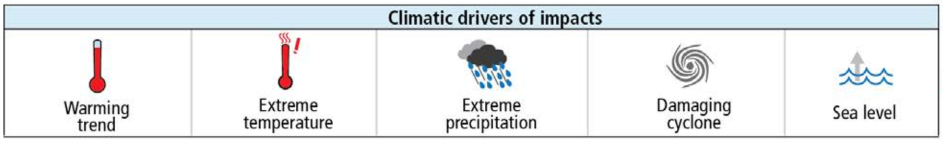
Climatic drivers of impacts



Risk & potential for adaptation

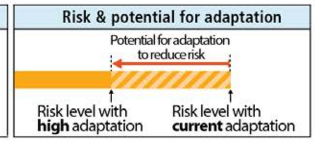


Table 23-6: Observed changes in key indicators in ecological and human systems attributable to climate factors.

Indicator	*Change in indicator*	*Confidence in detection*	*Confidence in attribution to change in climate factors [**]*	*Key references*	*Section*
Bio-Physical Systems					
Glacier retreat	Fast mass loss of 30 Swiss glaciers since the 1980s	High confidence	Medium confidence	Huss, 2010	18.3.1.3 WG1 10.5
Infrastructure					
Storm losses	Increase since 1970s	High confidence	No causal role for climate	Barredo, 2010	23.3.7
Hail losses	Increase in parts of Germany	Low confidence	Low confidence	Kunz *et al.*, 2009	23.3.7
Flood losses	Increasing general trend in economic losses in Europe since 1970s; none in some locations	Medium confidence	No causal role for climate	Barredo, 2009; Barredo et al., 2012	23.3.1
Agriculture, Fisheries, Forestry, and Bioenergy Production					
C3 crop yield	CO_2 induced positive contribution to yield since preindustrial for C3 crops	High confidence (high agreement, robust evidence)	High confidence (high agreement, robust evidence)	Amthor, 2001; Long *et al.*, 2006; McGrath and Lobell, 2011	7.2.1
Wheat yield	Stagnation of wheat yields in some countries in recent decades	High confidence	Medium confidence	Lobell *et al*. 2011 ; Brisson et al., 2010; Kristensen et al., 2011	23.4.1
Phenology –leaf greening	Earlier greening, Earlier leaf emergence and fruit set in temperate and boreal climate,	High confidence (high agreement, robust evidence)	High confidence (high agreement, robust evidence)	Menzel *et al.*, 2006	4.4.1.1
Phytoplankton productivity	Increased phytoplankton productivity in NE. Atlantic, decrease in warmer regions, due to warming trend and hydroclimatic variations	High confidence	Medium confidence	Beaugrand *et al.*, 2002; Edwards and Richardson, 2004	6.3.2
Ocean systems	Northward movement of species and increased species richness due to warming trend	High confidence	Medium confidence	Philippart *et al.* , 2011	6.3.2
Environmental quality and biodiversity					
Biodiversity	Increased number of colonization events by alien plant species in Europe	Medium confidence (high agreement, medium evidence)	Medium confidence	Walther *et al.*, 2009	4.2.4.6
Migratory birds	Decline over the period 1990-200 of species that did not advance their spring migration	Medium confidence (medium agreement, medium evidence)	Medium confidence	Moller *et al.*, 2008	4.4.1.1
Tree species	Upward shift in tree line in Europe	Medium evidence (medium agreement, high evidence)	Medium confidence	Gehrig-Fasel *et al.*, 2007, Lenoir *et al.*, 2008	18.3.2.1
Forest fires	Increase in burnt area	High confidence	High confidence (high agreement, robust evidence)	Camia and Amatulli 2009; Hoinka et al., 2009; Carvalho et al., 2010; Salis et al., in press; Pereira et al., 2005; Koutsias et al., 2012	23.4.4

NOTE: The studies included in this table are those with good evidence of a detection of a long term trend in the outcome of interested, and where there has been an assessment of the attribution of the trend to an observed change in climate factor. It is not possible to make an attribution to anthropogenic climate change at this scale – see chapter 18 for a more complete discussion.

Sum of effects on cultural services	∧ (1) ∨ (1)	∧ (1) ∨ (1)	No (1) ∨ (1)	∧ (1) ∨ (3)	∨ (2)

Key:
∨ = decreasing impacts
∧ = increasing impacts
No = neutral effect
(1) = number in brackets refers to the number of studies supporting the change (increasing, decreasing, neutral) in ecosystem service.

Footnotes:
* A decline in ecosystem services implies an increased risk of the specified natural hazard
^ Entries for biodiversity are those that were found during the literature search for climate change impacts on ecosystem services. A wider discussion of the impacts of climate change on biodiversity can be found in Section 23.6 and AR5 4.3.4.

Figure 23-2: First row: Projected changes in the mean number of heat waves occurring in the months May to September for the period 2071-2100 compared to 1971-2000 (number per 30 years). Heat waves are defined as periods of more than 5 consecutive days with daily maximum temperature exceeding the mean maximum temperature of the May to September season of the control period (1971-2000) by at least 5°C. Second and third rows: Projected seasonal changes in heavy precipitation defined as the 95th percentile of daily precipitation (only days with precipitation > 1mm/day are considered) for the period 2071-2100 compared to 1971-2000 (in %) in the months December to January (DJF) and June to August (JJA). Fourth row: Projected changes in the 95th percentile of the length of dry spells for the period 2071-2100 compared to 1971-2000 (in days). Dry spells are defined as periods of at least 5 consecutive days with daily precipitation below 1mm. Hatched areas indicate regions with robust (at least 66% of models agree in the sign of change) and/or statistical significant change (significant on a 95% confidence level using Mann-Whitney-U test). For the eastern parts of Black Sea, Eastern Anatolia and Southeast Anatolia (Turkey), no regional climate model projections are available. Changes represent the mean over 8 (RCP4.5, left side) and 9 (RCP8.5, right side) regional model simulations compiled within the EURO-CORDEX initiative. Adapted from Jacob et al. (2013). **[Illustration to be redrawn to conform to IPCC publication specifications.]**

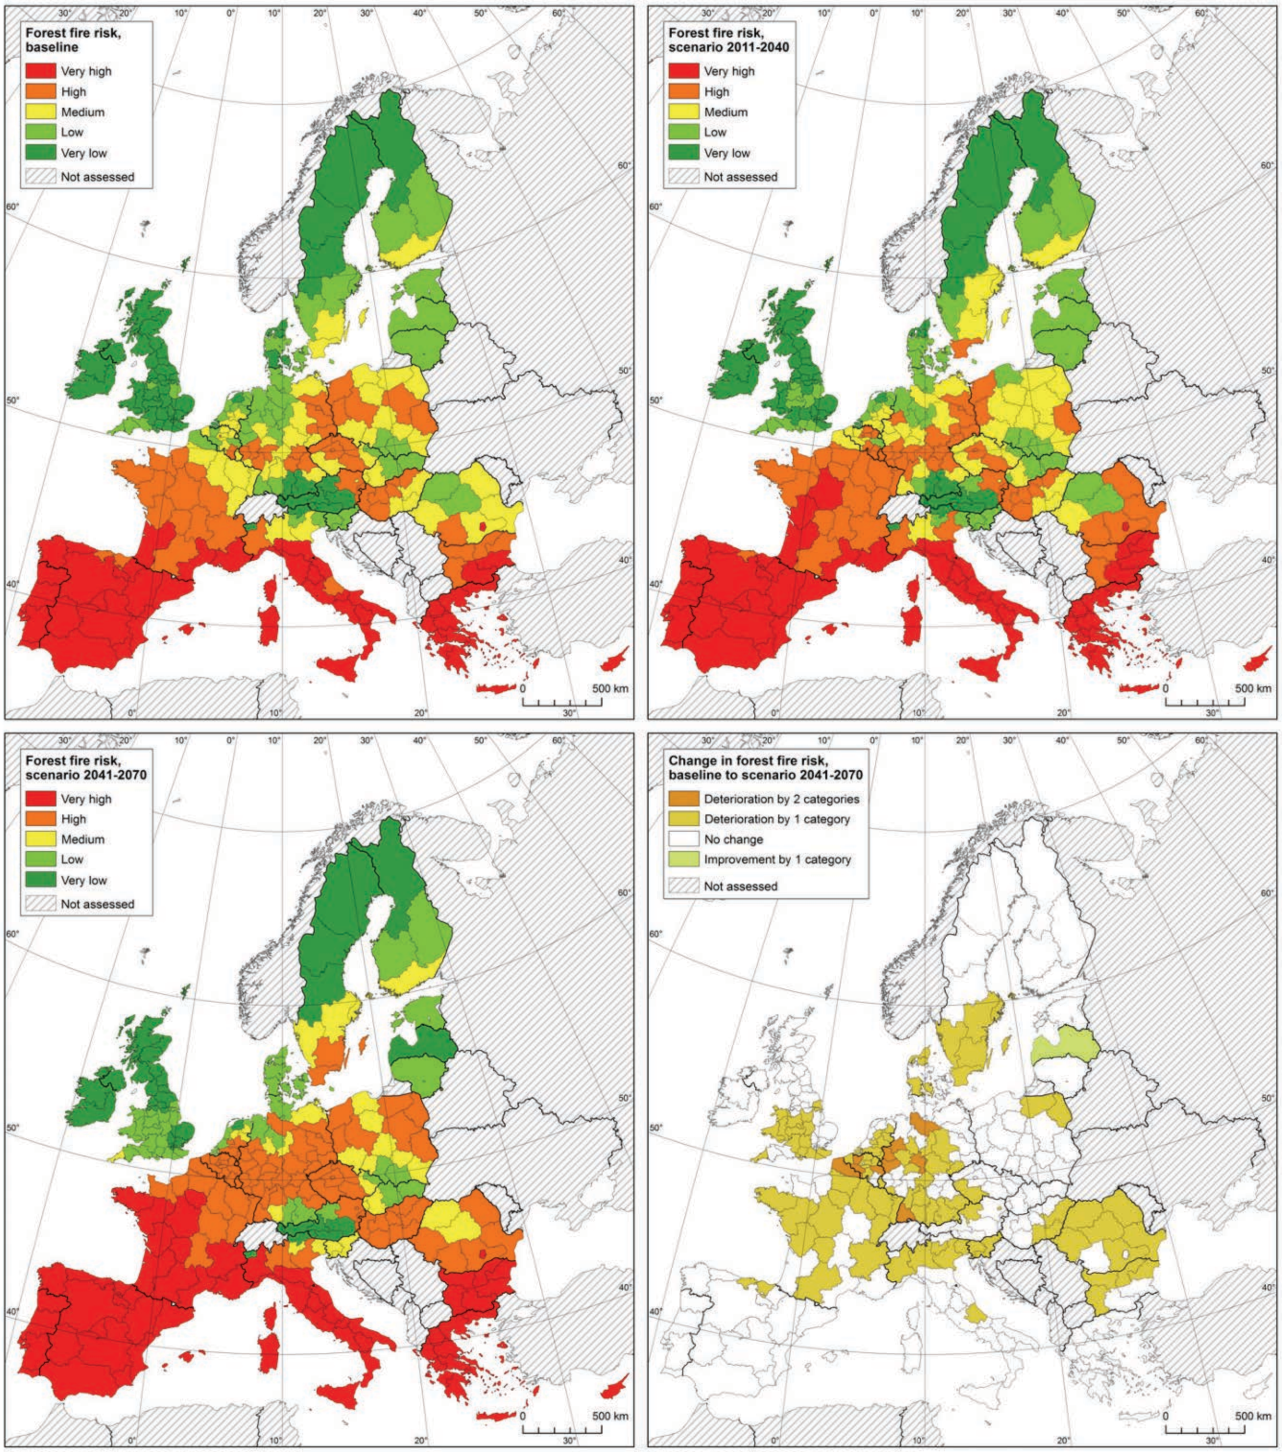

Figure 23-5: Changes in forest fire risk in Europe for two time periods: baseline (left) and 2041–2070 (right), based on high-resolution regional climate models and the SRES A1B emission scenario. Source: Lung et al., 2013.
[Illustration to be redrawn to conform to IPCC publication specifications.]

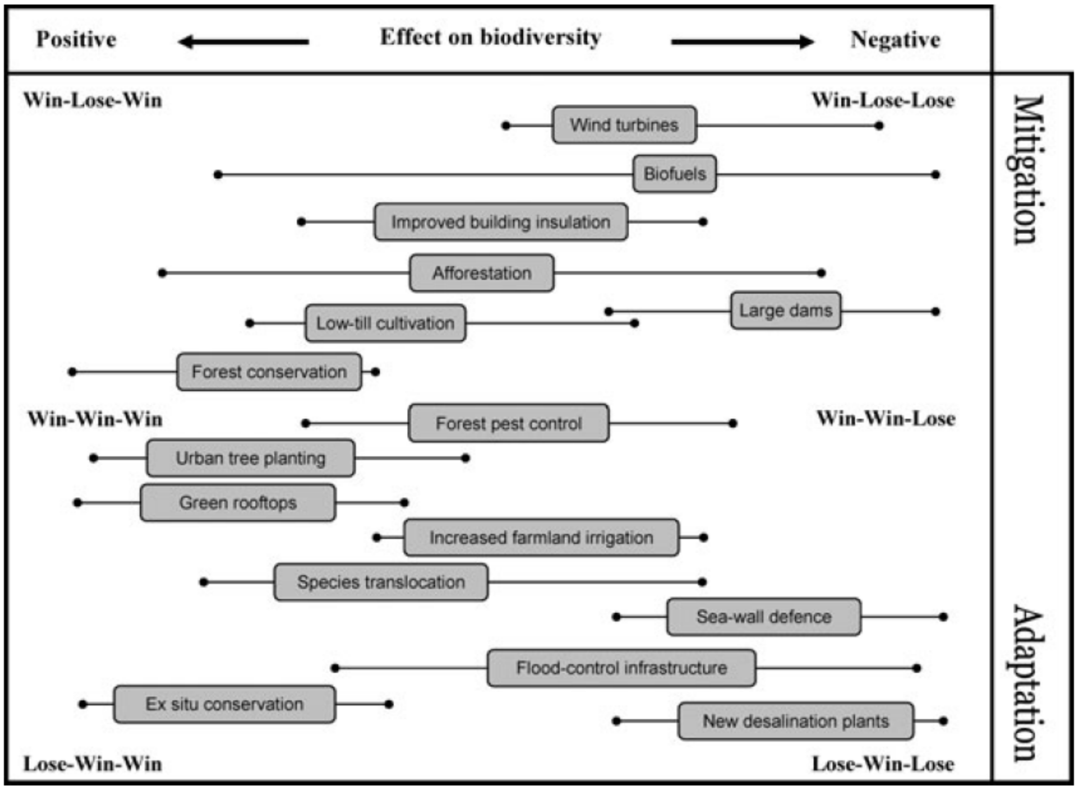

Figure 23-6: Adaptation and mitigation options and their effects on biodiversity. The horizontal axis ranges from positive effects on biodiversity (left-hand side) to negative effects (right-hand side). Each mitigation/adaptation option is located on the biodiversity effect axis (solid bars), including an estimate of the uncertainties associated with the assessment (error bars). The various options are given vertically with mitigation at the top and adaptation at the bottom. Options located toward the centre of the vertical axis have benefits for both mitigation and adaptation. Thus, options located at the centre left of the figure have benefits for mitigation, adaptation and biodiversity and hence are labelled as 'win-win-win'. Other combinations of benefits and dis-benefits are labelled accordingly, e.g. win-lose-win, lose-win-lose, etc. Based on Paterson et al., 2009.

Executive Summary

Warming trends and increasing temperature extremes have been observed across most of the Asian region over the past century (*high confidence*) [24.3]. Increasing numbers of warm days and decreasing numbers of cold days have been observed, with the warming trend continuing into the new millennium. Precipitation trends including extremes are characterized by strong variability, with both increasing and decreasing trends observed in different parts and seasons of Asia.

Water scarcity is expected to be a major challenge for most of the region due to increased water demand and lack of good management (*medium confidence*) [24.4.3]. Water resources are important in Asia because of the massive population and vary among regions and seasons. However, there is *low confidence* in future precipitation projections at a subregional scale and thus in future freshwater availability in most parts of Asia. Population growth and increasing demand arising from higher standards of living could worsen water security in many parts in Asia and affect many people in future. Integrated water management strategies could help adapt to climate change, including developing water saving technologies, increasing water productivity, and water reuse.

The impacts of climate change on food production and food security in Asia will vary by region with many regions to experience a decline in productivity (*medium confidence*) [24.4.4]. This is evident in the case of rice production. Most models, using a range of GCMs and SRES scenarios, show that higher temperatures will lead to lower rice yields as a result of shorter growing periods. There are a number of regions that are already near the heat stress limits for rice. However, CO_2 fertilization may at least in part offset yield losses in rice and other crops. In Central Asia, some areas could be winners (cereal production in northern and eastern Kazakhstan could benefit from the longer growing season, warmer winters and slight increase in winter precipitation), while others could be losers (western Turkmenistan and Uzbekistan, where frequent droughts could negatively affect cotton production, increase water demand for irrigation, and exacerbate desertification). In the Indo-Gangetic Plains of South Asia there could be a decrease of about 50% in the most favorable and high yielding wheat area due to heat stress at 2x CO_2. Sea-level rise will inundate low lying areas and will especially affect rice growing regions. There are many potential adaptation strategies being practiced and being proposed but research studies on their effectiveness are still few.

Terrestrial systems in many parts of Asia have responded to recent climate change with shifts in the phenologies, growth rates, and the distributions of plant species, and permafrost degradation, and the projected changes in climate during the 21st Century will increase these impacts (*high confidence*) [24.4.2]. Boreal trees will *likely* invade treeless arctic vegetation, while evergreen conifers will *likely* invade deciduous larch forest. Large changes may also occur in arid and semiarid areas, but uncertainties in precipitation projections make these more difficult to predict. The rates of vegetation change in the more densely populated parts of Asia may be reduced by the impact of habitat fragmentation on seed dispersal, while the impacts of projected climate changes on the vegetation of the lowland tropics are currently poorly understood. Changes in animal distributions have also been projected, in response to both direct impacts of climate change and indirect impacts though changes in the availability of suitable habitats.

Coastal and marine systems in Asia are under increasing stress from both climatic and non-climatic drivers (*high confidence*) [24.4.3]. It is *likely* that mean sea-level rise will contribute to upward trends in extreme coastal high water levels [WG1 Section 3.7.6]. In the Asian Arctic, rising sea-levels are expected to interact with projected changes in permafrost and the length of the ice-free season to cause increased rates of coastal erosion (*high agreement, medium evidence*). Mangroves, salt marshes and seagrass beds may decline unless they can move inland, while coastal freshwater swamps and marshes will be vulnerable to saltwater intrusion with rising sea-levels**.** Widespread damage to coral reefs correlated with episodes of high sea-surface temperature has been reported in recent decades and there is *high confidence* that damage to reefs will increase during the 21^{st} century as a result of both warming and ocean acidification. Marine biodiversity is expected to increase at temperate latitudes as warm-water species expand their ranges northwards (*high confidence*), but may decrease in the tropics if thermal tolerance limits are exceeded (*medium confidence*).

Multiple stresses caused by rapid urbanization, industrialization and economic development will be compounded by climate change (*high confidence*) [24.4, 24.5, 24.6, 24.7]. Climate change is expected to adversely affect the sustainable development capabilities of most Asian developing countries by aggravating pressures on natural resources and the environment. Development of sustainable cities in Asia with fewer fossil fuel driven vehicles and with more trees and greenery would have a number of co-benefits, including improved public health.

Extreme climate events will have an increasing impact on human health, security, livelihoods, and poverty, with the type and magnitude of impact varying across Asia (*high confidence*) [24.4.6]. More frequent and intense heat-waves in Asia will increase mortality and morbidity in vulnerable groups. Increases in heavy rain and temperature will increase the risk of diarrheal diseases, dengue fever and malaria. Increases in floods and droughts will exacerbate rural poverty in parts of Asia due to negative impacts on the rice crop and resulting increases in food prices and the cost of living.

Studies of observed climate changes and their impacts are still inadequate for many areas, particularly in North, Central and West Asia (*high confidence*) [24.8]. Improved projections for precipitation, and thus water supply, are most urgently needed. Understanding of climate change impacts on ecosystems in Asia is currently limited by the incompleteness and inaccessibility of biodiversity information. Major research gaps in the tropics include the temperature dependence of carbon fixation by tropical trees and the thermal tolerances and acclimation capacities of both plants and animals. Interactions between climate change and the direct impacts of rising CO_2 on crops and natural ecosystems are also currently poorly understood. More research is needed on impacts, vulnerability and adaptation in urban settlements, especially cities with populations under 500,000. More generally, there is a need to develop low-cost adaptation measures appropriate to the least developed parts of the region.

24.1. Introduction

Asia is defined here as the land and territories of 51 countries/regions (see Figure 24-1). It can be broadly divided into six subregions based on geographical position and coastal peripheries. These are (in alphabetical order) Central Asia (5 countries), East Asia (7 countries/regions), North Asia (2 countries), South Asia (8 countries), Southeast Asia (12 countries) and West Asia (17 countries). The population of Asia was reported to be about 4,299 million in 2013, which is about 60% of the world population (UN, 2013). The population density was reportedly about 134 per square kilometer in 2012 (PRB, 2012). The highest life expectancy at birth is 84 (Japan) and the lowest is 50 (Afghanistan) (CIA, 2013). The GDP per capita ranged from US$620 (Afghanistan for 2011) to US$46,720 (Japan for 2012) (World Bank, 2013).

[INSERT FIGURE 24-1 HERE
Figure 24-1: The land and territories of 51 countries in Asia.
NOTE: Currently in production and will be brought to specification using the current UN-accepted maps.]

24.2. Major Conclusions from Previous Assessments

Major highlights from previous assessments for Asia include:

- Warming trends including higher extremes are strongest over the continental interiors of Asia, and warming in the period 1979 onwards was strongest over China in winter, and northern and eastern Asia in spring and autumn (see WGI AR4 Section 3.2.2.7 and SREX Section 3.3.1).
- From 1900 to 2005, precipitation increased significantly in northern and central Asia but declined in parts of southern Asia (see WGI AR4 SPM).
- Future climate change is *likely* to affect water resource scarcity with enhanced climate variability and more rapid melting of glaciers (see WGII AR4 Section 10.4.2)
- Increased risk of extinction for many plant and animal species in Asia is *likely* as a result of the synergistic effects of climate change and habitat fragmentation (see WGII AR4 Section 10.4.4).

- Projected sea-level rise is *very likely* to result in significant losses of coastal ecosystems (see WGII AR4 Sections 10.4.3.2, 10.6.1).
- There will be regional differences within Asia in the impacts of climate change on food production (see WGII AR4 Section 10.4.1.1).
- Due to projected sea-level rise, a million or so people along the coasts of South and Southeast Asia will *likely* be at risk from flooding (*high confidence*, see WGII AR4 Section 10.4.3.1).
- It is *likely* that climate change will impinge on sustainable development of most developing countries of Asia as it compounds the pressures on natural resources and the environment associated with rapid urbanisation, industrialisation and economic development (see WGII AR4 Section 10.7).
- Vulnerabilities of industry, infrastructure, settlements and society to climate change are generally greater in certain high-risk locations, particularly coastal and riverine areas (see WGII AR4 Section 7.3, 7.4, 7.5).

_____ START BOX 24-1 HERE _____

Box 24-1. What's New on Asia in AR5?

- Improved country coverage on observed and future impacts of climate change
- Increase in the number of studies reflecting advances in research tools (e.g. more use of remote sensing and modeling of impacts); with an evaluation of detection and attribution where feasible.
- More conclusions have confidence statements, while confidence levels have changed in both directions since AR4.
- Expanded coverage of issues: for example discussion of the Himalayas has been expanded to cover observed and projected impacts (see Box 3-2), including those on: tourism (see Section10.6.2); livelihood assets such as water and food (see Sections 9.3.3.1, 13.3.1.1, 18.5.3 and 19.6.3); poverty (see Section 13.3.2.3); culture (see Sections 12.3.2); flood risks (see Sections 18.3.1.1 and 24.2.1); health risks (see Section 24.4.6.2); and ecosystems (see Section 24.4.2.2).

_____ END BOX 24-1 HERE _____

24.3. Observed and Projected Climate Change

24.3.1. Observed Climate Change

Temperature. It is *very likely* that mean annual temperature has increased over the past century over most of the Asia region, but there are areas of the interior and at high latitudes where the monitoring coverage is insufficient for the assessment of trends (see WGI AR5 Chapter 2, Figure 24-2). New analyses continue to support the AR4 and SREX conclusions that it is *likely* that the numbers of cold days and nights have decreased and the numbers of warm days and nights have increased across most of Asia since about 1950, and heat wave frequency has increased since the middle of the 20th century in large parts of Asia (see WGI AR5 Section 2.6.1).

As a part of the polar amplification, large warming trends (>2°C per 50 years) in the second half of the 20th century were observed in the northern Asian sector (see WGI AR5 Section 14.8.8). Over the period 1901-2009, the warming trend was particularly strong in the cold season between November and March, with an increase of 2.4°C in the mid-latitude semi-arid area of Asia (see WGI AR5 Section 14.8.8). Increasing annual mean temperature trends at the country scale in East and South Asia have been observed during the 20th century (Table 24-SM-1). In West Asia, upward temperature trends are notable and robust in recent decades (see WGI AR5 Section 14.8.10). Across Southeast Asia, temperature has been increasing at a rate of 0.14°C to 0.20°C per decade since the 1960s, coupled with a rising number of hot days and warm nights, and a decline in cooler weather (see WGI AR5 Section 14.8.12).

Precipitation and Monsoons. Most areas of the Asian region lack sufficient observational records to draw conclusions about trends in annual precipitation over the past century (see WGI AR5 Chapter 2, Figure 24-2, Table 24-SM-2). Precipitation trends, including extremes, are characterized by strong variability, with both increasing and decreasing trends observed in different parts and seasons of Asia (see WGI AR5 Chapter 14 and Table 24-SM-2). In northern Asia, the observations indicate some increasing trends of heavy precipitation events, but in central Asia, no spatially coherent trends were found (see WGI AR5 Section 14.8.8). Both the East Asian summer and winter monsoon circulations have experienced an interdecadal scale weakening after the 1970s, due to natural variability of the coupled climate system, leading to enhanced mean and extreme precipitation along the Yangtze River valley (30°N), but deficient mean precipitation in North China in summer (see WGI AR5 Section 14.8.9). A weakening of the East Asian summer monsoon since the 1920s was also found in sea level pressure gradients (*low confidence*, see WGI AR5 Section 2.7.4). In West Asia, a weak but non-significant downward trend in mean precipitation was observed in recent decades, although with an increase in intense weather events (see WGI AR5 Section 14.8.10). In South Asia, seasonal mean rainfall shows interdecadal variability, noticeably a declining trend with more frequent deficit monsoons under regional inhomogeneities (see WGI AR5 Section 14.8.11). Over India, the increase in the number of monsoon break days and the decline in the number of monsoon depressions are consistent with the overall decrease in seasonal mean rainfall (see WGI AR5 Section 14.8.11). But an increase in extreme rainfall events occurred at the expense of weaker rainfall events over the central Indian region and in many other areas (see WGI AR5 Section 14.2.2.1). In South Asia, the frequency of heavy precipitation events is increasing, while light rain events are decreasing (see WGI AR5 Section 14.8.11). In Southeast Asia, annual total wet-day rainfall has increased by 22 mm per decade, while rainfall from extreme rain days has increased by 10 mm per decade, but climate variability and trends differ vastly across the region and between seasons (see WGI AR5 Section 14.4.12, 14.8.12). In Southeast Asia, between 1955 and 2005 the ratio of rainfall in the wet to the dry seasons increased. While an increasing frequency of extreme events has been reported in the northern parts of Southeast Asia, decreasing trends in such events are reported in Myanmar (see WGI AR5 Section 14.4.12). In Peninsular Malaya during the southwest monsoon season, total rainfall and the frequency of wet days decreased, but rainfall intensity increased in much of the region. On the other hand, during the northeast monsoon, total rainfall, the frequency of extreme rainfall events, and rainfall intensity all increased over the peninsula (see WGI AR5 Section 14.4.12).

Tropical and Extratropical Cyclones. Significant trends in tropical cyclones making landfall are not found on shorter timescales. Time series of cyclone indices show weak upward trends in the western North Pacific since the late 1970s, but interpretation of longer-term trends is constrained by data quality concerns (see WGI AR5 Section 2.6.3). A decrease in extratropical cyclone activity and intensity over the last 50 years has been reported for northern Eurasia (60°N-40°N), including lower latitudes in East Asia (see WGI AR5 Section 2.6.4).

Surface Wind Speeds. Over land in China, including the Tibetan region, a weakening of the seasonal and annual mean winds, as well as the maximums, is reported from around the 1960s or 1970s to the early 2000s (*low confidence,* see WGI AR5 Section 2.7.2).

Oceans. A warming maximum is observed at 25°N-65°N with signals extending to 700 m depth and is consistent with poleward displacement of the mean temperature field (see WGI AR5 Section 3.2.2). The pH measurements between 1983 and 2008 in the western North Pacific showed a -0.0018 ± 0.0002 yr^{-1} decline in winter and -0.0013 ± 0.0005 yr^{-1} decline in summer (see WGI AR5 Section 3.8.2). Over the period 1993-2010, large rates of sea-level rise in the western tropical Pacific were reported, corresponding to an increase in the strength of the trade winds in the central and eastern tropical Pacific (see WGI AR5 Section 13.6.1). Spatial variation in trends in Asian regional sea level may also be specific to a particular sea or ocean basin. For example, a rise of 5.4 ± 0.3 mm yr^{-1} in the Sea of Japan from 1993 to 2001 is nearly two times the GMSL trend, with more than 80% of this rise being thermosteric, and regional changes of sea level in the Indian Ocean that have emerged since the 1960s are driven by changing surface winds associated with a combined enhancement of Hadley and Walker cells (see WGI AR5 Section 13.6.1).

24.3.2. Projected Climate Change

The AR4 assessed that warming is *very likely* in the 21st century (Christensen *et al.*, 2007), and that assessment still holds for all land areas of Asia in the mid- and late-21^{st}-century, based on the CMIP5 simulations under all four RCP scenarios (Figures 24-2, 24-SM-1, and Table 24-SM-3). Ensemble-mean changes in mean annual temperature exceed 2˚C above the late-20^{th}-century baseline over most land areas in the mid-21^{st}-century under RCP8.5, and range from greater than 3˚C over South and Southeast Asia to greater than 6˚C over high latitudes in the late-21^{st}-

century. The ensemble-mean changes are less than 2˚C above the late-20th-century baseline in both the mid- and late-21st-century under RCP2.6, with the exception of changes between 2˚C and 3˚C over the highest latitudes.

Projections of future annual precipitation change are qualitatively similar to those assessed in the AR4 (Christensen *et al.*, 2007) (Figure 24-2). Precipitation increases are *very likely* at higher latitudes by the mid-21st-century under the RCP8.5 scenario, and over eastern and southern areas by the late-21st-century. Under the RCP2.6 scenario, increases are *likely* at high latitudes by the mid-21st century, while it is *likely* that changes at low latitudes will not substantially exceed natural variability.

[INSERT FIGURE 24-2 HERE
Figure 24-2: Observed and projected changes in annual average temperature and precipitation in Asia.]

Tropical and Extra-Tropical Cyclones. The future influence of climate change on tropical cyclones is *likely* to vary by region, but there is *low confidence* in region-specific projections of frequency and intensity. However, better process understanding and model agreement in specific regions indicate that precipitation will likely be more extreme near the centers of tropical cyclones making landfall in West, East, South and Southeast Asia (see WGI AR5 Sections 14.6, 14.8.9, 14.8.10, 14.8.11, 14.8.12). There is *medium confidence* that a projected poleward shift in the North Pacific storm track of extratropical cyclones is *more likely than not*. There is *low confidence* in the magnitude of regional storm track changes and the impact of such changes on regional surface climate (see WGI AR5 Section 14.6)

Monsoons. Future increases in precipitation extremes related to the monsoon are *very likely* in East, South and Southeast Asia (see WGI AR5 Sections 14.2.1, 14.8.9, 14.8.11, 14.8.12). More than 85% of CMIP5 models show an increase in mean precipitation in the East Asian summer monsoons, while more than 95% of models project an increase in heavy precipitation events (see WGI AR5 Section 14.2.2 and Figure 14.4). All models and all scenarios project an increase in both the mean and extreme precipitation in the Indian summer monsoon (see WGI AR5 Section 14.2.2 and SAS in Figure 14.4). In these two regions, the interannual standard deviation of seasonal mean precipitation also increases (see WGI AR5 Section 14.2.2).

Oceans. The ocean in subtropical and tropical regions will warm in all RCP scenarios and will show the strongest warming signal at the surface (see WGI AR5 Section 12.4.7 and Figure 12.12). Negligible change or a decrease in mean significant wave heights are projected for the trade and monsoon wind regions of the Indian Ocean (see WGI AR5 Section 13.7.3).

24.4. Observed and Projected Impacts, Vulnerabilities, and Adaptation

The key observed and projected climate change impacts in Asia are summarized based on subsections 24.4.1 to 24.4.6 (Tables 24-1, 24-SM-4 and 24-SM-5).

[INSERT TABLE 24-1 HERE
Table 24-1: Key risks from climate change and the potential for risk reduction through mitigation and adaptation in Asia.]

24.4.1 Freshwater Resources

24.4.1.1. Sub-Regional Diversity

Freshwater resources are very important in Asia because of the massive population and heavy economic dependence on agriculture, but water availability is highly uneven and requires assessment on the subregional scale because of Asia’s huge range of climates (Pfister *et al.*, 2009). Adequate water supply is one of the major challenges in many regions (Vörösmarty *et al.*, 2010), particularly Central Asia. Growing demand for water is driven by soaring populations, increasing per-capita domestic use, due to urbanization and thriving economic growth, and increasing use of irrigation.

24.4.1.2. Observed Impacts

The impact of changes in climate, particularly precipitation, on water resources varies cross Asia (Table 24-SM-4). There is *medium confidence* that water scarcity in northern China has been exacerbated by decreasing precipitation, doubling population, and expanding water withdrawal from 1951 to 2000 (Xu *et al.*, 2010). There is no evidence that suggests significant changes of groundwater in the Kherlen River Basin in Mongolia over the past half century (Brutsaert and Sugita, 2008). Apart from water availability, there is *medium confidence* that climate change also leads to degradation of water quality in most regions of Asia (Delpla *et al.*, 2009; Park *et al.*, 2010), although this is also heavily influenced by human activities (Winkel *et al.*, 2011).

Glaciers are important stores of water and any changes have the potential to influence downstream water supply in the long term (see Section 24.9.2). Glacier mass loss shows a heterogeneous pattern across Asia (Gardner *et al.*, 2013). Glaciers in the polar section of the Ural Mountains, in the Kodar Mountains of Southeast Siberia, in the Suntar Khayata and Chersky Ranges of Northeast Siberia, in Georgia and Azerbaijan on the southern flank of the Greater Caucasus Range, on the Tibetan Plateau (see Box 3-1) and the surrounding areas, and on Puncak Jaya, Papua, Indonesia lost 9-80% of their total area in different periods within the 1895-2010 time interval (Ananicheva *et al.*, 2005; Ananicheva *et al.*, 2006; Anisimov *et al.*, 2008; Prentice and Glidden, 2010; Allison, 2011; Shahgedanova *et al.*, 2012; Yao *et al.*, 2012a; Stokes *et al.*, 2013) due to increased temperature (Casassa *et al.*, 2009; Shrestha and Aryal, 2011). Changes in the Kamchatka glaciers are driven by both warming and volcanic activity, with the area of some glaciers decreasing, while others increased because they are covered by ash and clinker (Anisimov *et al.*, 2008).

24.4.1.3. Projected Impacts

Projected impacts of climate change on future water availability in Asia differ substantially among river basins and seasons (A1B scenario with 5 GCMs: Immerzeel *et al.*, 2010; A1B with MRI-AGCMS: Nakaegawa *et al.*, 2013) . There is *high confidence* that water demand in most Asian countries is increasing because of increases in population, irrigated agriculture (Lal, 2011) and industry.

Tropical Asia. Future projections (A1B with MRI-AGCMs) suggest a decrease in river runoff in January in the Chao Phraya River basin in Thailand (Champathong *et al.*, 2013). In a study of the Mahanadi River Basin in India, a water availability projection (A2, CGCM2) indicated increasing possibility of floods in September but increasing water scarcity in April (Asokan and Dutta, 2008). In the Ganges, an increase in river runoff could offset the large increases in water demand due to population growth in a +4ºC world (ensemble GCMs), due to a projected large increase in average rainfall, although high uncertainties remains at the seasonal scale (Fung *et al.*, 2011).

Northern and Temperate Asia. Projections (A2 and B2 with the GLASS model) suggest an increase in average water availability in Russia in the 2070s (Alcamo *et al.*, 2007). In China, a projection (downscaling HadAM3H A2 and B2 scenarios with the PRECIS regional model) suggests that there will be insufficient water for agriculture in the 2020s and 2040s due to the increases in water demand for non-agricultural uses, although precipitation may increase in some areas (Xiong *et al.*, 2010). In the late 21st century (MRI-AGCM, A1B), river discharge in northern Japan is projected to increase in February but decrease in May, due to increased winter precipitation and decreased spring snowmelt (Sato *et al.*, 2013).

Central and West Asia. Given the already very high level of water stress in many parts of Central Asia, projected temperature increases and precipitation decreases (SRES scenarios from IPCC AR4 23 models) in the western part of Kazakhstan, Uzbekistan, and Turkmenistan could exacerbate the problems of water shortage and distribution (Lioubimtseva and Henebry, 2009). Considering the dependence of Uzbekistan's economy on its irrigated agriculture, which consumes more than 90% of the available water resources of the Amu Darya basin, climate change impacts on river flows would also strongly affect the economy (Schlüter *et al.*, 2010).

24.4.1.4. Vulnerabilities to Key Drivers

It is suggested that freshwater resource will be influenced by changes in rainfall variability, snowmelt or glacier retreat in the river catchment (Im *et al.*, 2010; Ma *et al.*, 2010; Sato *et al.*, 2012; Yamanaka *et al.*, 2012; Nakaegawa *et al.*, 2013), and evapotranspiration, which are associated with climate change (Jian *et al.*, 2009). Mismanagement of water resources has increased tension due to water scarcity in arid areas (Biswas and Seetharam, 2008; Lioubimtseva and Henebry, 2009; Siegfried *et al.*, 2010; Aarnoudse *et al.*, 2012). Unsustainable consumption of groundwater for irrigation and other uses is considered to be the main cause of groundwater depletion in the Indian states of Rajasthan, Punjab and Haryana (Rodell *et al.*, 2009).

24.4.1.5. Adaptation Options

Adaptation of freshwater resources to climate change can be identified as developing adaptive/integrated water resource management (Sadoff and Muller, 2009; Schlüter *et al.*, 2010) of the trade-offs balancing water availability against increasing demand, in order to cope with uncertainty and change (Molle and Hoanh, 2009). Examples of the options include: developing water saving technologies in irrigation (Ngoundo *et al.*, 2007); water infrastructure development in the Ganges river basin (Bharati *et al.*, 2011); increasing water productivity in the Indus and Ganges river basins (Cai *et al.*, 2010), Taiwan, China and the Philippines (Barker and Levine, 2012), and Uzbekistan (Tischbein *et al.*, 2011); changing cropping systems and patterns in West Asia (Thomas, 2008); and water re-use in China (Yi *et al.*, 2011). During the second half of the 20th century, Asia built many reservoirs and almost tripled its surface water withdrawals for irrigation. Reservoirs partly mitigate seasonal differences and increase water availability for irrigation (Biemans *et al.*, 2011). Water management in river basins would benefit from integrated coordination among countries (Kranz *et al.*, 2010). For example, water management in the Syr Darya river basin relates to Kyrgyzstan, Tajikistan, Uzbekistan, Turkmenistan, and Kazakhstan (Siegfried *et al.*, 2010), while the Indus and Ganges-Brahmaputra-Meghna river basins concern Bangladesh, India, Nepal and Pakistan (Uprety and Salman, 2011).

24.4.2. Terrestrial and Inland Water Systems

24.4.2.1. Sub-Regional Diversity

Boreal forests and grasslands dominate in North Asia, deserts and semi-deserts in Central and West Asia, and alpine ecosystems on the Tibetan Plateau. Human-dominated landscapes predominate in the other subregions, but the major natural ecosystems are temperate deciduous and subtropical evergreen forests in East Asia, with boreal forest in the northeast and grasslands and deserts in the west, while Southeast Asia was largely covered in tropical forests. South Asia also has tropical forests, with semi-desert in the northwest and alpine ecosystems in the north. Asia includes several of the world’s largest river systems, as well as the world’s deepest freshwater lake, Lake Baikal, the semi-saline Caspian Sea, and the saline Aral Sea.

24.4.2.2. Observed Impacts

Biological changes consistent with climate trends have been reported in the north and at high altitudes, where rising temperatures have relaxed constraints on plant growth and the distributions of organisms. Few changes have been reported from tropical lowlands and none linked to climate change with *high confidence*, although data is insufficient to distinguish lack of observations from lack of impacts. Impacts on inland water systems have been difficult to disentangle from natural variability and other human impacts (Bates *et al.*, 2008; Vörösmarty *et al.*, 2010; Zheng, 2011; see Section 4.3.3.3). For example, the shrinking of the Aral Sea over the last 50 years has resulted largely from excessive water extraction from rivers, but was probably exacerbated by decreasing precipitation and increasing temperature (Lioubimtseva and Henebry, 2009; Kostianoy and Kosarev, 2010).

Phenology and Growth Rates. In humid temperate East Asia, plant observations and satellite measurements of ‘greenness’ (Normalized Difference Vegetation Index, NDVI; see 4.3.2.2) show a trend to earlier leafing in spring since the 1980s, averaging 2 days a decade, although details vary between sites, species and periods (Table 24-SM-6) (detected with *high confidence* and attributed to warming with *medium confidence*.). Earlier spring flowering and delayed autumn senescence have also been recorded (Table 24-SM-6). Trends in semi-arid temperate regions were heterogeneous in space and time (Liu *et al*., 2013a; Yu *et al*., 2013a, 2013b). Earlier greening has been reported from boreal forests (Delbart *et al*., 2008) and from the Hindu-Kush-Himalayan region (Panday and Ghimire, 2012; Shrestha *et al*., 2012), but with spatial and temporal heterogeneity. Patterns were also heterogeneous in Central Asia (Kariyeva *et al*., 2012). On the Tibetan Plateau, spring growth advanced until the mid-1990s, but the trend subsequently differs between areas and NDVI datasets (Yu *et al*., 2010; Yu *et al*., 2012; Dong *et al*., 2013; Jin *et al*., 2013; Shen *et al*., 2013; Yu *et al*., 2013a; Zhang *et al*., 2013a; Zhang *et al*., 2013b).

Satellite NDVI for Asia for 1988-2010 shows a general greening trend (i.e. increasing NDVI, a rough proxy for increasing plant growth), except where water is limiting (Dorigo *et al*., 2012). Changes at high latitudes (>60^{o}N) show considerable spatial and temporal variability, despite a consistent warming trend, reflecting water availability and non-climatic factors (Bi *et al*., 2013; Jeong *et al*., 2013). Arctic tundra generally showed increased greening since 1982, while boreal forests were variable (Goetz *et al*., 2011; de Jong *et al*., 2012; Epstein *et al*., 2012; Xu *et al*., 2013). An overall greening trend for 2000-2011 north of the boreal forest correlated with increasing summer warmth and ice retreat (Dutrieux *et al*., 2012). In China, trends have varied in space and time, reflecting positive impacts of warming and negative impacts of increasing drought stress (Peng *et al*., 2011; Sun *et al*., 2012; Xu *et al*., 2012). The steppe region of northern Kazakhstan showed an overall browning (decreasing NDVI) trend for 1982-2008, linked to declining precipitation (de Jong *et al*., 2012). In Central Asia, where NDVI is most sensitive to precipitation (Gessner *et al*., 2013), there was a heterogeneous pattern for 1982-2009, with an initial greening trend stalled or reversed in some areas (Mohammat *et al*., 2013).

Tree-ring data for 800-1989 for temperate East Asia suggests recent summer temperatures have exceeded those during past warm periods of similar length, although this difference was not statistically significant (Cook *et al*., 2012). Where temperature limits tree growth, growth rates have increased with warming in recent decades (Duan *et al*., 2010; Sano *et al*., 2010; Shishov and Vaganov, 2010; Borgaonkar *et al*., 2011; Xu *et al*., 2011; Li *et al*., 2012; Chen *et al*., 2012a, 2012b, 2012c, 2012d; Chen *et al*., 2013), while where drought limits growth, there have been increases (Li *et al*., 2006; Davi *et al*., 2009; Shao *et al*., 2010; Yang *et al*., 2010) or decreases (Li *et al*., 2007; Davi *et al* , 2009; Dulamsuren *et al*., 2010a, 2011; Kang *et al*., 2012; Wu *et al*., 2012; Kharuk *et al*., 2013; Liu *et al*., 2013b) reflecting decreasing or increasing water stress (*high confidence* in detection, *medium confidence* in attribution to climate change). In boreal forest, trends varied between species and locations, despite consistent warming (Lloyd and Bunn, 2007; Goetz *et al*., 2011).

Distributions of Species and Biomes. Changes in species distributions consistent with a response to warming have been widely reported: upwards in elevation (Soja *et al*., 2007; Bickford *et al*., 2010; Kharuk *et al*., 2010a, 2010b, 2010e; Moiseev *et al*., 2010; Chen *et al*., 2011; Jump *et al*., 2012; Telwala *et al*., 2013; Grigor’ev *et al*., 2013) or polewards (Tougou *et al*., 2009; Ogawa-Onishi and Berry, 2013) (*high confidence* in detection, *medium confidence* in attribution to climate change). Changes in the distributions of major vegetation types (biomes) have been reported from the north and high altitudes, where trees are invading treeless vegetation, and forest understories are being invaded from adjacent biomes (Soja *et al*., 2007; Kharuk *et al*., 2006; Bai *et al*., 2011; Singh *et al*., 2012; Wang and Liu, 2012; Ogawa-Onishi and Berry, 2013). In central Siberia, dark needle conifers (DNC) and birch have invaded larch-dominated forest over the last three decades (Kharuk *et al*., 2010c, d; Osawa *et al*., 2010; Lloyd *et al*., 2011). Meanwhile, warming has driven larch stand crown closure and larch invasion into tundra at a rate of 3–10 m/year in the northern forest-tundra ecotone (Kharuk *et al*., 2006). Shrub expansion in arctic tundra has also been observed (Blok *et al*., 2011; Myers-Smith *et al*., 2011; see 28.2.3.1.). Soil moisture and light are the main factors governing the forest-steppe ecotone (Soja *et al*., 2007; Zeng *et al*., 2008; Eichler *et al*., 2011; Kukavskaya *et al*., 2013) and Mongolian taiga forests have responded heterogeneously to recent climate changes, but declines in larch growth and regeneration are more widespread than increases (Dulamsuren *et al*., 2010a, 2010b).

Permafrost. Permafrost degradation, including reduced area and increased active layer thickness, has been reported from parts of Siberia, Central Asia, and the Tibetan Plateau (Romanovsky *et al.*, 2010; Wu and Zhang, 2010; Zhao *et al.*, 2010; Yang *et al.*, 2013) (*high confidence*). Most permafrost observatories in Asian Russia show substantial warming of permafrost during the last 20-30 years (Romanovsky *et al.*, 2008, 2010). Permafrost formed during the Little Ice Age is thawing at many locations and Late Holocene permafrost has begun to thaw at some undisturbed locations in northwest Siberia. Permafrost thawing is most noticeable within the discontinuous permafrost zone, while continuous permafrost is starting to thaw in a few places, so the boundary between continuous and discontinuous permafrost is moving northwards (Romanovsky *et al.*, 2008, 2010). Thawing permafrost may lead to increasing emissions of greenhouse gases from decomposition of accumulated organic matter (see Section 4.3.3.4 and 19.6.3.5). In Mongolia, mean annual permafrost temperature at 10-15 m depth increased over the past 10-40 years in the Hovsgol, Hangai and Hentei Mountain regions. Permafrost warming during the past 15–20 years was greater than during the previous 15-20 years (Sharkhuu *et al.*, 2008; Zhao *et al.*, 2010). In the Kazakh part of the Tien Shan Mountains, permafrost temperature and active layer thickness have increased since the early 1970s. Significant permafrost warming also occurred in the eastern Tien Shan Mountains, in the headwaters of the Urumqi River (Marchenko *et al.*, 2007; Zhao *et al.*, 2010). Monitoring across the Qinghai-Tibet Plateau over recent decades has also revealed permafrost degradation caused by warming and other impacts. Areas of permafrost are shrinking, the active layer depth is increasing, the lower altitudinal limit is rising, and the seasonal frost depth is thinning (Li *et al.*, 2008; Wu and Zhang, 2010; Zhao *et al.*, 2010). In the alpine headwater regions of the Yangtze and Yellow Rivers, rising temperatures and permafrost degradation have resulted in lower lake levels, drying swamps and shrinking grasslands (Cheng and Wu, 2007; Wang *et al.*, 2011).

24.4.2.3. Projected Impacts

Phenology and Growth Rates. Trends towards an earlier spring greening and longer growing season are expected to continue in humid temperate and boreal forest areas, although photoperiod or chilling requirements may reduce responses to warming in some species (Ge *et al.*, 2013; Hadano *et al.*, 2013; Richardson *et al.*, 2013). Changes in precipitation will be important for semi-arid and arid ecosystems, as may the direct impacts of atmospheric CO_2 concentrations, making responses harder to predict (Liancourt *et al.*, 2012; Poulter *et al.*, 2013). The ‘general flowering’ at multi-year intervals in lowland rainforests in Southeast Asia is triggered by irregular droughts (Sakai *et al.*, 2006), so changes in drought frequency or intensity could have large impacts.

Distributions of Species and Biomes. Climate change is expected to modify the vegetation distribution across the region (Tao and Zhang, 2010; Wang, 2013), but responses will be slowed by limitations on seed dispersal, competition from established plants, rates of soil development, and habitat fragmentation (Corlett and Westcott, 2013) (*high confidence*). Rising CO_2 concentrations are expected to favor increased woody vegetation in semi-arid areas (Higgins and Scheiter, 2012; Donohue *et al.*, 2013; Poulter *et al.*, 2013; Wang, 2013) (*medium confidence*). In North Asia, rising temperatures are expected to lead to large changes in the distribution of potential natural ecosystems (Ni, 2011; Tchebakova *et al.*, 2011; Insarov *et al.*, 2012; Pearson *et al.*, 2013) (*high confidence*). It is *likely* that the boreal forest will expand northward and eastward, and that tundra will decrease, although differences in models, time periods, and other assumptions have resulted in widely varying projections for the magnitude of this change (Woodward and Lomas, 2004; Kaplan and New, 2006; Lucht *et al.*, 2006; Golubyatnikov and Denisenko, 2007; Sitch *et al.*, 2008; Korzukhin and Tcelniker, 2010; Tchebakova *et al.*, 2010, 2011; Pearson *et al.*, 2013). Boreal forest expansion and the continued invasion of the existing larch-dominated forest by dark-needle conifers could lead to larch reaching the Arctic shore, while the traditional area of larch dominance turns into mixed forest (Kharuk *et al.*, 2006; Kharuk *et al.*, 2010c). Both the replacement of summer-green larch with evergreen conifers and expansion of trees and shrubs into tundra decrease albedo, causing regional warming and potentially accelerating vegetation change (Kharuk *et al.*, 2006; McGuire *et al.*, 2007; Kharuk *et al.*, 2010d; Pearson *et al.*, 2013). The future direction and rate of change of steppe vegetation are unclear because of uncertain precipitation trends (Golubyatnikov and Denisenko, 2007; Tchebakova *et al.*, 2010). The role of CO_2-fertilization is also potentially important here (Poulter *et al.*, 2013; see WG1 AR5 Box 6.3).

In East Asia, subtropical evergreen forests are projected to expand north into the deciduous forest and tropical forests to expand along China's southern coast (Choi *et al.*, 2011; Wang, 2013), but vegetation change may lag climate change by decades or centuries (Corlett and Westcott, 2013). On the Tibetan Plateau, projections suggest that alpine vegetation will be largely replaced by forest and shrubland, with tundra and steppe retreating to the north (Liang *et al.*, 2012; Wang, 2013). Impacts in Central and West Asia will depend on changes in precipitation. In India, a dynamic vegetation model (A2 and B2 scenarios) projected changes in more than a third of the forest area by 2100, mostly from deciduous to evergreen forest in response to increasing rainfall, although fragmentation and other human pressures are expected to slow these changes (Chaturvedi *et al.*, 2011). By 2100, large areas of tropical and subtropical lowland Asia are projected to experience combinations of temperature and rainfall outside the current global range, under a variety of model projections and emission scenarios (Williams *et al.*, 2007; Beaumont *et al.*, 2010; García-López and Allué, 2013), but the potential impacts of these novel conditions on biodiversity are largely unknown (Corlett, 2011).

In Southeast Asia, projected climate (A2 and B1 scenarios) and vegetation changes are expected to produce widespread declines in bat species richness, northward range shifts for many species, and large reductions in the distributions of most species (Hughes *et al.*, 2012). Projections for various bird species in Asia under a range of scenarios also suggest major impacts on distributions (Menon *et al.*, 2009; Li *et al.*, 2010; Ko *et al.*, 2012). Projections for butterflies in Thailand (A2 and B2 scenarios) suggest that species richness within protected areas will decline c. 30% by 2070-2099 (Klorvuttimontara *et al.*, 2011). Projections for dominant bamboos in the Qinling Mountains (A2 and B2 scenarios) suggest substantial range reductions by 2100, with potentially adverse consequences for the giant pandas which eat them (Tuanmu *et al.*, 2012). Projections for snow leopard habitat in the Himalayas (B1, A1B and A2 scenarios) suggest contraction by up to 30% as forests replace open habitats (Forrest *et al.*, 2012).

Permafrost. In the Northern Hemisphere, a 20-90% decrease in permafrost area and a 50-300 cm increase in active layer thickness driven by surface warming is projected for 2100 by different models and scenarios (Schaefer *et al.*, 2011). It is *likely* that permafrost degradation in North Asia will spread from the southern and low-altitude margins, advancing northwards and upwards, but rates of change vary greatly between model projections (Cheng and Wu, 2007; Riseborough *et al.*, 2008; Romanovsky *et al.*, 2008; Anisimov, 2009; Eliseev *et al.*, 2009; Nadyozhina *et al.*, 2010; Schaefer *et al.*, 2011; Wei *et al.*, 2011). Substantial retreat is also expected on the Qinghai-Tibet Plateau (Cheng and Wu, 2007). Near-surface permafrost is expected to remain only in Central and Eastern Siberia and parts of the QTP in the late 21st century.

Inland Waters. Climate change impacts on inland waters will interact with dam construction, pollution, and land-use changes (Vörösmarty *et al.*, 2010) (see also 24.9.1 and Section 3.3.2). Increases in water temperature will impact species and temperature-dependent processes (Hamilton, 2010; Dudgeon, 2011; Dudgeon, 2012). Coldwater fish will be threatened as rising water temperatures make much of their current habitat unsuitable (Yu *et al.*, 2013c). Climate change is also expected to change flow regimes in running waters and consequently impact habitats and species that are sensitive to droughts and floods (see Box CC-RF). Habitats that depend on seasonal inundation, including floodplain grasslands and freshwater swamp forests, will be particularly vulnerable (Maxwell, 2009; Bezuijen, 2011; Arias *et al.*, 2012). Reduced dry season flows are expected to combine with sea-level rise to increase saltwater intrusion in deltas (Hamilton, 2010; Dudgeon, 2012), although non-climatic impacts will continue to dominate in most estuaries (Syvitski *et al.*, 2009). For most Asian lakes, it is difficult to disentangle the impacts of water pollution, hydro-engineering, and climate change (Battarbee *et al.*, 2012).

24.4.2.4. Vulnerabilities to Key Drivers

Permafrost melting in response to warming is expected to impact ecosystems across large areas (Cheng and Wu, 2007; Tchebakova *et al.*, 2011) (*high confidence*). The biodiversity of isolated mountains may also be particularly vulnerable to warming, because many species already have small geographical ranges that will shrink further (La Sorte and Jetz, 2010; Liu *et al.*, 2010; Chou *et al.*, 2011; Noroozi *et al.*, 2011; Peh *et al.*, 2011; Jump *et al.*, 2012; Tanaka *et al.*, 2012a; Davydov *et al.*, 2013). Many freshwater habitats are similarly isolated and their restricted-range species may be equally vulnerable (Dudgeon, 2012). In flatter topography, higher velocities of climate change (the speeds that species need to move to maintain constant climate conditions) increase the vulnerabilities of species that are unable to keep pace, as a result of limited dispersal ability, habitat fragmentation, or other non-climatic constraints (Corlett and Westcott, 2013). In the tropics, temperature extremes above the present range are a potential threat to organisms and ecosystems (Corlett, 2011; Jevanandam *et al.*, 2013; Mumby *et al.*, 2013). For much of interior Asia, increases in drought stress, as a result of declining rainfall and/or rising temperatures, are the key concern. Because aridity is projected to increase in the northern Mongolian forest belt during the 21st century (Sato *et al.*, 2007), larch cover will *likely* be reduced (Dulamsuren *et al.*, 2010a). In the boreal forest region, a longer, warmer growing season will increase vulnerability to fires, although other human influences may overshadow climate impacts in accessible areas (Flannigan *et al.*, 2009; Liu *et al.*, 2012; Li *et al.*, 2013; see Section 4.3.3.1.1). If droughts intensify in lowland Southeast Asia, the synergies between warmth, drought, logging, fragmentation and fire (Daniau *et al.*, 2012), and tree mortality (Kumagai and Porporato, 2012; Tan *et al.*, 2013), possibly acerbated by feedbacks between deforestation, smoke aerosols and reduced rainfall (Aragão, 2012; Tosca *et al.*, 2012), could greatly increase the vulnerability of fragmented forest landscapes (*high confidence*).

24.4.2.5. Adaptation Options

Suggested strategies for maximizing the adaptive capacity of ecosystems include reducing non-climate impacts, maximizing landscape connectivity, and protecting 'refugia' where climate change is expected to be less than the regional mean (Hannah, 2010; Game *et al.*, 2011; Klorvuttimontara *et al.*, 2011; Murthy *et al.*, 2011; Ren *et al.*, 2011; Shoo *et al.*, 2011; Mandych *et al.*, 2012). Additional options for inland waters include operating dams to maintain environmental flows for biodiversity, protecting catchments, and preserving river floodplains (Vörösmarty *et al.*, 2010). Habitat restoration may facilitate species movements across climatic gradients (Klorvuttimontara *et al.*, 2011; Hughes *et al.*, 2012) and long-distance seed dispersal agents may need protection (McConkey *et al.*, 2012). Assisted migration of genotypes and species is possible where movements are constrained by poor dispersal, but risks and benefits need to be considered carefully (Liu *et al.*, 2010; Olden *et al.*, 2010; Tchebakova *et al.*, 2011; Dudgeon, 2012; Ishizuka and Goto, 2012; Corlett and Westcott, 2013). *Ex situ* conservation can provide back-up for populations and species most at risk from climate change (Chen *et al.*, 2009).

24.4.3. Coastal Systems and Low-Lying Areas

24.4.3.1. Sub-Regional Diversity

Asia's coastline includes the global range of shore types. Tropical and subtropical coasts support 45% of the world's mangrove forest (Giri *et al.*, 2011) and low-lying areas in equatorial Southeast Asia support most of the world's peat swamp forests, as well as other forested swamp types. Intertidal salt marshes are widespread along temperate and arctic coasts, while a variety of non-forested wetlands occur inland. Asia supports 40% of the world's coral reef area, mostly in Southeast Asia, with the world's most diverse reef communities in the 'coral triangle' (Spalding *et al.*, 2001; Burke *et al.*, 2011). Seagrass beds are widespread and support most of the world's seagrass species (Green and Short, 2003). Six of the seven species of sea turtle are found in the region and five nest on Asian beaches (Spotila, 2004). Kelp forests and other seaweed beds are important on temperate coasts (Bolton, 2010; Nagai *et al.*, 2011). Arctic sea-ice supports a specialized community of mammals and other organisms (see Sections 28.2.3.3. and 28.2.3.4.).

24.4.3.2. Observed Impacts

Most of Asia's non-Arctic coastal ecosystems are under such severe pressure from non-climate impacts that climate impacts are hard to detect (see Section 5.4.2). Most large deltas in Asia are sinking (as a result of groundwater withdrawal, floodplain engineering, and trapping of sediments by dams) much faster than global sea-level is rising (Syvitski *et al.*, 2009). Widespread impacts can be attributed to climate change only for coral reefs, where the temporal and spatial patterns of bleaching correlate with higher than normal sea surface temperatures (see Section 5.4.2.4 and CC-CR) (*very high confidence*). Increased water temperatures may also explain declines in large seaweed beds in temperate Japan (Nagai *et al.*, 2011; see Section 5.4.2.3). Warming coastal waters have also been implicated in the northwards expansion of tropical and subtropical macroalgae and toxic phytoplankton (Nagai *et al.*, 2011), fish (Tian *et al.*, 2012), and tropical corals, including key reef-forming species (Yamano *et al.*, 2011), over recent decades. The decline of large temperate seaweeds and expansion of tropical species in southwest Japan has been linked to rising sea surface temperatures (Tanaka *et al.*, 2012b), and these changes have impacted fish communities (Terazono *et al.*, 2012).

In Arctic Asia, changes in permafrost and the effects of sea-level rise and sea-ice retreat on storm-wave energy have increased erosion (Are *et al.*, 2008; Razumov, 2010; Handmer *et al.*, 2012). Average erosion rates range from 0.27 m/year (Chukchi Sea) to 0.87 m/year (East Siberian Sea), with a number of segments in the Laptev and East Siberian Sea experiencing rates greater than 3 m/year (Lantuit *et al.*, 2012).

24.4.3.3. Projected Impacts

Marine biodiversity at temperate latitudes is expected to increase as temperature constraints on warm-water taxa are relaxed (see Section 6.4.1.1) (*high confidence*), but biodiversity in tropical regions may fall if, as evidence suggests, tropical species are already near their thermal maxima (Cheung *et al.*, 2009, 2010; Nguyen *et al*., 2011) (*medium confidence*). Individual fish species are projected to shift their ranges northwards in response to rising sea surface temperatures (Tseng *et al.*, 2011; Okunishi *et al.*, 2012; Tian *et al.*, 2012). The combined effects of changes in distribution, abundance and physiology may reduce the body size of marine fishes, particularly in the tropics and intermediate latitudes (Cheung *et al.*, 2013).

Continuation of current trends in sea-surface temperatures and ocean acidification would result in large declines in coral-dominated reefs by mid-century (Hoegh-Guldberg, 2011; Burke *et al.*, 2011; see Section 5.4.2.4 and Box CC-CR) (*high confidence*). Warming would permit the expansion of coral habitats to the north but acidification is expected to limit this (Yara *et al.*, 2012). Acidification is also expected to have negative impacts on other calcified marine organisms (algae, molluscs, larval echinoderms), while impacts on non-calcified species are unclear (Branch *et al.*, 2013; Kroeker *et al.*, 2013; See CC-OA). On rocky shores, warming and acidification are expected to lead to range shifts and changes in biodiversity (see Section 5.4.2.2).

Future rates of sea-level rise are expected to exceed those of recent decades (see WGI AR5 Section 13.5.1), increasing coastal flooding, erosion, and saltwater intrusion into surface and groundwaters. In the absence of other impacts, coral reefs may grow fast enough to keep up with rising sea-levels (Brown *et al.*, 2011; Villanoy *et al.*, 2012; see Section 5.4.2.4), but beaches may erode and mangroves, salt marshes, and seagrass beds will decline, unless they receive sufficient fresh sediment to keep pace or they can move inland (Gilman *et al.*, 2008; Bezuijen, 2011; Kintisch, 2013; see Section 5.3.2.3). Loucks *et al.* (2010) predict a 96% decline in tiger habitat in Bangladesh's Sunderbans mangroves with a 28 cm sea-level rise if sedimentation does not increase surface elevations. Rising winter temperatures are expected to result in poleward expansion of mangrove ecosystems (see Section 5.4.2.3). Coastal freshwater wetlands may be vulnerable to saltwater intrusion with rising sea-levels, but in most river deltas local subsidence for non-climatic reasons will be more important (Syvitski *et al.*, 2009).
Current trends in cyclone frequency and intensity are unclear (see 24.3.2 and Box CC-TC), but a combination of cyclone intensification and sea-level rise could increase coastal flooding (Knutson *et al.*, 2010) and losses of coral reefs and mangrove forests would exacerbate wave damage (Gedan *et al.*, 2011; Villanoy *et al.*, 2012).

In the Asian Arctic, rates of coastal erosion are expected to increase as a result of interactions between rising sea-levels and changes in permafrost and the length of the ice-free season (Pavlidis *et al.*, 2007; Lantuit *et al.*, 2012) (*high agreement, medium evidence*). The largest changes are expected for coasts composed of loose permafrost rocks and therefore subject to intensive thermal abrasion. If sea-level rises by 0.5 m over this century, modeling studies predict that the rate of recession will increase 1.5-2.6-fold for the coasts of the Laptev Sea, East Siberian Sea, and West Yamal in the Kara Sea, compared to the rate observed in the first years of the 21st century.

24.4.3.4. Vulnerabilities to Key Drivers

Offshore marine systems are most vulnerable to rising water temperatures and ocean acidification, particularly for calcifying organisms such as corals. Sea-level rise will be the key issue for many coastal areas, particularly if combined with changes in cyclone frequency or intensity, or in Arctic Asia, with a lengthening open-water season. The expected continuing decline in the extent of sea-ice in the arctic may threaten the survival of some ice-associated organisms (see Section 28.2.2.1), with expanded human activities in previously inaccessible areas an additional concern (Post *et al.*, 2013).

24.4.3.5. Adaptation Options

The connectivity of marine habitats and dispersal abilities of marine organisms increase the capacity for autonomous (spontaneous) adaptation in coastal systems (Cheung *et al.*, 2009). Creating marine protected areas where sea surface temperatures are projected to change least may increase their future resilience (Levy and Ban, 2013). For coral reefs, potential indicators of future resilience include later projected onset of annual bleaching conditions (van Hooidonk *et al.*, 2013), past temperature variability, the abundance of heat-tolerant coral species, coral recruitment rates, connectivity, and macroalgae abundance (McClanahan *et al.*, 2012). Similar strategies may help identify reefs that are more resilient to acidification (McLeod *et al.*, 2013). Hard coastal defenses, such as sea walls, protect settlements at the cost of preventing adjustments by mangroves, salt marshes and seagrass beds to rising sea-levels. Landward buffer zones that provide an opportunity for future inland migration could mitigate this problem (Tobey *et al.*, 2010). More generally, maintaining or restoring natural shorelines where possible is expected to provide coastal protection and other benefits (Tobey *et al.*, 2010; Crooks *et al.*, 2011). Projected increases in the navigability of the Arctic Ocean because of declining sea-ice suggest the need for a revision of environmental regulations in order to minimize the risk of marine pollution (Smith and Stephenson, 2013).

24.4.4. Food Production Systems and Food Security

It is projected that climate change will affect food security by the middle of the 21st century, with the largest numbers of food-insecure people located in South Asia (see Chapter 7).

24.4.4.1. Sub-Regional Diversity

AR4 Section 10.4.1.1 pointed out that there will be regional differences within Asia in the impacts of climate change on food production. Research since then has validated this divergence and new data are available especially for West and Central Asia (Tables 24-SM-4 and 24-SM-5). In AR4 Section 10.4.1, climate change was projected to lead mainly to reductions in crop yield. New research shows there will also be gains for specific regions and crops in given areas. Thus, the current assessment encompasses an enormous variability, depending on the regions and the crops grown.

24.4.4.2. Observed Impacts

There are very limited data globally for observed impacts of climate change on food production systems (see Chapter 7) and this is true also for Asia. In Jordan, it was reported that the total production and average yield for wheat and barley were lowest in 1999 for the period 1996-2006 (Al-Bakri *et al.*, 2010), which could be explained by the low rainfall during that year, which was 30% of the average (*high confidence* in detection, *low confidence* in attribution). In China, rice yield responses to recent climate change at experimental stations were assessed for the period 1981–2005 (Zhang *et al.*, 2010). In some places, yields were positively correlated with temperature when they were also positively related with solar radiation. However, in other places, lower yield with higher temperature was accompanied by a positive correlation between yield and rainfall (*high confidence* in detection, *high confidence* in attribution). In Japan, where mean air temperature rose by about 1ºC over the 20th century, effects of recent warming include phenological changes in many crops, increases in fruit coloring disorders and incidences of chalky rice kernels, reductions in yields of wheat, barley, vegetables, flowers, milk and eggs, and alterations in the type of disease and pest (*high confidence* in detection, *high confidence* in attribution) (Sugiura *et al.*, 2012).

24.4.4.3. Projected Impacts

Production. AR4 Section 10.4.1.1 mainly dealt with cereal crops (rice, wheat corn). Since then, impacts of climate change have been modeled for additional cereal crops and subregions. It is *very likely* that climate change effects on crop production in Asia will be variable, negative for specific regions and crops in given areas and positive for other regions and crops (*high agreement, medium evidence*). It is also *likely* that an elevated CO_2 concentration in the atmosphere will be beneficial to most crops (*high agreement, medium evidence*).

In semi-arid and arid regions of Western Asia, rainfed agriculture is sensitive to climate change both positively and negatively (Ratnakumar *et al.*, 2011). In the mountainous Swat and Chitral districts of Pakistan (average altitudes 960 and 1500 m above sea level, respectively), there were mixed results as well (Hussain and Mudasser, 2007). Projected temperature increases of 1.5 and 3°C would lead to wheat yield declines (by 7% and 24% respectively) in Swat district but to increases (by 14% and 23%) in Chitral district. In India, climate change impacts on sorghum were analyzed using the InfoCrop-SORGHUM simulation model (Srivastava *et al.*, 2010). A changing climate was projected to reduce monsoon sorghum grain yield by 2-14% by 2020, with worsening yields by 2050 and 2080. In the Indo-Gangetic Plains, a large reduction in wheat yields is projected (see below), unless appropriate cultivars and crop management practices are adopted (Ortiz *et al.*, 2008). A systematic review and meta-analysis of data in 52 original publications projected mean changes in yield by the 2050s across South Asia of 16% for maize and 11% for sorghum (Knox *et al.*, 2012). No mean change in yield was projected for rice.

In China, modeling studies of the impacts of climate change on crop productivity have had mixed results. Rice is the most important staple food in Asia. Studies show that climate change will alter productivity in China but not always negatively. For example, an ensemble-based probabilistic projection shows rice yield in southeastern China would change on average by 7.5% to 17.5% (–10.4% to 3.0%), 0.0% to 25.0% (–26.7% to 2.1%), and –10.0% to 25.0% (–39.2% to –6.4%) during the 2020s, 2050s, and 2080s, respectively, in response to climate change, with (without) consideration of CO_2 fertilization effects, using all 10 combinations of two emission scenarios (A1FI and B1) and five GCMs (HadCM3, PCM, CGCM2, CSIRO2, and ECHAM4) relative to 1961–1990 levels (Tao and Zhang, 2013a). With rising temperatures, the process of rice development accelerates and reduces the duration for growth. Wassmann *et al.* (2009a, 2009b) concluded that, in terms of risks of increasing heat stress, there are parts of Asia where current temperatures are already approaching critical levels during the susceptible stages of the rice plant. These include: Pakistan/North India (October), South India (April, August), East India/Bangladesh (March-June), Myanmar/Thailand/Laos/Cambodia (March-June), Vietnam (April/August), Philippines (April/June), Indonesia (August) and China (July/August).

There have also been simulation studies for other crops in China. In the Huang-Huai-Hai Plain, China's most productive wheat growing region, modeling indicated that winter wheat yields would increase on average by 0.2 Mg ha^{-1} in 2015-2045 and by 0.8 Mg ha^{-1} in 2070-2099, due to warmer nighttime temperatures and higher precipitation, under A2 and B2 scenarios using the HadCM3 model (Thomson *et al.*, 2006). In the North China Plain, an ensemble-based probabilistic projection projected that maize yield will change by -9.7 to -9.1%, -19.0 to -15.7%, and -25.5% to -24.7%, during 2020s, 2050s, and 2080s as a percentage of 1961–1990 yields (Tao *et al.*, 2009). In contrast, winter wheat yields could increase with high probability in future due to climate change (Tao and Zhang, 2013b).

It should be noted that crop physiology simulation models such as those discussed above may overstate the impact of CO_2 fertilization. Free atmosphere carbon exchange (FACE) experiments show that measurable CO_2 fertilization effects are typically less than modeled results (see Section 7.3). Extreme weather events are also expected to negatively affect agricultural crop production (IPCC, 2012). For example, extreme temperatures could lower yields of rice (Mohammed and Tarpley, 2009; Tian *et al.*, 2010). With higher precipitation, flooding could also lead to lower crop production (see SREX Chapter 4).

Farming Systems and Crop Areas. Since the release of the AR4 (see WGII AR4 Section 10.4.1.2), more information is available on the impacts of climate change on farming systems and cropping areas in more countries in Asia and especially in Central Asia. Recent studies validate the *likely* northward shifts of crop production with current croplands under threat from the impacts of climate change (*medium agreement, medium evidence*). Cooler regions are *likely* to benefit as warmer temperatures increase arable areas (*high agreement, medium evidence*).

Central Asia is expected to become warmer in the coming decades and increasingly arid, especially in the western parts of Turkmenistan, Uzbekistan, and Kazakhstan (Lioubimtseva and Henebry, 2009). Some parts of the region could be winners (cereal production in northern and eastern Kazakhstan could benefit from the longer growing season, warmer winters and a slight increase in winter precipitation), while others could be losers (particularly western Turkmenistan and Uzbekistan, where frequent droughts could negatively affect cotton production, increase already extremely high water demands for irrigation, and exacerbate the already existing water crisis and human-induced desertification). In India, the Indo-Gangetic Plains are under threat of a significant reduction in wheat yields (Ortiz *et al.*, 2008). This area produces 90 million tons of wheat grain annually (about 14-15% of global wheat production). Climate projections based on a doubling of CO_2 using a CCM3 model downscaled to a 30 arc-second resolution as part of the WorldClim data set showed that there will be a 51% decrease in the most favorable and high yielding area due to heat stress. About 200 million people (using the current population) in this area whose food intake relies on crop harvests would experience adverse impacts.

Rice growing areas are also expected to shift with climate change throughout Asia. In Japan, increasing irrigation water temperature (1.6–2.0°C) could lead to a northward shift of the isochrones of safe transplanting dates for rice seedlings (Ohta and Kimura, 2007). As a result, rice cultivation period will be prolonged by approximately 25–30 days. This will allow greater flexibility in the cropping season than at present, resulting in a reduction in the frequency of cool-summer damage in the northern districts. Sea-level rise threatens coastal and deltaic rice production areas in Asia, such as those in Bangladesh and the Mekong River Delta (Wassmann *et al.*, 2009b). For example, about 7% of Vietnam’s agriculture land may be submerged due to sea-level rise (Dasgupta *et al.*, 2009). In Myanmar, salt water intrusion due to sea-level rise could also decrease rice yield (Wassmann *et al.*, 2009b).

Fisheries and Aquaculture. Asia dominates both capture fisheries and aquaculture (FAO, 2010). More than half of the global marine fish catch in 2008 was in the West Pacific and Indian Ocean, and the lower Mekong River basin supports the largest freshwater capture fishery in the world (Dudgeon, 2011). Fish production is also a vital component of regional livelihoods, with 85.5% of the world’s fishers (28 m) and fish farmers (10 m) in Asia in 2008. Many more people fish part-time. Fish catches in the Asian Arctic are relatively small, but important for local cultures and regional food security (Zeller *et al.*, 2011).

Inland fisheries will continue to be vulnerable to a wide range of on-going threats, including overfishing, habitat loss, water abstraction, drainage of wetlands, pollution, and dam construction, making the impacts of climate change hard to detect (see also 24.9.1). Most concerns have centered on rising water temperatures and the potential impacts of climate change on flow regimes, which in turn are expected to affect the reproduction of many fish species (Allison *et al.*, 2009; Barange and Perry, 2009; Bezuijen, 2011; Dudgeon, 2011; see also Section 24.4.2.3). Sea-level rise is expected to impact both capture fisheries and aquaculture production in river deltas (De Silva and Soto, 2009). For marine capture fisheries, Cheung *et al.* (2009, 2010) used a dynamic bioclimate envelope model to project the distributions of 1066 species of exploited marine fish and invertebrates for 2005-2055, based on the SRES A1B scenario and a stable-2000 $C0_2$ scenario. This analysis suggests that climate change may lead to a massive redistribution of fisheries catch potential, with large increases in high-latitude regions, including Asian Russia, and large declines in the tropics, particularly Indonesia. Other studies have made generally similar predictions, with climate change impacts on marine productivity expected to be large and negative in the tropics, in part because of the vulnerability of coral reefs to both warming and ocean acidification (see also Section 24.4.3.3), and large and positive in arctic and subarctic regions, because of sea-ice retreat and poleward species shifts (Sumaila *et al.*, 2011; Blanchard *et al.*, 2012; Doney *et al.*, 2012) (*high confidence*). Predictions of a reduction in the average maximum body weight of marine fishes by 14-24% by 2050 under a high-emission scenario are an additional threat to fisheries (Cheung *et al.*, 2013).

Future Food Supply and Demand. AR4 Section 10.4.1.4 was largely based on global models that included Asia. There are now a few quantitative studies in Asia and its individual countries. In general, these show that the risk of hunger, food insecurity and loss of livelihood due to climate change will *likely* increase in some regions (*medium agreement, low evidence*).

Rice is a key staple crop in Asia and 90% or more of the world's rice production is from Asia. An Asia-wide study revealed that climate change scenarios (using 18 GCMs for A1B, 14 GCMs for A2, and 17 GCMs for B1) would reduce rice yield over a large portion of the continent (Masutomi *et al.*, 2009). The most vulnerable regions were western Japan, eastern China, the southern part of the Indochina peninsula, and the northern part of South Asia. In Russia, climate change may also lead to "food production shortfall", which was defined as an event in which the annual potential (i.e. climate-related) production of the most important crops in an administrative region in a specific year falls below 50% of its climate-normal (1961–1990) average (Alcamo *et al.*, 2007). The study shows that the frequency of shortfalls in five or more of the main crop growing regions in the same year is around 2 years/decade under normal climate but could climb to 5–6 years/decade in the 2070s, depending on the scenario and climate model (using the GLASS and WaterGAP-2 models and ECHAM and HadCM3 under the A2 and B2 scenarios). The increasing shortfalls were attributed to severe droughts. The study estimated that the number of people living in regions that may experience one or more shortfalls each decade may grow to 82–139 million in the 2070s. Increasing frequency of extreme climate events will pose an increasing threat to the security of Russia's food system.

In contrast, climate change may provide a windfall for wheat farmers in parts of Pakistan. Warming temperatures would make it possible to grow at least two crops (wheat and maize) a year in mountainous areas (Hussain and Mudasser, 2007). In the northern mountainous areas, wheat yield was projected to increase by 50% under SRES A2 and by 40% under the B2 scenario, whereas in the sub-mountainous, semi-arid and arid areas, it is likely to decrease, by the 2080s (Iqbal *et al.*, 2009).

24.4.4.4. Vulnerabilities to Key Drivers

Food production and food security are most vulnerable to rising air temperatures (Wassmann *et al.*, 2009a, 2009b). Warmer temperatures could depress yields of major crops such as rice. However, warmer temperatures could also make some areas more favorable for food production (Lioubimtseva and Henebry, 2009). Increasing CO_2 concentration in the atmosphere could lead to higher crop yields (Tao and Zhang, 2013a). Sea-level rise will be a key issue for many coastal areas as rich agricultural lands may be submerged and taken out of production (Wassmann *et al.*, 2009b).

24.4.4.5. Adaptation Options

Since AR4, there have been additional studies of recommended and potential adaptation strategies and practices in Asia (Table 24-SM-7) and there is new information for West and Central Asia. There are also many more crop-specific and country-specific adaptation options available. Farmers have been adapting to climate risks for generations. Indigenous and local adaptation strategies have been documented for Southeast Asia (Peras *et al.*, 2008; Lasco *et al.*, 2010; Lasco *et al.*, 2011) and could be used as a basis for future climate change adaptation. Crop breeding for high temperature condition is a promising option for climate change adaptation in Asia. For example, in the North China Plain simulation studies show that using high-temperature sensitive varieties, maize yield in the 2050s could increase on average by 1.0–6.0%, 9.9–15.2%, and 4.1–5.6%, by adopting adaptation options of early planting, fixing variety growing duration, and late planting, respectively (Tao and Zhang, 2010). In contrast, no adaptation will result in yield declines of 13.2–19.1%.

24.4.5. Human Settlements, Industry, and Infrastructure

24.4.5.1. Sub-Regional Diversity

Around one in every five urban dwellers in Asia lives in large urban agglomerations and almost 50% of these live in small cities (UN, 2012). North and Central Asia are the most urbanized areas, with over 63% of the population living in urban areas, with the exception of Kyrgyzstan and Tajikistan (UN-Habitat, 2010; UN ESCAP, 2011). South and Southwest Asia are the least urbanized subregions, with only a third of their populations living in urban areas. However, these regions have the highest urban population growth rates within Asia at an average of 2.4% per year during 2005-2010 (UN ESCAP, 2011). By the middle of this century, Asia's urban population will increase by 1.4 billion and will account for over 50% of the global population (UN, 2012).

24.4.5.2. Observed Impacts

Asia experienced the highest number of weather- and climate-related disasters in the world during the period 2000-2008 and suffered huge economic losses, accounting for the second highest proportion (27.5%) of the total global economic loss (IPCC, 2012). Flood mortality risk is heavily concentrated in Asia. Severe floods in Mumbai in 2005 have been attributed to both climatic factors and non-climatic factors. Strengthened capacities to address the mortality risk associated with major weather-related hazards, such as floods, have resulted in a downward trend in mortality risk relative to population size, as in East Asia, where it is now a third of its 1980 level (UNISDR, 2011).

24.4.5.3. Projected Impacts

A large proportion of Asia's population lives in low elevation coastal zones that are particularly at risk from climate change hazards, including sea-level rise, storm surges and typhoons (see Sections 5.3.2.1 and 8.2.2.5, Box CC-TC). Depending on the region, half to two-thirds of Asia's cities with 1 million or more inhabitants are exposed to one or multiple hazards, with floods and cyclones the most important (UN, 2012).

Floodplains and Coastal Areas. Three of the world's five most populated cities (Tokyo, Delhi and Shanghai) are located in areas with high risk of floods (UN, 2012). Flood risk and associated human and material losses are heavily concentrated in India, Bangladesh, and China. At the same time, the East Asia region in particular is experiencing increasing water shortages, negatively affecting its socioeconomic, agricultural, and environmental conditions, which is attributed to lack of rains and high evapotranspiration, as well as over-exploitation of water resources (IPCC, 2012). Large parts of South, East and Southeast Asia are exposed to a high degree of cumulative climate-related risk (UN-Habitat, 2011). Asia has more than 90% of the global population exposed to tropical cyclones (IPCC, 2012); see Box CC-TC). Damage due to storm surge is sensitive to change in the magnitude of tropical cyclones. By the 2070s, the top Asian cities in terms of population exposure (including all environmental and socioeconomic factors) to coastal flooding are expected to be Kolkata, Mumbai, Dhaka, Guangzhou, Ho Chi Minh City, Shanghai, Bangkok, Rangoon, and Hai Phòng (Hanson *et al.*, 2011). The top Asian cities in terms of assets exposed are expected to be Guangdong, Kolkata, Shanghai, Mumbai, Tianjin, Tokyo, Hong Kong, and Bangkok. Asia includes 15 of the global top 20 cities for projected population exposure and 13 of the top 20 for asset exposure.

Other Issues in Human Settlements. Asia has a large – and rapidly expanding – proportion of the global urban exposure and vulnerability related to climate change hazards (see SREX Section 4.4.3). In line with the rapid urban growth and sprawl in many parts of Asia, the periurban interface between urban and rural areas deserves particular attention when considering climate change vulnerability (see also Section 18.4.1). Garschagen *et al.* (2011) find, for example, that periurban agriculturalists in the Vietnamese Mekong Delta are facing a multiple burden since they are often exposed to overlapping risks resulting from (a) socio-economic transformations, such as land title insecurity and price pressures; (b) local biophysical degradation, as periurban areas serve as sinks for urban wastes; and (c) climate change impacts, as they do not benefit from the inner-urban disaster risk management measures.

Nevertheless, the periurban interface is still underemphasized in studies on impacts, vulnerability and adaptation in Asia.

Groundwater sources, which are affordable means of high-quality water supply in cities of developing countries, are threatened due to over-withdrawals. Aquifer levels have fallen by 20-50 m in cities such as Bangkok, Manila and Tianjin and between 10-20 m in many other cities (UNESCO, 2012). The drop in groundwater levels often results in land subsidence, which can enhance hazard exposure due to coastal inundation and sea-level rise, especially in settlements near the coast, and deterioration of groundwater quality. Cities susceptible to human-induced subsidence (mainly, developing country cities in deltaic regions with rapidly growing populations) could see significant increases in exposure (Nicholls *et al.*, 2008). Settlements on unstable slopes or landslide-prone areas face increased prospects of rainfall-induced landslides (IPCC, 2012).

Industry and Infrastructure. The impacts of climate change on industry include both direct impacts on industrial production and indirect impacts on industrial enterprises due to the implementation of mitigation activities (Li, 2008). The impact of climate change on infrastructure deterioration cannot be ignored, but can be addressed by changes to design procedures, including increases in cover thickness, improved quality of concrete, and coatings and barriers (Stewart *et al.*, 2012). Climate change and extreme events may have a greater impact on large and medium-sized construction projects (Kim *et al.*, 2007).

Estimates suggest that by upgrading the drainage system in Mumbai, losses associated with a 1-in-100 year flood event today could be reduced by as much as 70%, and through extending insurance to 100% penetration, the indirect effects of flooding could be almost halved, speeding recovery significantly (Ranger *et al.*, 2011). On the east coast of India, clusters of districts with poor infrastructure and demographic development are also the regions of maximum vulnerability. Hence, extreme events are expected to be more catastrophic in nature for the people living in these districts. Moreover, the lower the district is in terms of the infrastructure index and its growth, the more vulnerable it is to the potential damage from extreme events and hence people living in these regions are prone to be highly vulnerable (Patnaik and Narayanan, 2009). In 2008, the embankments on the Kosi River (a tributary of the Ganges) failed, displacing over sixty thousand people in Nepal and three and a half million in India. Transport and power systems were disrupted across large areas. However, the embankment failure was not caused by an extreme event but represented a failure of interlinked physical and institutional infrastructure systems in an area characterized by complex social, political, and environmental relationships (Moench, 2010).

24.4.5.4. Vulnerabilities to Key Drivers

Disruption of basic services such as water supply, sanitation, energy provision, and transportation systems have implications for local economies and “strip populations of their assets and livelihoods”, in some cases leading to mass migration (UN-Habitat, 2010). Such impacts are not expected to be evenly spread among regions and cities, across sectors of the economy, or among socioeconomic groups. They tend to reinforce existing inequalities and disrupt the social fabric of cities and exacerbate poverty.

24.4.5.5. Adaptation Options

An ADB and UN report estimates that “about two-thirds of the $8 trillion needed for infrastructure investment in Asia and the Pacific between 2010 and 2020 will be in the form of new infrastructure, which creates tremendous opportunities to design, finance and manage more sustainable infrastructure” (ADB *et al.*, 2012).) Adaptation measures that offer a ‘no regrets’ solution are proposed for developing countries, “where basic urban infrastructure is often absent (e.g. appropriate drainage infrastructure), leaving room for actions that both increase immediate well-being and reduce vulnerability to future climate change” (Hallegatte and Corfee-Morlot, 2011). The role of urban planning and urban planners in adaptation to climate change impacts has been emphasized (Fuchs *et al.*, 2011; IPCC, 2012; Tyler and Moench, 2012). The focus on solely adapting through physical infrastructure in urban areas requires complementary adapting planning, management, governance and institutional arrangements to be able to deal with the uncertainty and the unprecedented challenges implied by climate change (Revi, 2008; Birkmann *et al.*, 2010; Garschagen and Kraas, 2011).

24.4.6. Human Health, Security, Livelihoods, and Poverty

24.4.6.1. Sub-Regional Diversity

Although rapidly urbanizing, Asia is still predominantly an agrarian society, with 57.28% of its total population living in rural areas, of which 81.02% are dependent on agriculture for their livelihoods (FAOSTAT, 2011). Rural poverty is higher than urban poverty, reflecting the heavy dependence on natural resources that are directly influenced by changes in weather and climate (Haggblade *et al.*, 2010; IFAD, 2010). Rural poverty is expected to remain more prevalent than urban poverty for decades to come (Ravallion *et al.*, 2007). However, climate change will also affect urbanizing Asia, where the urban poor will be impacted indirectly, as evident from the food price rises in the Middle East and other areas in 2007-2008. Certain categories of urban dwellers, such as urban wage labor households, are particularly vulnerable (Hertel *et al.*, 2010).

Agriculture has been identified as a key driver of economic growth in Asia (World Bank, 2007). Although economic growth was impressive in recent decades, there are still gaps in development compared to the rest of the world (World Bank, 2011). Southeast Asia is the third poorest performing region after Sub-Saharan Africa and Southern Asia in terms of the Human Development Indicators (UN, 2009). Impacts on human security in Asia will primarily manifest through impacts on water resources, agriculture, coastal areas, resource-dependent livelihoods, and urban settlements and infrastructure, with implications for human health and well-being. Regional disparities on account of socioeconomic context and geographical characteristics largely define the differential vulnerabilities and impacts within countries in Asia (Thomas, 2008; Sivakumar and Stefanski, 2011).

24.4.6.2. Observed Impacts

Floods and Health. Epidemics have been reported after floods and storms (Bagchi, 2007) as a result of decreased drinking water quality (Harris *et al.*, 2008; Hashizume *et al.*, 2008; Solberg, 2010; Kazama *et al.*, 2012), mosquito proliferation (Pawar *et al.*, 2008), and exposure to rodent-borne pathogens (Kawaguchi *et al.*, 2008; Zhou *et al.*, 2011) and the intermediate snail hosts of *Schistosoma* (Wu *et al.*, 2008). Contaminated urban flood waters have caused exposure to pathogens and toxic compounds, for example in India and Pakistan (Sohan *et al.*, 2008; Warraich *et al.*, 2011). Mental disorders and posttraumatic stress syndrome have also been observed in disaster prone areas (Udomratn, 2008) and, in India, have been linked to age and gender (Telles *et al.*, 2009). See also Chapter 11.4.2. for flood-attributable deaths.

Heat and Health. The effects of heat on mortality and morbidity have been studied in many countries, with a focus on the elderly and people with cardiovascular and respiratory disorders (Kan *et al.*, 2007; Guo *et al.*, 2009; Huang *et al.*, 2010). Associations between high temperatures and mortality have been shown for populations in India and Thailand (McMichael *et al.*, 2008) and in several cities in East Asia (Kim *et al.*, 2006; Chung *et al.*, 2009). Several studies have analyzed the health effects of air pollution in combination with increased temperatures (Lee *et al.*, 2007; Qian *et al.*, 2010; Wong *et al.*, 2010; Yi *et al.*, 2010). Intense heat waves have been shown to affect outdoor workers in South and East Asia (Nag *et al.*, 2007; Hyatt *et al.*, 2010).

Drought and Health. Dust storms in Southwest, Central and East Asia result in increased hospital admissions and worsen asthmatic conditions, as well as causing skin and eye irritations (Griffin, 2007; Hashizume *et al.*, 2010; Kan *et al.*, 2012). Droughts may also lead to wildfires and smoke exposure, with increased morbidity and mortality, as observed in Southeast Asia (Johnston *et al.*, 2012). Drought can also disrupt food security, increasing malnutrition (Kumar *et al.*, 2005) and thus susceptibility to infectious diseases.

Water-borne Diseases. Many pathogens and parasites multiply faster at higher temperatures. Temperature increases have been correlated with increased incidence of diarrheal diseases in East Asia (Huang *et al.*, 2008; Zhang *et al.*, 2008; Onozuka *et al.*, 2010). Other studies from South and East Asia have shown an association between diarrheal outbreaks and a combination of higher temperatures and heavy rainfall (Hashizume *et al.*, 2007; Majra and Gur, 2009; Chou *et al.*, 2010). Increasing coastal water temperatures correlated with outbreaks of systemic *Vibrio vulnificus* infection in Israel (Paz *et al.*, 2007) and South Korea (Kim and Jang, 2010). Cholera outbreaks in coastal populations in South Asia have been associated with increased water temperatures and algal blooms (Huq *et al.*, 2005). The ENSO cycle and Indian Ocean Dipole have been associated with cholera epidemics in Bangladesh (Pascual, 2000; Rodó *et al.*, 2002; Hashizume *et al.*, 2011).

Vector-borne Diseases. Increasing temperatures affect vector-borne pathogens during the extrinsic incubation period and shorten vector life-cycles, facilitating larger vector populations and enhanced disease transmission, whilst the vector's ability to acquire and maintain a pathogen tails off (Paaijmans *et al.*, 2012). Dengue outbreaks in South and Southeast Asia are correlated with temperature and rainfall with varying time lags (Su, 2008; Hii *et al.*, 2009; Hsieh and Chen, 2009; Shang *et al.*, 2010; Sriprom *et al.*, 2010; Hashizume *et al.*, 2012). Outbreaks of vaccine-preventable Japanese encephalitis have been linked to rainfall in studies from the Himalayan region (Partridge *et al.*, 2007; Bhattachan *et al.*, 2009), and to rainfall and temperature in South and East Asia (Bi *et al.*, 2007; Murty *et al.*, 2010). Malaria prevalence is often influenced by non-climate variability factors, but studies from India and Nepal have found correlations with rainfall (Devi and Jauhari, 2006; Dev and Dash, 2007; Dahal, 2008; Laneri *et al.*, 2010). Temperature was linked to distribution and seasonality of malaria mosquitoes in Saudi Arabia (Kheir *et al.*, 2010). The re-emergence of malaria in central China has been attributed to rainfall and increases in temperature close to water bodies (Zhou *et al.*, 2010). In China, temperature, precipitation, and the virus-carrying index among rodents have been found to correlate with the prevalence of hemorrhagic fever with renal syndrome (Guan *et al.*, 2009).

Livelihoods and Poverty. An estimated 51% of total income in rural Asia comes from non-farm sources (Haggblade *et al.*, 2009, 2010), mostly local non-farm business and employment. The contribution of remittances to rural income has grown steadily (Estudillo and Otsuka, 2010). Significant improvements have been made in poverty eradication over the past decade (World Bank, 2008), with rapid reductions in poverty in East Asia, followed by South Asia (IFAD, 2010). A significant part of the reduction has come from population shifts, rapid growth in agriculture, and urban contributions (Janvry and Sadoulet, 2010). Climate change negatively impacts livelihoods (see Table 24-SM-4) and these impacts are directly related to natural resources affected by changes in weather and climate. Factors that have made agriculture less sustainable in the past include input non-responsive yields, soil erosion, natural calamities, and water and land quality related problems (Dev, 2011). These have predisposed rural livelihoods to climate change vulnerability. Livelihoods are impacted by droughts (Harshita, 2013; Selvaraju *et al.*, 2006), floods (Nuorteva *et al.*, 2010; Dun, 2011; Nguyen, 2007; Keskinen *et al.*, 2010) and typhoons (Huigen and Jens, 2006; Gaillard *et al.*, 2007; Uy *et al.*, 2011). Drought disproportionately impacts small farmers, agricultural laborers, and small businessmen (Selvaraju *et al.*, 2006), who also have least access to rural safety net mechanisms, including financial services (IFAD, 2010), despite recent developments in microfinance services in parts of Asia. Past floods have exposed conditions such as lack of access to alternative livelihoods, difficulty in maintaining existing livelihoods, and household debts leading to migration in the Mekong region (Dun, 2011). Similar impacts of repeated floods leading to perpetual vulnerability were found in the Tonle Sap Lake area of Cambodia (Nuorteva *et al.*, 2010; Keskinen *et al.*, 2010). Typhoon impacts are mainly through damage to the livelihood assets of coastal populations in the Philippines and the level of ownership of livelihood assets has been a major determinant of vulnerability (Uy *et al.*, 2011).

24.4.6.3. Projected Impacts

Health Effects. An emerging public health concern in Asia is increasing mortality and morbidity due to heat waves. An ageing population will increase the number of people at risk, especially those with cardiovascular and respiratory disorders. Urban heat island effects have increased (Tan *et al.*, 2010), although local adaptation of the built environment and urban planning will determine the impacts on public health. Heat stress disorders among workers and consequent productivity losses have also been reported (Lin *et al.*, 2009; Langkulsen *et al.*, 2010). The relationship between temperature and mortality is often U-shaped (Guo *et al.*, 2009), with increased mortality also during cold events, particularly in rural environments, even if temperatures do not fall below 0°C (Hashizume *et al.*, 2009). However, some studies in developing areas suggest that factors other than climate can be important, so warming may not decrease cold-related deaths much in these regions (Honda and Ono, 2009).

Climate change will affect the local transmission of many climate-sensitive diseases. Increases in heavy rain and temperature are projected to increase the risk of diarrheal diseases in, for example, China (Zhang *et al.*, 2008). However, the impact of climate change on malaria risk will differ between areas, as projected for West and South Asia (Husain and Chaudhary, 2008; Garg *et al.*, 2009; Majra and Gur, 2009), while a study suggested that the impact of socioeconomic development will be larger than that of climate change (Béguin *et al.*, 2011).
Climate change is also expected to affect the spatiotemporal distribution of dengue fever in the region, although the level of evidence differs across geographical locations (Banu *et al.*, 2011). Some studies have developed climate change-disease prevalence models, for example one for schistosomiasis in China shows an increased northern distribution of the disease with climate change (Zhou *et al.*, 2008; Kan *et al.*, 2012). Impacts of climate change on fish production (Qiu *et al.*, 2010) are being studied, along with impacts on chemical pathways in the marine environment and consequent impacts on food safety (Tirado *et al.*, 2010), including seafood safety (Marques *et al.*, 2010).

Livelihood and Poverty. Floods, droughts and changes in seasonal rainfall patterns are expected to negatively impact crop yields, food security and livelihoods in vulnerable areas (Dawe *et al.*, 2008; Kelkar *et al.*, 2008; Douglas, 2009). Rural poverty in parts of Asia could be exacerbated (Skoufias *et al.*, 2011) due to impacts on the rice crop and increases in food prices and the cost of living (Hertel *et al.*, 2010; Rosegrant, 2011). The poverty impacts of climate change will be heterogeneous among countries and social groups (see Table 24-SM-5). In a low crop productivity scenario, producers in food exporting countries, such as Indonesia, the Philippines and Thailand, would benefit from global food price rises and reduce poverty, while countries such as Bangladesh would experience a net increase in poverty of 15% by 2030 (Hertel *et al.*, 2010). These impacts will also differ within food exporting countries, with disproportionate negative impacts on farm laborers and the urban poor. Skoufias *et al.* (2011) project significant negative impacts of a rainfall shortfall on the welfare of rice farmers in Indonesia, compared to a delay in rainfall onset. These impacts may lead to global mass migration and related conflicts (Laczko and Aghazarm, 2009; Barnett and Webber, 2010; Warner, 2010; World Bank, 2010). In North Asia, climate-driven changes in tundra and forest-tundra biomes may influence indigenous peoples who depend on nomadic tundra pastoralism, fishing and hunting (Kumpula *et al.*, 2011).

24.4.6.4. Vulnerabilities to Key Drivers

Key vulnerabilities vary widely within the region. Climate change can exacerbate current socio-economic and political disparities and add to the vulnerability of Southeast Asia and Central Asia to security threats that may be transnational in nature (Jasparro and Taylor, 2008; Lioubimtseva and Henebry, 2009). Apart from detrimental impacts of extreme events, vulnerability of livelihoods in agrarian communities also arises from geographic settings, demographic trends, socio-economic factors, access to resources and markets, unsustainable water consumption, farming practices and lack of adaptive capacity (Mulligan *et al.*, 2011; Acosta-Michlik and Espaldon, 2008; Allison *et al.*, 2009; Knox *et al.*, 2011; Lioubimtseva and Henebry, 2009; Byg and Salick, 2009; Salick and Ross, 2009; Salick *et al.*, 2009; Xu *et al.*, 2009; UN, 2009). Urban wage laborers were found to be more vulnerable to cost of living related poverty impacts of climate change than those who directly depend on agriculture for their livelihoods (Hertel *et al.*, 2010). In Indonesia, drought-associated fires increase vulnerability of agriculture, forestry and human settlements, particularly in peatland areas (Murdiyarso and Lebel, 2007). Human health is also a major area of focus for Asia (Munslow and O'Dempsey, 2010), where the magnitude and type of health effects from climate change depend on differences in socioeconomic and demographic factors, health systems, the natural and built environment, land use changes, and migration, in relation to local resilience and adaptive capacity. The role of institutions is also critical, particularly in influencing vulnerabilities arising from gender (Ahmed and Fajber, 2009), caste and ethnic differences (Jones and Boyd, 2011), and securing climate-sensitive livelihoods in rural areas (Agrawal and Perrin, 2008).

24.4.6.5. Adaptation Options

Disaster preparedness on a local community level could include a combination of indigenous coping strategies, early-warning systems, and adaptive measures (Paul and Routray, 2010). Heat warning systems have been successful in preventing deaths among risk groups in Shanghai (Tan *et al.*, 2007). New work practices to avoid heat stress among outdoor workers, in Japan and the UAE have also been successful (Morioka *et al.*, 2006; Joubert *et al.*, 2011). Early warning models have been developed for haze exposure from wildfires, in for example Thailand (Kim Oanh and Leelasakultum, 2011), and are being tested in infectious disease prevention and vector control programs, as for malaria in Bhutan (Wangdi *et al.*, 2010) and Iran (Haghdoost *et al.*, 2008), or are being developed, as for dengue fever region-wide (Wilder-Smith *et al.*, 2012).

Some adaptation practices provide unexpected livelihood benefits, as with the introduction of traditional flood mitigation measures in China which could positively impact local livelihoods, leading to reductions in both the physical and economic vulnerabilities of communities (Xu *et al.*, 2009). A greater role of local communities in decision making is also proposed (Alauddin and Quiggin, 2008) and in prioritization and adoption of adaptation options (Prabhakar *et al.*, 2010; Prabhakar and Srinivasan, 2011). Defining adequate community property rights, reducing income disparity, exploring market-based and off-farm livelihood options, moving from production-based approaches to productivity and efficiency decision-making based approaches, and promoting integrated decision-making approaches, have also been suggested (Merrey *et al.*, 2005; Brouwer *et al.*, 2007; Paul *et al.*, 2009; Niino, 2011; Stucki and Smith, 2011).

Climate resilient livelihoods can be fostered through the creation of bundles of capitals (natural, physical, human, financial and social capital) and poverty eradication (Table 24-SM-8). Greater emphasis on agricultural growth has been suggested as an effective means of reducing rural poverty (Janvry and Sadoulet, 2010; Rosegrant, 2011). Bundled approaches are known to facilitate better adaptation than individual adaptation options (Acosta-Michlik and Espaldon, 2008; Fleischer *et al.*, 2011). Community-based approaches have been suggested to identify adaptation options that address poverty and livelihoods, as these techniques help capture information at the grassroots (Huq and Reid, 2007; van Aalst *et al.*, 2008), and help integration of disaster risk reduction, development, and climate change adaptation (Heltberg *et al.*, 2010), connect local communities and outsiders (van Aalst *et al.*, 2008), address the location-specific nature of adaptation (Iwasaki *et al.*, 2009; Rosegrant, 2011), help facilitate community learning processes (Bass and Ramasamy, 2008), and help design location-specific solutions (Ensor and Berger, 2009). Some groups can become more vulnerable to change after being 'locked into' specialized livelihood patterns, as with fish farmers in India (Coulthard, 2008).

Livelihood diversification, including livelihood assets and skills, has been suggested as an important adaptation option for buffering climate change impacts on certain kinds of livelihoods (Selvaraju *et al.*, 2006; Nguyen, 2007; Agrawal and Perrin, 2008; IFAD, 2011; Keskinen *et al.*, 2010; Uy *et al.*, 2011). The diversification should occur across assets, including productive assets, consumption strategies and employment opportunities (Agrawal and Perrin, 2008). Ecosystem-based adaptation has been suggested to secure livelihoods in the face of climate change (Jones *et al.*, 2012), integrating the use of biodiversity and ecosystem services into an overall strategy to help people adapt (IUCN, 2009). Among financial means, low-risk liquidity options such as microfinance programs and risk transfer products can help lift the rural poor from poverty and accumulate assets (Barrett *et al.*, 2007; Jarvis *et al.*, 2011).

24.4.7 Valuation of Impacts and Adaptation

Economic valuation in Asia generally covers impacts and vulnerabilities of disperse sectors such as food production, water resources and human health (Aydinalp and Cresser, 2008; Kelkar *et al.*, 2008; Lioubimtseva and Henebry, 2009; Su *et al.*, 2009; Srivastava *et al.*, 2010). Multi-sector evaluation that unpacks the relationships between and across sectors, particularly in a context of resource scarcity and competition, is very limited. Information is scarce especially for North, Central and West Asia.

Generally, annual losses from drought are expected to increase based on various projection under diverse scenarios, but such losses are expected to be reduced if adaptation measures are implemented (ADB, 2009; Sutton *et al.*, 2013). It is also stressed that there are great uncertainties associated with the economic aspects of climate change. In China, the total loss due to drought projected in 2030 is expected to range from $1.1-1.7 billion for regions in northeast China and about $0.9 billion for regions in north China (CWF *et al.*, 2009), with adaptation measures having the potential to avert half of the losses. In India, the estimated countrywide agricultural loss in 2030 of over $7 billion that will severely affect the income of 10% of the population could be reduced by 80% if cost-effective climate resilience measures are implemented (CWF *et al.*, 2009).

In Indonesia, the Philippines, Thailand and Vietnam, under the A2 scenario, the PAGE2002 integrated assessment model projects a mean loss of 2.2% of gross domestic product (GDP) by 2100 on an annual basis, if only the market impact (mainly related to agriculture and coastal zones) is considered (ADB, 2009). This is well above the world's projected mean GDP loss of 0.6% each year by 2100 due to market impact alone. In addition, the mean cost for the four countries could reach 5.7% of the GDP if non-market impacts related to health and ecosystems are included and 6.7% of the GDP if catastrophic risks are also taken into account. The cost of adaptation for agriculture and coastal zones is expected to be about $5 billion/year by 2020 on average. Adaptation that is complemented with global mitigation measures is expected to be more effective in reducing the impacts of climate change (IPCC, 2007; ADB, 2009; UNFCCC, 2009; MNRE, 2010; Begum *et al.*, 2011).

24.5. Adaptation and Managing Risks

24.5.1. Conservation of Natural Resources

Natural resources are already under severe pressure from land-use change and other impacts in much of Asia. Deforestation in Southeast Asia has received most attention (Sodhi *et al.*, 2010; Miettinen *et al.*, 2011a), but ecosystem degradation, with the resulting loss of natural goods and services, is also a major problem in other ecosystems. Land-use change is also a major source of regional greenhouse gas emissions, particularly in Southeast Asia (see WGI AR5 Section 6.3.2.2 and Table 6.3). Projected climate change is expected to intensify these pressures in many areas (see Sections 24.4.2.3 and 24.4.3.3), most clearly for coral reefs, where increases in sea surface temperature and ocean acidification are a threat to all reefs in the region and the millions of people who depend on them (see Section 5.4.2.4 and Boxes CC-CR and CC-OA). Adaptation has so far focused on minimizing non-climate pressures on natural resources and restoring connectivity to allow movements of genes and species between fragmented populations (see Section 24.4.2.5). Authors have also suggested a need to identify and protect areas that will be subject to the least damaging climate change ('climate refugia') and to identify additions to the protected area network that will allow for expected range shifts, for example by extending protection to higher altitudes or latitudes. Beyond the intrinsic value of wild species and ecosystems, ecosystem-based approaches to adaptation aim to use the resilience of natural systems to buffer human systems against climate change, with potential social, economic and cultural co-benefits for local communities (see Box CC-EA).

24.5.2. Flood Risks and Coastal Inundation

Many coasts in Asia are exposed to threats from floods and coastal inundation (see also 24.4.5.3). Responding to a large number of climate change impact studies for each Asian country over the past decade (e.g. Karim and Mimura, 2008; Pal and Al-Tabbaa, 2009), various downscaled tools to support, formulate and implement climate change adaptation policy for local governments are under development. One of the major tools is vulnerability assessment and policy option identification with Geographical Information Systems (GIS). These tools are expected to be of assistance in assessing city-specific adaptation options by examining estimated impacts and identified vulnerability for some coastal cities and areas in Asian countries (e.g. Brouwer *et al.*, 2007; Taylor, 2011; Storch and Downs, 2011). These tools and systems sometimes take the form of integration of top down approaches and bottom-up (community-based) approaches (see Section 14.5). Whereas top-down approaches give scientific knowledge to local actors, community-based approaches are built on existing knowledge and expertise to strengthen coping and adaptive capacity by involving local actors (van Aalst *et al.*, 2008). Community-based approaches may have a limitation in that they place greater responsibility on the shoulders of local people without necessarily increasing their capacity proportionately (Allen, 2006). As the nature of adaptive capacity varies depending on the formulation of social capital and institutional context in the local community, it is essential for the approaches to be based on an understanding of local community structures (Adger, 2003).

24.5.3. Economic Growth and Equitable Development

Climate change challenges fundamental elements in social and economic policy goals such as prosperity, growth, equity and sustainable development (Mearns and Norton, 2010). Economic, social, and environmental equity is an enduring challenge in many parts of Asia. Generally, the level of wealth (typically GDP) has been used as a measure of human vulnerability of a country but this approach has serious limitations (Mattoo and Subramanian, 2012; Dellink *et al.*, 2009). In many cases, social capital, an indicator of equity in income distribution within countries, is a more important factor in vulnerability and resilience than GDP per capita (Lioubimtseva and Henebry, 2009; Islam *et al.*, 2006). Furthermore, political and institutional instabilities can undermine the influence of economic development (Lioubimtseva and Henebry, 2009). Poor and vulnerable countries are at greater risk of inequity and loss of livelihoods from the impacts of climate extremes as their options for coping with such events are limited. Many factors contribute to this limitation, including poverty, illiteracy, weak institutions and infrastructures, poor access to resources, information and technology, poor health care, and low investment and management capabilities. The overexploitation of land resources including forests, increases in population, desertification and land degradation pose additional threats (UNDP, 2006). This is particularly true for developing countries in Asia with a high level of natural resource dependency. Provision of adequate resources based on the burden sharing and the equity principle will serve to strengthen appropriate adaptation policies and measures in such countries (Su *et al.*, 2009).

24.5.4. Mainstreaming and Institutional Barriers

Mainstreaming climate change adaptation into sustainable development policies offers a potential opportunity for good practice to build resilience and reduce vulnerability, depending on effective, equitable and legitimate actions to overcome barriers and limits to adaptation (ADB, 2005; Lim *et al.*, 2005; Lioubimtseva and Henebry, 2009). The level of adaptation mainstreaming is most advanced in the context of official development assistance, where donor agencies and international financial institutions have made significant steps towards taking climate change adaptation into account in their loan and grant making processes (Gigli and Agrawala, 2007; Klein *et al.*, 2007). While some practical experiences of adaptation in Asia at the regional, national and local level are emerging, there can be barriers that impede or limit adaptation. These include challenges related to competing national priorities, awareness and capacity, financial resources for adaptation implementation, institutional barriers, biophysical limits to ecosystem adaptation, and social and cultural factors (Lasco *et al.*, 2009; Moser and Ekstrom, 2010; Lasco *et al.*, 2012). Issues with resource availability might not only result from climate change, but also from weak governance mechanisms and the breakdown of policy and regulatory structures, especially with common-pool resources (Moser and Ekstrom, 2010). Furthermore, the impact of climate change depends on the inherent vulnerability of the socio-ecological systems in a region as much as on the magnitude of the change (Evans, 2010). Recent studies linking climate-related resource scarcities and conflict call for enhanced regional cooperation (Gautam, 2012).

24.5.5. Role of Higher Education in Adaptation and Risk Management

To enhance the development of young professionals in the field of climate change adaptation, the topic could be included in higher education, especially in formal education programs. Shaw *et al.* (2011) mentioned that higher education in adaptation and disaster risk reduction in the Asia-Pacific region can be done through environment disaster linkage, focus on hydro-meteorological disasters, and emphasizing synergy issues between adaptation and risk reduction. Similar issues are also highlighted by other authors (Chhokar, 2010; Niu *et al.*, 2010; Nomura and Abe, 2010; Ryan *et al.*, 2010). Higher education should be done through lectures and course work, field studies, internships, and establishing education-research link by exposing the students to field realities. In this regard, guiding principles could include: an inclusive curriculum, focus on basic theory, field orientation, multidisciplinary courses and practical skill enhancement. Bilateral or multilateral practical research programs on adaptation and risk management by the graduate students and young faculty members would expose them to the real field problems.

24.6. Adaptation and Mitigation Interactions

Integrated mitigation and adaptation responses focus on either land-use changes or technology development and use. Changes in land use, such as agroforestry, may provide both mitigation and adaptation benefits (Verchot *et al.*, 2007), or otherwise, depending on how they are implemented. Agroforestry practices provide carbon storage and may decrease soil erosion, increase resilience against floods, landslides and drought, increase soil organic matter, reduce the financial impact of crop failure, as well as have biodiversity benefits over other forms of agriculture, as shown, for example, in Indonesia (Clough *et al.*, 2011). Integrated approaches are often needed when developing mitigation-adaptation synergies, as seen in waste-to-compost projects in Bangladesh (Ayers and Huq, 2009). Other adaptation measures that increase biomass and/or soil carbon content, such as ecosystem protection and reforestation, will also contribute to climate mitigation by carbon sequestration. However, exotic monocultures may fix more carbon than native mixtures while supporting less biodiversity and contributing less to ecological services, calling for compromises that favor biodiversity-rich carbon storage (Diaz *et al.*, 2009). The potential for both adaptation and mitigation through forest restoration is greatest in the tropics (Sasaki *et al.*, 2011). At higher latitudes (>45^{o}N), reforestation can have a net warming influence by reducing surface albedo (Anderson-Teixeira *et al.*, 2012). Expansion of biofuel crops on abandoned and marginal agricultural lands could potentially make a large contribution to mitigation of carbon emissions from fossil fuels, but could also have large negative consequences for both carbon and biodiversity if it results directly or indirectly in the conversion of carbon-rich ecosystems to cropland (Fargione *et al.*, 2010; Qin *et al.*, 2011). Mechanisms, such as REDD+, that put an economic price on land-use emissions, could reduce the risks of such negative consequences (Thomson *et al.*, 2010), but the incentive structures need to be worked out very carefully (Busch *et al.*, 2012).

Forests and their management are also often emphasized for providing resilient livelihoods and reducing poverty (Chhatre and Agrawal, 2009; Noordwijk, 2010; Persha *et al.*, 2010; Larson, 2011). Securing rights to resources is essential for greater livelihood benefits for poor indigenous and traditional people (Macchi *et al.*, 2008) and the need for REDD+ schemes to respect and promote community forest tenure rights has been emphasized (Angelsen, 2009). It has been suggested that indigenous people can provide a bridge between biodiversity protection and climate change adaptation (Salick and Ross, 2009): a point that appears to be missing in the current discourse on ecosystem-based adaptation. There are arguments against REDD+ supporting poverty reduction due to its inability to promote productive use of forests, which may keep communities in perpetual poverty (Campbell, 2009), but there is a contrasting view that REDD+ can work in forests managed for timber production (Putz *et al.*, 2012; Guariguata *et al.*, 2008), especially through reduced impact logging (Guariguata *et al.*, 2008) and other approaches such as assuring the legality of forest products, certifying responsible management, and devolving control over forests to empowered local communities (Putz *et al*., 2012).

On rivers and coasts, the use of hard defenses (e.g. sea-walls, channelization, bunds, dams) to protect agriculture and human settlements from flooding may have negative consequences for both natural ecosystems and carbon sequestration by preventing natural adjustments to changing conditions (see 24.4.3.5). Conversely, setting aside landward buffer zones along coasts and rivers would be positive for both. The very high carbon sequestration potential of the organic-rich soils in mangroves (Donato *et al.*, 2011) and peat swamp forests (Page *et al.*, 2011) provides opportunities for combining adaptation with mitigation through restoration of degraded areas.

Mitigation measures can also result in public health benefits (Bogner *et al.*, 2008; Haines *et al.*, 2009). For example, sustainable cities with fewer fossil-fuel driven vehicles (mitigation) and more trees and greenery (carbon storage and adaptation to the urban heat island effect) would have a number of co-benefits, including public health – a promising strategy for “triple win” interventions (Romero-Lankao *et al.*, 2011). Other examples include efforts to decarbonize electricity production in India and China that are projected to decrease mortality due to reduced PM5 and PM2.5 particulates (Markandya *et al.*, 2009); policies to increase public transportation, promote walking and cycling, and reduce private cars that will increase air quality and decrease the health burden, particularly in urban environments as projected in India (Woodcock *et al.*, 2009) ; and abandoning the use of biomass fuel or coal for indoor cooking and heating to improve indoor air quality and respiratory and cardiac health among, in particular, women and children in India and China (Wilkinson *et al.*, 2009). Conversely, actions to reduce current environmental-public health issues may often have beneficial mitigation effects, like traffic emissions reduction programs in China (Wu *et al.*, 2011) and India (Reynolds and Kandikar, 2008).

24.7. Intra-regional and Inter-regional Issues

24.7.1. Trans-boundary Pollution

Many Asian countries and regions face long-distance and trans-boundary air pollution problems. In eastern China, Japan and the Korean Peninsula, these include dust storms that originate in the arid and semi-arid regions upwind, with impacts on climate, human health and ecosystems (Huang *et al.*, 2013). The susceptibility of the land surface to wind erosion is strongly influenced by vegetation cover, which is in turn sensitive to climate change and other human impacts. In the humid tropics of Southeast Asia, in contrast, the major trans-boundary pollution issue involves smoke aerosols from burning of biomass and peatlands, mostly during clearance for agriculture (Miettinen *et al.*, 2011b; Gautam *et al.*, 2013). Apart from the large impact on human health, these aerosols may be having a significant effect on rainfall in equatorial regions, leading to the possibility of climate-feedbacks, with fires reducing rainfall and promoting further fires (Tosca *et al.*, 2012). Pollutants of industrial origin are also a huge problem in many parts of the region, with well-documented impacts on human health (see Section 24.4.6) and the climate (see WGI AR5 Chapters 7 and 8).

24.7.2. Trade and Economy

The ASEAN Free Trade Agreement (AFTA) and the Indonesia–Japan Economic Partnership Agreement (IJEPA) have positively impacted the Indonesian economy and reduced water pollution, but increased CO_2 emissions by 0.46% compared to the business-as-usual situation, mainly due to large emission increases in the transportation sector (Gumilang *et al.*, 2011). Full liberalization of tariffs and GDP growth concentrated in China and India has led to transport emissions growing much faster than the value of trade, due to a shift towards distant trading partners (Cristea *et al.*, 2013). China's high economic growth and flourishing domestic and international trade has resulted in increased consumption and pollution of water resources (Guan and Hubacek, 2007). Japanese imports from the ASEAN region are negatively correlated with per capita carbon emissions (Atici, 2012) due to strict regulations in Japan that prevent import from polluting sectors. Export-led growth is central to the economic progress and well-being of Southeast Asian countries. Generally, as exports rise, carbon emissions tend to rise. International trading systems that help address the challenge of climate change need further investigation.

24.7.3. Migration and Population Displacement

Floods and droughts are predominant causes for internal displacement (Internal Displacement Monitoring Center, 2011). In 2010 alone, 38.3 million people were internally displaced; 85% because of hydrological hazards and 77% in Asia. Floods are increasingly playing a role in migration in the Mekong Delta (Warner, 2010). Often some migrants return to the vulnerable areas (Piguet, 2008) giving rise to ownership, rights of use, and other issues (Kolmannskog, 2008). Increasing migration has led to increasing migration-induced remittances contributing to Asian economies, but has had negligible effect on the poverty rate (Vargas-Silva *et al.*, 2009). In Bangladesh, migrant workers live and work under poor conditions, such as crowded shelters, inadequate sanitation, conflict and competition with the local population, and exploitation (Penning-Rowsell *et al.*, 2011). Forced migration can result from adaptation options such as construction of dams, but the negative outcomes could be allayed by putting proper safeguards in place (Penning-Rowsell *et al.*, 2011). Managed retreat of coastal communities is a suggested option to address projected sea-level rise (Alexander *et al.*, 2012). A favorable approach to deal with migration is within a development framework and through adaptation strategies (Penning-Rowsell *et al.*, 2011; ADB, 2012).

24.8. Research and Data Gaps

Studies of observed climate changes and their impacts are still inadequate for many areas, particularly in North, Central and West Asia (Table 24-2). Improved projections for precipitation, and thus water supply, are most urgently needed. Another priority is developing water management strategies for adaptation to changes in demand and supply. More research is also needed on the health effects of changes in water quality and quantity. Understanding of climate change impacts on ecosystems and biodiversity in Asia is currently limited by the poor quality and low accessibility of biodiversity information (UNEP, 2012). National biodiversity inventories are incomplete and few sites have the baseline information needed to identify changes. For the tropics, major research gaps include the temperature dependence of carbon fixation by tropical trees, the thermal tolerances and acclimation capacities of both plants and animals, and the direct impacts of rising CO_2 (Corlett, 2011; Zuidema *et al.*, 2013). Rising CO_2 is also expected to be important in cool-arid ecosystems, where lack of experimental studies currently limits our ability to make predictions (Poulter *et al.*, 2013). Boreal forest dynamics will be influenced by complex interactions between rising temperatures and CO_2, permafrost thawing, forest fires, and insect outbreaks (Osawa *et al.*, 2010; Zhang *et al.*, 2011), and understanding this complexity will require enhanced monitoring of biodiversity and species ranges, improved modeling, and greater knowledge of species biology (Meleshko and Semenov, 2008).

Rice is the most studied crop but there are still significant uncertainties in model accuracy, CO_2-fertilization effects, and regional differences (Masutomi *et al.*, 2009; Zhang *et al.*, 2010; Shuang-He *et al.*, 2011). For other crops, there is even greater uncertainty. Studies are also needed of the health effects of interactions between heat and air pollution in urban and rural environments. More generally, research is needed on impacts, vulnerability and adaptation in urban settlements, especially cities with populations under 500,000, which share half the region's urban population. Greater understanding is required of the linkages between local livelihoods, ecosystem functions, and land resources for creating a positive impact on livelihoods in areas with greater dependence on natural resources (Paul *et al.*, 2009). Increasing regional collaboration in scientific research and policy making has been suggested for reducing climate change impacts on water, biodiversity and livelihoods in the Himalayan region (Xu *et al.*, 2009) and could be considered elsewhere. The literature suggests that work must begin now on building understanding of the impacts of climate change and moving forward with the most cost-effective adaptation measures (ADB, 2007; Cai *et al.*, 2008; Mathy and Guivarch, 2010; Stage, 2010). For devising mitigation policies, the key information needed is again the most cost-effective measures (Nguyen, 2007; Cai *et al.*, 2008; Mathy and Guivarch, 2010).

[INSERT TABLE 24-2 HERE
Table 24-2: The amount of information supporting conclusions regarding observed and projected impacts in Asia.

24.9. Case Studies

24.9.1. Transboundary Adaptation Planning and Management – Lower Mekong River Basin

The *Lower Mekong River Basin (LMB)* covers an area of approximately 606,000 sq. km across the countries of Thailand, Laos, Cambodia and Vietnam. More than 60 million people are heavily reliant on natural resources, in particular agriculture and fisheries, for their well-being (MRC, 2009; Dugan *et al.*, 2010; Figure 24-SM-2). Thailand and Vietnam produced 51% of the world's rice exports in 2008, mostly in the LMB (Mainuddin *et al.*, 2011).

Observations of climate change over the past 30-50 years in the LMB include: an increase in temperature, an increase in rainfall in the wet season and decreases in the dry season, intensified flood and drought events, and sea-level rise (ICEM, 2010; IRG, 2010). Agricultural output has been noticeably impacted by intensified floods and droughts which caused almost 90% of rice production losses in Cambodia during 1996-2001 (Brooks and Adger, 2003; MRC, 2009).Vietnam and Cambodia are two of the countries most vulnerable to climate impacts on fisheries (Allison *et al.*, 2009; Halls, 2009).

Existing studies about future climate impacts in the Mekong Basin broadly share a set of common themes (MRC, 2009; Murphy and Sampson, 2013): increased temperature and annual precipitation; increased depth and duration of flood in the Mekong Delta and Cambodia floodplain; prolonged agricultural drought in the south and the east of the basin; and sea-level rise and salinity intrusion in the Mekong delta. Hydropower dams along the Mekong River and its tributaries will also have severe impacts on fish productivity and biodiversity, by blocking critical fish migration routes, altering the habitat of non-migratory fish species, and reducing nutrient flows downstream (Costanza *et al.*, 2011; Baran and Guerin, 2012; Ziv *et al.*, 2012). Climate impacts, though less severe than the impact of dams, will exacerbate these changes (Wyatt and Baird, 2007; Grumbine *et al.*, 2012; Orr *et al.*, 2012; Räsänen *et al.*, 2012; Ziv *et al.*, 2012).

National climate change adaptation plans have been formulated in all four LMB countries, but transboundary adaptation planning across the LMB does not exist to date. Effective future transboundary adaptation planning and management will benefit from: a shared climate projection across the LMB for transboundary adaptation planning; improved coordination among adaptation stakeholders and sharing of best practices across countries; mainstreaming climate change adaptation into national and sub-national development plans with proper translation from national adaptation strategies into local action plans; integration of transboundary policy recommendations into national climate change plans and policies; integration of adaptation strategies on a landscape scale between ministries and different levels of government within a country (MRC, 2009; Lian and Bhullar, 2011; Lebel *et al.*, 2012; Kranz *et al.*, 2010)

A study of the state-of-adaptation practice in the LMB showed that only 11% (45 of 417) of climate-change related projects in the LMB were on-the-ground adaptation efforts driven by climate risks (Ding, 2012; Neo, 2012; Schaffer and Ding, 2012). Common features of 'successful' projects include: robust initial gap assessment, engagement of local stakeholders, and a participatory process throughout (Brown, 2012; Khim, 2012; Mondal, 2012; Panyakul, 2012; Roth and Grunbuhel, 2012). A multi-stakeholder Regional Adaptation Action Network has been proposed with the intent of scaling up and improving mainstreaming of adaptation through tangible actions following the theory and successful examples of the Global Action Networks (GANs) (Waddell, 2005; Waddell and Khagram, 2007; WCD, 2000; GAVI, 2011; Schaffer and Ding, 2012) .

24.9.2. Glaciers of Central Asia

In the late 20th century, central Asian glaciers occupied 31,628 km^2 (Dolgushin and Osipova). All recent basin-scale studies document multidecadal area loss (Figure 24-3); where multiple surveys are available, most show accelerating loss. The rate of glacier area change varies (Table 24-SM-9). Rates between –0.05%/yr and –0.76%/yr have been reported in the Altai (Surazakov *et al.*, 2007; Shahgedanova *et al.*, 2010; Yao *et al.*, 2012b) and Tien Shan (Lettenmaier *et al.*, 2009; Sorg *et al.*, 2012), and between –0.13%/yr and–0.30%/yr in the Pamir (Konovalov and Desinov, 2007; Aizen, 2011a, 2011b, 2011c; Yao *et al.*, 2012b). These ranges reflect varying sub-regional distributions of glacier size (smaller glaciers shrink faster) and debris cover (which retards shrinkage), but also varying proportions of ice at high altitudes, where as yet warming has produced little increase in melt (Narama *et al.*, 2010). Most studies also document mean-annual (e.g. Glazyrin and Tadzhibaeva, 2011, for 1961-1990) and summertime (e.g. Shahgedanova *et al.*, 2010) warming, with slight cooling in the central and eastern Pamir (Aizen, 2011b). Precipitation increases have been observed more often than decreases (e.g. Braun *et al.*, 2009; Glazyrin and Tadzhibaeva, 2011).

[INSERT FIGURE 24-3 HERE
Figure 24-3: Losses of glacier area in the Altai-Sayan, Pamir and Tien Shan. Remote sensing data analysis from 1960s (Corona) through 2008 (Landsat, ASTER and Alos Prism).]

Aizen *et al.* (2007) calculated 21st-century losses of 43% of the volume of Tien Shan glaciers for an 8^{o}C temperature increase accompanied by a 24% precipitation increase, but probable complete disappearance of glaciers if precipitation decreased by 16%; a more moderate 2^{o}C increase led to little loss, but only if accompanied by a 24% precipitation increase. Drawing on CMIP5 simulations, (Radić *et al.*, 2013) simulated losses by 2100 of between 25% and 90% of 2006 ice volume (including Tibet but excluding the Altai and Sayan; range of all single-model simulations); the 14-GCM model mean losses are 55% for RCP4.5 and 75% for RCP8.5. Similarly, Marzeion *et al.* (2012) found 21st-century volume losses of 50% for RCP2.6, about 57% for both RCP4.5 and RCP6.0, and 67% for RCP8.5.

The glaciers have therefore been a diminishing store of water, and the diminution is projected to continue. Paradoxically, this implies more meltwater, possibly explaining limited observations of increased runoff (Sorg *et al*., 2012), but also an eventual decrease of meltwater yield (see Section 3.4.4). More immediately, it entails a hazard due to the formation of moraine-dammed glacial lakes (Bolch *et al.*, 2011).

Frequently Asked Questions

FAQ 24.1: What will the projected impact of future climate change be on freshwater resources in Asia?
[to be placed in Section 24.4.1]
Asia is a huge and diverse region, so both climate change and the impact on freshwater resources will vary greatly depending on location. But throughout the region, adequate water resources are particularly important because of the massive population and heavy dependence of the agricultural sector on precipitation, river runoff and groundwater. Overall, there is *low confidence* in the projections of specifically how climate change will impact future precipitation on a subregional scale, and thus in projections of how climate change might impact the availability of water resources. However, water scarcity is expected to be a big challenge in many Asian regions because of increasing water demand from population growth and consumption per capita with higher standards of living. Shrinkage of glaciers in central Asia is expected to increase due to climate warming, which will influence downstream river runoff in these regions. Better water management strategies could help ease water scarcity. Examples include developing water saving technologies in irrigation, building reservoirs, increasing water productivity, changing cropping systems and water reuse.

FAQ 24.2: How will climate change affect food production and food security in Asia?
[to be placed in Section 24.4.4]
Climate change impacts on temperature and precipitation will affect food production and food security in various ways in specific areas throughout this diverse region. Climate change will have a generally negative impact on crop production Asia, but with diverse possible outcomes [*medium confidence*]. For example most simulation models show that higher temperatures will lead to lower rice yields as a result of a shorter growing period. But some studies indicate that increased atmospheric CO_2 that leads to those higher temperatures could enhance photosynthesis and increase rice yields. This uncertainty on the overall effects of climate change and CO_2 fertilization is generally true for other important food crops such as wheat, sorghum, barley, and maize among others.

Yields of some crops will increase in some areas (e.g. cereal production in north and east Kazakhstan) and decrease in others (e.g. wheat in the Indo-Gangetic Plain of South Asia). In Russia, climate change may lead to a food production shortfall, defined as an event in which the annual potential production of the most important crops falls 50% or more below it's normal average. Sea-level rise is projected to decrease total arable areas and thus food supply in many parts of Asia. A diverse mix of potential adaptation strategies, such as crop breeding, changing crop varieties, adjusting planting time, water management, diversification of crops and a host of indigenous practices will all be applicable within local contexts.

FAQ 24.3: Who is most at risk from climate change in Asia? *[to be placed in Section 24.4.6]*
People living in low-lying coastal zones and flood plains are probably most at risk from climate change impacts in Asia. Half of Asia's urban population lives in these areas. Compounding the risk for coastal communities, Asia has more than 90% of the global population exposed to tropical cyclones. The impact of such storms, even if their frequency or severity remains the same, is magnified for low lying and coastal zone communities because of rising sea level [*medium confidence*]. Vulnerability of many island populations is also increasing due to climate change impacts. Settlements on unstable slopes or landslide prone-areas, common in some parts of Asia, face increased likelihood of rainfall-induced landslides.

Asia is predominantly agrarian, with 58% of its population living in rural areas, of which 81% are dependent on agriculture for their livelihoods. Rural poverty in parts of Asia could be exacerbated due to negative impacts from climate change on rice production, and a general increase in food prices and the cost of living [*high confidence*].

Climate change will have widespread and diverse health impacts. More frequent and intense heatwaves will increase mortality and morbidity in vulnerable groups in urban areas [*high confidence*]. The transmission of infectious disease, such as cholera epidemics in coastal Bangladesh, and schistosomiasis in inland lakes in China, and diarrheal outbreaks in rural children will be affected due to warmer air and water temperatures and altered rain patterns and water flows [*medium confidence*]. Outbreaks of vaccine-preventable Japanese encephalitis in the Himalayan region and malaria in India and Nepal have been linked to rainfall. Changes in the geographical distribution of vector-borne diseases, as vector species that carry and transmit diseases migrate to more hospitable environments, will occur [*medium confidence*]. These effects will be most noted close to the edges of the current habitats of these species.

Cross-Chapter Box

Box CC-TC. Building Long-Term Resilience from Tropical Cyclone Disasters

[Yoshiki Saito (Japan), Kathleen McInnes (Australia)]

Tropical cyclones (also referred to as hurricanes and typhoons in some regions or strength) cause powerful winds, torrential rains, high waves and storm surge, all of which can have major impacts on society and ecosystems. Bangladesh and India account for 86% of mortality from tropical cyclones (Murray et al., 2012), which is mainly due to the rarest and most severe storm categories (i.e. Categories 3, 4, and 5 on the Saffir-Simpson scale).

About 90 tropical cyclones occur globally each year (Seneviratne et al., 2012) although interannual variability is large. Changes in observing techniques particularly after the introduction of satellites in the late 1970s, confounds the assessment of trends in tropical cyclone frequencies and intensities. Therefore, IPCC (2012) "Special Report on Managing the Risks of Extreme Events and Disasters to Advance Climate Change Adaptation (SREX)" concluded that there is *low confidence* that any observed long-term (i.e. 40 years or more) increases in tropical cyclone activity are robust, after accounting for past changes in observing capability (Seneviratne et al., 2012; Chapter 2). There is also *low confidence* in the detection and attribution of century scale trends in tropical cyclones. Future changes to tropical cyclones arising from climate change are *likely* to vary by region. This is because there is *medium confidence* that for certain regions, shorter-term forcing by natural and anthropogenic aerosols has had a measurable effect on tropical cyclones. Tropical cyclone frequency is *likely* to decrease or remain unchanged over the 21st century, while intensity (i.e. maximum wind speed and rainfall rates) is *likely* to increase (AR5 WG1 Ch 14.6). Regionally specific projections have *lower confidence* (see AR5 WG1 Box 14.2).

Longer-term impacts from tropical cyclones include salinisation of coastal soils and water supplies and subsequent food and water security issues from the associated storm surge and waves (Terry and Chui, 2012). However, preparation for extreme tropical cyclone events through improved governance and development to reduce their impacts provides an avenue for building resilience to longer-term changes associated with climate change.

Densely populated Asian deltas are particularly vulnerable to tropical cyclones due to their large population density in expanding urban areas (Nicholls et al., 2007). Extreme cyclones in Asia since 1970 caused over 0.5 million fatalities (Murray et al., 2012) e.g., cyclones Bhola in 1970, Gorky in 1991, Thelma in 1998, Gujarat in 1998, Orissa in 1999, Sidr in 2007, and Nargis in 2008. Tropical cyclone Nargis hit Myanmar on 2 May 2008 and caused over 138,000 fatalities. Several-meter high storm surges widely flooded densely populated coastal areas of the Irrawaddy Delta and surrounding areas (Revenga et al., 2003; Brakenridge et al., 2013). The flooded areas were captured by a NASA MODIS image on 5 May 2008 (see Figure TC-1).

[INSERT FIGURE TC-1 HERE
Figure TC-1: The intersection of inland and storm surge flooding. Red shows May 5, 2008 MODIS mapping of the tropical cyclone Nargis storm surge along the Irrawaddy Delta and to the east, Myanmar. The blue areas to the north were flooded by the river in prior years. Source: Brakenridge et al., 2013.]

Murray et al. (2012) compared the response to cyclone Sidr in Bangladesh in 2007 and Nargis in Myanmar in 2008 and demonstrated how disaster risk reduction methods could be successfully applied to climate change adaptation.

Sidr, despite being of similar strength to Nargis, caused far fewer fatalities (3,400 compared to over 138000) and this was attributed to advancement in preparedness and response in Bangladesh through experience in previous cyclones such as Bhola and Gorky. The responses included the construction of multistoried cyclone shelters, improvement of forecasting and warning capacity, establishing a coastal volunteer network, and coastal reforestation of mangroves. The strategies of disaster risk management for tropical cyclones in coastal areas, that create protective measures, anticipate and plan for extreme events, increase the resilience of potentially exposed communities. The integration of activities relating to education, training, and awareness-raising into relevant ongoing processes and practices is important for the long-term success of disaster risk reduction and management (Murray et al., 2012). Birkmann and Teichman (2010) caution that while the combination of risk reduction and climate change adaptation strategies may be desirable, different spatial and temporal scales, norm systems, and knowledge types and sources between the two goals can confound their effective combination.

Table 24-1: Key risks from climate change and the potential for risk reduction through mitigation and adaptation in Asia. Key risks are identified based on assessment of the literature and expert judgments, with supporting evaluation of evidence and agreement in the referenced chapter sections. Each key risk is characterized as very low, low, medium, high, or very high. Risk levels are presented for the near-term era of committed climate change (here, for 2030-2040), in which projected levels of global mean temperature increase do not diverge substantially across emissions scenarios. Risk levels are also presented for the longer-term era of climate options (here, for 2080-2100), for global mean temperature increase of 2°C and 4°C above preindustrial levels. For each timeframe, risk levels are estimated for the current state of adaptation and for a hypothetical highly adapted state. As the assessment considers potential impacts on different physical, biological, and human systems, risk levels should not necessarily be used to evaluate relative risk across key risks. Relevant climate variables are indicated by symbols.

Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation (Very low – Medium – Very high)
Increased risk of crop failure and lower crop production could lead to food insecurity in Asia (*medium confidence*)	Autonomous adaptation of farmers on-going in many parts of Asia.		24.4.4	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	
Water shortage in arid areas of Asia (*medium confidence*)	Limited capacity for water resource adaptation; options include developing water saving technology, changing drought-resilient crops, building more water reservoirs.		24.4.1.3, 24.4.1.4	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	
Increased flooding leading to widespread damage to infrastructure and settlements in Asia (*medium confidence*)	Adaptation measures include extreme weather exposure reduction via effective land-use planning, selective relocation and structural measures; reduction in the vulnerability of lifeline infrastructure and services (water, energy, waste management, food, biomass, mobility, local ecosystems and telecommunications) and measures to assist vulnerable sectors and households.		24.4.5.1, 24.4.5.2, 24.4.5.3, 24.4.5.5,	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	
Increased risk of flood-related deaths, injuries, infectious diseases and mental disorders (*medium confidence*)	Disaster preparedness including early-warning systems and local coping strategies.		24.4.6.2, 24.4.6.3, 24.4.6.5	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	
Increased risk of heat-related mortality (*high confidence*)	Heat health-warning systems, urban planning to reduce heat islands and improvement of built environment.		24.4.6.2, 24.4.6.3, 24.4.6.5	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	

Climatic drivers of impacts

Warming trend	Extreme temperature	Drying trend	Extreme precipitation	Damaging cyclone	Storm surge	Sea level	Ocean acidification

Risk & potential for adaptation

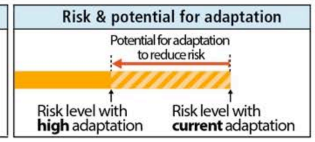

Table 24-1 (continued)

Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
Increased risk of drought-related water and food shortage causing malnutrition (*high confidence*)	Disaster preparedness including early-warning systems and local coping strategies.		24.4.6.2, 24.4.6.3, 24.4.6.5	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high
Increased risk of water and vector-borne diseases (*medium confidence*)	Early-warning systems, vector control programs, water management and sanitation programs.		24.4.6.2, 24.4.6.3, 24.4.6.5	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high
Exacerbated poverty, inequalities and new vulnerabilities (*high confidence*)	Insufficient emphasis and limited understanding on urban poverty, interaction between livelihoods, poverty and climate change.		24.4.5 24.4.6	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high
Coral reef decline in Asia (*high confidence*)	The limited adaptation options include minimizing additional stresses in marine protected areas sited where sea surface temperatures are expected to change least and reef resilience is expected to be highest.		24.4.3.3, 24.4.3.5, CC-CR, CC-OA	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high
Mountain-top extinctions in Asia (*high confidence*)	Adaptation options are limited. Reducing non-climate impacts and maximizing habitat connectivity will reduce risks to some extent, while assisted migration may be practical for some species.		24.4.2.4, 24.4.2.5	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high

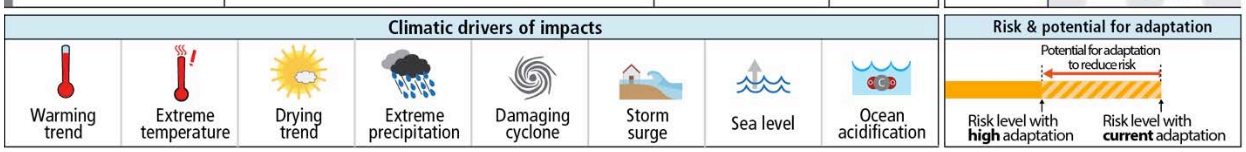

Table 24-2: The amount of information supporting conclusions regarding observed and projected impacts in Asia.

/ = Relatively abundant/sufficient information; knowledge gaps need to be addressed but conclusions can be drawn based on existing information
X = Limited information/no data; critical knowledge gaps, difficult to draw conclusions
NR = Not relevant

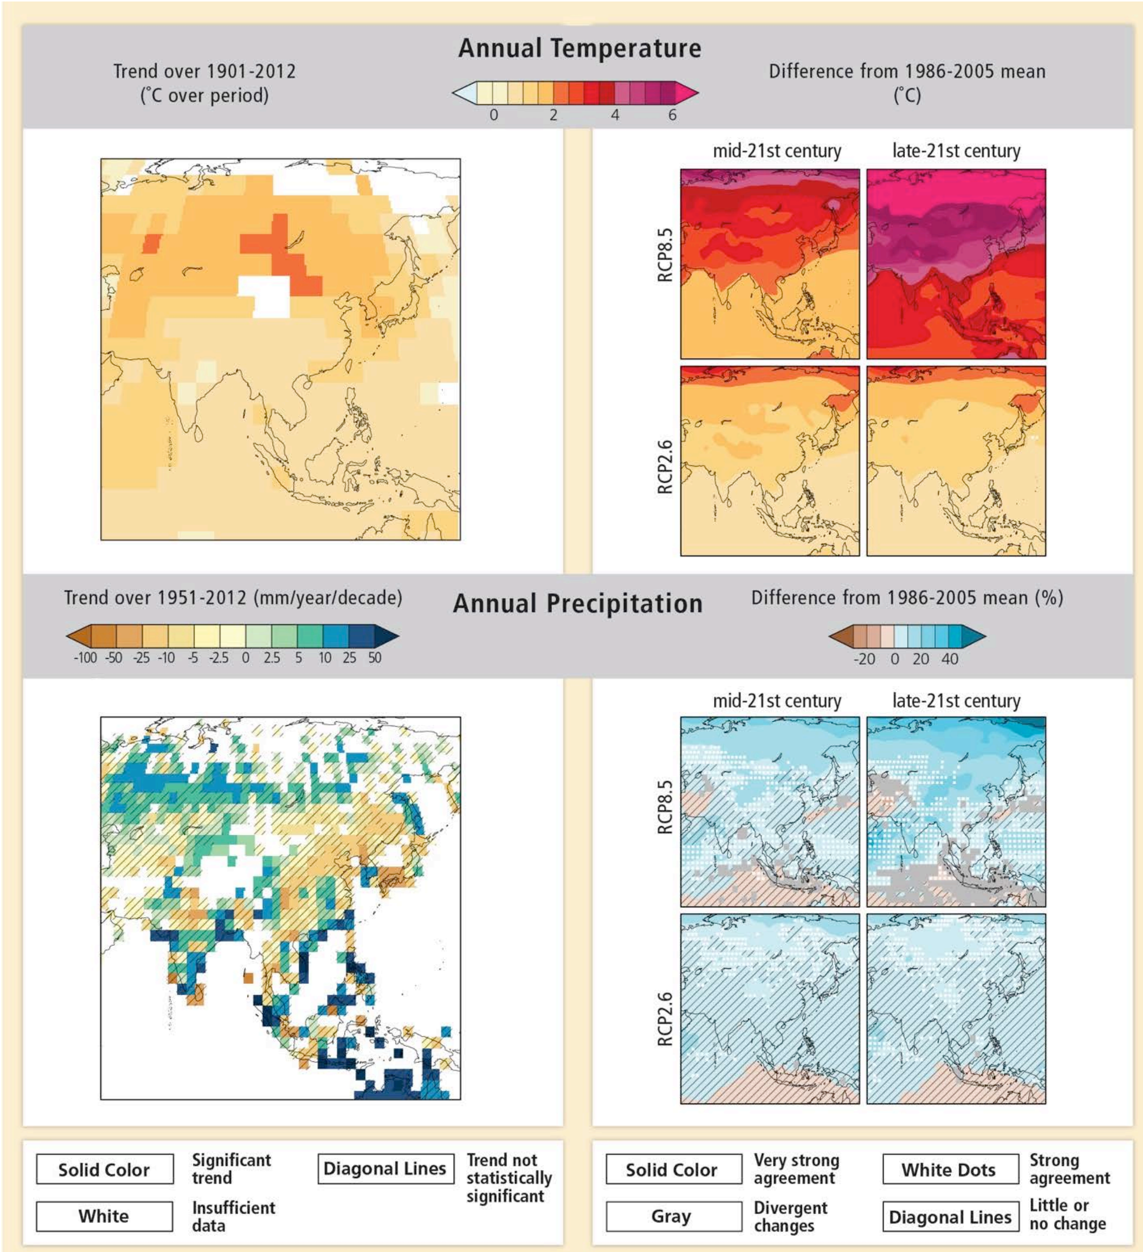

Figure 24-2: Observed and projected changes in annual average temperature and precipitation in Asia. (Top panel, left) Observed temperature trends from 1901-2012 determined by linear regression. [WGI AR5 Figures SPM.1 and 2.21] (Bottom panel, left) Observed precipitation change from 1951-2010 determined by linear regression. [WGI AR5 Figure SPM.2] For observed temperature and precipitation, trends have been calculated where sufficient data permits a robust estimate (i.e., only for grid boxes with greater than 70% complete records and more than 20% data availability in the first and last 10% of the time period). Other areas are white. Solid colors indicate areas where change is significant at the 10% level. Diagonal lines indicate areas where change is not significant. (Top and bottom panel, right) CMIP5 multi-model mean projections of annual average temperature changes and average percent change in annual mean precipitation for 2046-2065 and 2081-2100 under RCP2.6 and 8.5. Solid colors indicate areas with very strong agreement, where the multi-model mean change is greater than twice the baseline variability, and >90% of models agree on sign of change. Colors with white dots indicate areas with strong agreement, where >66% of models show change greater than the baseline variability and >66% of models agree on sign of change. Gray indicates areas with divergent changes, where >66% of models show change greater than the baseline variability, but <66% agree on sign of change. Colors with diagonal lines indicate areas with little or no change, less than the baseline variability in >66% of models. (There may be significant change at shorter timescales such as seasons, months, or days.). Analysis uses model data and methods building from WGI AR5 Figure SPM.8. See also Annex I of WGI AR5. Frequently Asked Questions

Executive Summary

The regional climate is changing (*very high confidence*). The region continues to demonstrate long term trends toward higher surface air and sea-surface temperatures, more hot extremes and fewer cold extremes, and changed rainfall patterns. Over the past 50 years, increasing greenhouse gas concentrations have contributed to rising average temperature in Australia *(high confidence)* and New Zealand (*medium confidence*) and decreasing rainfall in south-western Australia (*high confidence*). [25.2, Table 25-1]

Warming is projected to continue through the 21st century (*virtually certain*) along with other changes in climate. Warming is expected to be associated with rising snow lines (*very high confidence*), more frequent hot extremes, less frequent cold extremes (*high confidence*), and increasing extreme rainfall related to flood risk in many locations (*medium confidence*). Annual average rainfall is expected to decrease in south-western Australia (*high confidence*) and elsewhere in most of far southern Australia and the north-east South Island and northern and eastern North Island of New Zealand (*medium confidence*), and to increase in other parts of New Zealand (*medium confidence*). Tropical cyclones are projected to increase in intensity but remain similar or decrease in numbers (*low confidence*), and fire weather is projected to increase in most of southern Australia (*high confidence*) and many parts of New Zealand (*medium confidence*). Regional sea level rise will *very likely* exceed the historical rate (1971-2010), consistent with global mean trends. [25.2, Table 25-1, Box 25-6; WGI 13.5, 13.6]

Uncertainty in projected rainfall changes remains large for many parts of Australia and New Zealand, which creates significant challenges for adaptation. For example, projections for average annual runoff in far south-eastern Australia range from little change to a 40% decline for 2°C global warming above current levels. The dry end of these scenarios would have severe implications for agriculture, rural livelihoods, ecosystems and urban water supply, and would increase the need for transformational adaptation (*high confidence*). [25.2, 25.5.1, 25.6.1, 25.7.2, Box 25-2, Box 25-5]

Recent extreme climatic events show significant vulnerability of some ecosystems and many human systems to current climate variability (*very high confidence*), and the frequency and/or intensity of such events is projected to increase in many locations (*medium* to *high confidence*). For example, high sea surface temperatures have repeatedly bleached coral reefs in north-eastern Australia (since the late 1970s) and more recently in western Australia. Recent floods in Australia and New Zealand caused severe damage to infrastructure and settlements and 35 deaths in Queensland alone (2011); the Victorian heat wave (2009) increased heat-related morbidity and was associated with more than 300 excess deaths, while intense bushfires destroyed over 2,000 buildings and led to 173 deaths; and widespread drought in south-east Australia (1997-2009) and many parts of New Zealand (2007-2009; 2012-13) resulted in substantial economic losses (e.g. regional GDP in the southern Murray Darling Basin was below forecast by about 5.7% in 2007/08, and New Zealand lost about NZ$3.6b in direct and off-farm output in 2007-09). [Table 25-1, 25.6.2, 25.8.1, Box 25-5, Box 25-6, Box 25-8]

Without adaptation, further changes in climate, atmospheric CO_2 and ocean acidity are projected to have substantial impacts on water resources, coastal ecosystems, infrastructure, health, agriculture and biodiversity (*high confidence*). Freshwater resources are projected to decline in far south-west and far south-east mainland Australia (*high confidence*) and for rivers originating in the north-east of the South Island and east and north of the North Island of New Zealand (*medium confidence*). Rising sea levels and increasing heavy rainfall are projected to increase erosion and inundation, with consequent damages to many low-lying ecosystems, infrastructure and housing; increasing heat waves will increase risks to human health; rainfall changes and rising temperatures will shift agricultural production zones; and many native species will suffer from range contractions and some may face local or even global extinction. [25.5.1, 25.6.1, 25.6.2, 25.7.2, 25.7.4, Box 25-1, Box 25-5, Box 25-8]

Some sectors in some locations have the potential to benefit from projected changes in climate and increasing atmospheric CO_2 (*high confidence*). Examples include reduced winter mortality (*low confidence*), reduced energy demand for winter heating in New Zealand and southern parts of Australia, and forest growth in cooler regions except where soil nutrients or rainfall are limiting. Spring pasture growth in cooler regions would also increase and be beneficial for animal production if it can be utilized. [25.7.1, 25.7.2, 25.7.4, 25.8.1]

Adaptation is already occurring and adaptation planning is becoming embedded in some planning processes, albeit mostly at the conceptual rather than implementation level (*high confidence*). Many solutions for reducing energy and water consumption in urban areas with co-benefits for climate change adaptation (e.g. greening cities and recycling water) are already being implemented. Planning for reduced water availability in southern Australia and for sea-level rise in both countries is becoming adopted widely, although implementation of specific policies remains piecemeal, subject to political changes, and open to legal challenges. [25.4, Box 25-1, Box 25-2, Box 25-9]

Adaptive capacity is generally high in many human systems, but implementation faces major constraints especially for transformational responses at local and community levels (*high confidence*). Efforts to understand and enhance adaptive capacity and adaptation processes have increased since the AR4, particularly in Australia. Constraints on implementation arise from: absence of a consistent information base and uncertainty about projected impacts; limited financial and human resources to assess local risks and to develop and implement effective policies and rules; limited integration of different levels of governance; lack of binding guidance on principles and priorities; different attitudes towards the risks associated with climate change, and different values placed on objects and places at risk. [25.4, 25.10.3, Box 25-1, Table 25-2]

Indigenous peoples in both Australia and New Zealand have higher than average exposure to climate change due to a heavy reliance on climate-sensitive primary industries and strong social connections to the natural environment, and face particular constraints to adaptation (*medium confidence*). Social status and representation, health, infrastructure and economic issues, and engagement with natural resource industries constrain adaptation and are only partly offset by intrinsic adaptive capacity (*high confidence*). Some proposed responses to climate change may provide economic opportunities, particularly in New Zealand related to forestry. Torres Strait communities are vulnerable even to small sea level rises (*high confidence*). [25.3, 25.8.2]

We identify eight *regional key risks* during the 21st century based on the severity of potential impacts for different levels of warming, uniqueness of the systems affected, and adaptation options (*high confidence*). These risks differ in the degree to which they can be managed via adaptation and mitigation, and some are more likely to be realized than others, but all warrant attention from a risk-management perspective.

- Some potential impacts can be delayed but now appear very difficult to avoid entirely, even with globally effective mitigation and planned adaptation:
  - ***significant change in community composition and structure of coral reef systems in Australia***, driven by increasing sea-surface temperatures and ocean acidification; the ability of corals to adapt naturally to rising temperatures and acidification appears limited and insufficient to offset the detrimental effects [25.6.2, 30.5, Box CC-CR]
  - ***loss of montane ecosystems and some native species in Australia***, driven by rising temperatures and snow lines, increased fire risk and drying trends; fragmentation of landscapes, limited dispersal and limited rate of evolutionary change constrain adaptation options [25.6.1]
- Some impacts have the potential to be severe but can be reduced substantially by globally effective mitigation combined with adaptation, with the need for transformational adaptation increasing with the rate and magnitude of climate change:
  - ***increased frequency and intensity of flood damage to settlements and infrastructure in Australia and New Zealand***, driven by increasing extreme rainfall although the amount of change remains uncertain; in many locations, continued reliance on increased protection alone would become progressively less feasible [Table 25-1, 25.4.2, Box 25-8, 25.10.3]
  - ***constraints on water resources in southern Australia***, driven by rising temperatures and reduced cool-season rainfall; integrated responses encompassing management of supply, recycling, water conservation and increased efficiency across all sectors are available and some are being implemented in areas already facing shortages [25.2, 25.5.2, Box 25-2]
  - ***increased morbidity, mortality and infrastructure damages during heat waves in Australia***, resulting from increased frequency and magnitude of extreme high temperatures; vulnerable populations include

the elderly and those with existing chronic diseases; population increases and ageing trends constrain effectiveness of adaptation responses [25.8.1]

- o ***increased damages to ecosystems and settlements, economic losses and risks to human life from wildfires in most of southern Australia and many parts of New Zealand***, driven by rising temperatures and drying trends; local planning mechanisms, building design, early warning systems and public education can assist with adaptation and are being implemented in regions that have experienced major events [25.2, Table 25-1, 25.6.1, 25.7.1, Box 25-6]

- For some impacts, severity depends on changes in climate variables that span a particularly large range, even for a given global temperature change. The most severe changes would present major challenges if realized:
  - o ***increasing risks to coastal infrastructure and low-lying ecosystems in Australia and New Zealand from continuing sea level rise, with widespread damages towards the upper end of projected changes***; managed retreat is a long-term adaptation strategy for human systems but options for some natural ecosystems are limited due to the rapidity of change and lack of suitable space for landward migration. Risks from sea level rise continue to increase beyond 2100 even if temperatures are stabilised. [Table 25-1, 25.4.2, Box 25-1, 25.6.1, 25.6.2; WGI 13.5]
  - o ***significant reduction in agricultural production in the Murray-Darling Basin and far south-eastern and south-western Australia if scenarios of severe drying are realised;*** more efficient water use, allocation and trading would increase the resilience of systems in the near term but cannot prevent significant reductions in agricultural production and severe consequences for ecosystems and some rural communities at the dry end of the projected changes [25.2, 25.5.2, 25.7.2, Box 25-2, Box 25-5]

Significant synergies and trade-offs exist between alternative adaptation responses, and between mitigation and adaptation responses; interactions occur both within Australasia and between Australasia and the rest of the world (*very high confidence*). Increasing efforts to mitigate and adapt to climate change imply an increasing complexity of interactions, particularly at the intersections among water, energy and biodiversity, but tools to understand and manage these interactions remain limited. Flow-on effects from climate change impacts and responses outside Australasia have the potential to outweigh some of the direct impacts within the region, particularly economic impacts on trade-intensive sectors such as agriculture (*medium confidence*) and tourism (*high agreement, limited evidence*), but they remain among the least explored issues. [25.7.5, 25.9.1, 25.9.2, Box 25-10]

Understanding of future vulnerability of human and mixed human-natural systems to climate change remains limited due to incomplete consideration of socio-economic dimensions (*very high confidence*). Future vulnerability will depend on factors such as wealth and its distribution across society, patterns of ageing, access to technology and information, labour force participation, societal values, and mechanisms and institutions to resolve conflicts. These dimensions have received only limited attention and are rarely included in vulnerability assessments, and frameworks to integrate social, psychological and cultural dimensions of vulnerability with bio-physical impacts and economic losses are lacking. In addition, conclusions for New Zealand in many sectors, even for bio-physical impacts, are based on limited studies that often use a narrow set of assumptions, models and data and hence have not explored the full range of potential outcomes. [25.3, 25.4, 25.11]

25.1. Introduction and Major Conclusions from Previous Assessments

Australasia is defined here as lands, territories, offshore waters and oceanic islands of the exclusive economic zones of Australia and New Zealand. Both countries are relatively wealthy with export-led economies. Both have Westminster-style political systems and have a relatively recent history of non-indigenous settlement (Australia in the late 18th, New Zealand in the early 19th century). Both retain significant indigenous populations.

Principal findings from the IPCC Fourth Assessment Report (AR4) for the region were (Hennessy *et al.*, 2007):

- Consistent with global trends, Australia and New Zealand had experienced warming of 0.4 to 0.7°C since 1950 with changed rainfall patterns and sea-level rise of about 70 mm across the region; there had also been a greater frequency and intensity of droughts and heat waves, reduced seasonal snow cover and glacial retreat.

- Impacts from recent climate changes were evident in increasing stresses on water supply and agriculture, and changed natural ecosystems; some adaptation had occurred in these sectors but vulnerability to extreme events such as fire, tropical cyclones, droughts, hail and floods remained high.
- The climate of the 21st century would be warmer (*virtually certain*), with changes in extreme events including more intense and frequent heat waves, fire, floods, storm surges and droughts but less frequent frost and snow (*high confidence*), reduced soil moisture in large parts of the Australian mainland and eastern New Zealand but more rain in western New Zealand (*medium confidence*).
- Significant advances had occurred in understanding future impacts on water, ecosystems, Indigenous people and health together with an increased focus on adaptation; potential impacts would be substantial without further adaptation, particularly for water security, coastal development, biodiversity, and major infrastructure, but impacts on agriculture and forestry would be variable across the region, including potential benefits in some areas.
- Vulnerability would increase mainly due to an increase in extreme events; human systems were considered to have a higher adaptive capacity than natural systems.
- Hotspots of high vulnerability by 2050 under a medium emissions scenario included:
  - significant loss of biodiversity in areas such as alpine regions, the Wet Tropics, the Australian south-west, Kakadu wetlands, coral reefs and sub-Antarctic islands;
  - water security problems in the Murray-Darling basin, south-western Australia and eastern New Zealand;
  - potentially large risks to coastal development in south-eastern Queensland and in New Zealand from Northland to the Bay of Plenty.

25.2. Observed and Projected Climate Change

Australasia exhibits a wide diversity of climates, such as moist tropical monsoonal, arid and moist temperate, including alpine conditions. Key climatic processes are the Asian-Australian monsoon and the southeast trade winds over northern Australia, and the subtropical high pressure belt and the mid-latitude storm tracks over southern Australia and New Zealand. Tropical cyclones also affect northern Australia, and, more rarely, ex-tropical cyclones affect some parts of New Zealand. Natural climatic variability is very high in the region, especially for rainfall and over Australia, with the El Nino-Southern Oscillation (ENSO) being the most important driver (McBride and Nicholls, 1983; Power *et al.*, 1998; Risbey *et al.*, 2009). The southern annular mode, Indian Ocean Dipole and the Interdecadal Pacific Oscillation are also important regional drivers (Thompson and Wallace, 2000; Salinger *et al.*, 2001; Cai *et al.*, 2009b). This variability poses particular challenges for detecting and projecting anthropogenic climate change and its impacts in the region. For example, changes in ENSO in response to anthropogenic climate change are uncertain (AR5 WGI Ch14) but, given current ENSO impacts, any changes would have the potential to significantly influence rainfall and temperature extremes, droughts, tropical cyclones, marine conditions and glacial mass balance (Mullan, 1995; Chinn *et al.*, 2005; Holbrook *et al.*, 2009; Diamond *et al.*, 2012; Min *et al.*, 2013).

Understanding of observed and projected climate change has received much attention since AR4, particularly in Australia, with a focus on the causes of observed rainfall changes and more systematic analysis of projected changes from different models and approaches. Climatic extremes have also been a research focus. Table 25-1 presents an assessment of this body of research for observed trends and projected changes for a range of climatic variables (including extremes) relevant for regional impacts and adaptation, including examples of the magnitude of projected change, and attribution, where possible. Most studies are based on CMIP3 models and SRES scenarios, but CMIP5 model results are considered where available (see also AR5 WGI Chap 14 & Atlas; WGII Chapter 21).

The region has exhibited warming to the present (*very high confidence*) and is *virtually certain* to continue to do so (Table 25-1). Observed and CMIP5-modelled past and projected future annual average surface temperatures are shown in Figures 25-1 and 25-2. For further details see WGI Atlas, AI.68-69. Changes in precipitation have been observed with *very high confidence* in some areas over a range of time scales, such as increases in north-western Australia since the 1950s, the autumn/winter decline since 1970 in south-western Australia and, since the 1990s, in south-eastern Australia, and over 1950-2004 increases in annual rainfall in the south and west of the South Island and west of the North Island of New Zealand, and decreases in the north-east of the South Island and east and north of the North Island. Based on multiple lines of evidence, annual average rainfall is projected to decrease with *high* *confidence* in south-western Australia. For New Zealand, annual average rainfall is projected to decrease in the north-eastern South Island and eastern and northern North Island, and increase in other parts of the country (*medium confidence*). The direction and magnitude of rainfall change in eastern and northern Australia remains a key uncertainty (Table 25-1).

This pattern of projected rainfall change is reflected in annual average CMIP5 model results (Figure 25-1), but with important additional dimensions relating to seasonal changes and spread across models (see also WGI Atlas, AI.70-71). Examples of the magnitude of projected annual change from 1990 to 2090 (percent model mean change +/- intermodel standard deviation) under RCP8.5 from CMIP5 are -20±13% in south-western Australia, -2±21% in the Murray Darling Basin, and -5±22% in southeast Queensland (Irving *et al.*, 2012). Projected changes during winter and spring are more pronounced and/or consistent across models than the annual changes, e.g. drying in south-western Australia (-32±11%, June to August), the Murray Darling Basin (-16±22%, June to August), and southeast Queensland (-15±26%, September to November), whereas there are increases of 15% or more in the west and south of the South Island of New Zealand (Irving *et al.*, 2012). Downscaled CMIP3 model projections for New Zealand indicate a stronger drying pattern in the south-east of the South Island and eastern and northern regions of the North Island in winter and spring (Reisinger *et al.*, 2010) than seen in the raw CMIP5 data; based on similar broader scale changes this pattern is expected to hold once CMIP5 data are also downscaled (Irving *et al.*, 2012).

Other projected changes of at least *high confidence* include regional increases in sea surface temperature, the occurrence of hot days, fire weather in southern Australia, mean and extreme sea level, and ocean acidity (see WGI 6.4.4 for projections); and decreases in cold days and snow extent and depth. Although changes to tropical cyclone occurrence and that of other severe storms are potentially important for future vulnerability, regional changes to these phenomena cannot be projected with at least *medium confidence* as yet (see Table 25-1).

[INSERT FIGURE 25-1 HERE
Figure 25-1: Observed and projected changes in annual average temperature and precipitation. (Top panel, left) Observed temperature trends from 1901-2012 determined by linear regression [WGI AR5 Figures SPM.1 and 2.21]. (Bottom panel, left) Observed precipitation change from 1951-2010 determined by linear regression [WGI AR5 Figure SPM.2]. For observed temperature and precipitation, trends have been calculated where sufficient data permits a robust estimate (i.e., only for grid boxes with greater than 70% complete records and more than 20% data availability in the first and last 10% of the time period). Other areas are white. Solid colors indicate areas where change is significant at the 10% level. Diagonal lines indicate areas where change is not significant. (Top and bottom panel, right) CMIP5 multi-model mean projections of annual average temperature changes and average percent change in annual mean precipitation for 2046-2065 and 2081-2100 under RCP2.6 and 8.5. Solid colors indicate areas with very strong agreement, where the multi-model mean change is greater than twice the baseline variability, and >90% of models agree on sign of change. Colors with white dots indicate areas with strong agreement, where >66% of models show change greater than the baseline variability and >66% of models agree on sign of change. Gray indicates areas with divergent changes, where >66% of models show change greater than the baseline variability, but <66% agree on sign of change. Colors with diagonal lines indicate areas with little or no change, less than the baseline variability in >66% of models. (There may be significant change at shorter timescales such as seasons, months, or days.). Analysis uses model data and methods building from WGI AR5 Figure SPM.8. See also Annex I of WGI AR5 [Boxes 21-3 and CC-RC].]

[INSERT FIGURE 25-2 HERE
Figure 25-2: Observed and simulated variations in past and projected future annual average near-surface air temperature over land areas of Australia (left) and New Zealand (right). Black lines show various estimates from observational measurements. Shading denotes the 5-95 percentile range of climate model simulations driven with 'historical' changes in anthropogenic and natural drivers (63 simulations), historical changes in 'natural' drivers only (34), the 'RCP2.6' emissions scenario (63), and the 'RCP8.5' (63). Data are anomalies from the 1986-2005 average of the individual observational data (for the observational time series) or of the corresponding historical all-forcing simulations. Further details are given in Box 21-3.]

Table 25-1: Observed and projected changes in key climate variables, and (where assessed) the contribution of human activities to observed changes. For further relevant information see WGI Chapters 3, 6 (ocean changes, including acidification), 11, 12 (projections), 13 (sea level) and 14 (regional climate phenomena).]

25.3. Socio-Economic Trends Influencing Vulnerability and Adaptive Capacity

25.3.1. Economic, Demographic and Social Trends

The economies of Australia and New Zealand rely on natural resources, agriculture, minerals, manufacturing and tourism, but the relative importance of these sectors differs between the two countries. Agriculture and mineral/energy resources accounted, respectively, for 11% and 55% (Australia) and 56% and 5% (New Zealand) of the value of total exports in 2010/2011 (ABS, 2012c; SNZ, 2012b). Water abstraction per capita in both countries is in the top half of the OECD, decreasing since 1990 in Australia but increasing in New Zealand; more than half is used for irrigation (OECD, 2010, 2013a). Between 1970 and 2011, GDP grew by an average of 3.2% p.a. in Australia and 2.4% p.a. in New Zealand, with annual GDP per capita growth of 1.8% and 1.2%, respectively (SNZ, 2011; ABS, 2012d). GDP is projected to grow on average by 2.5-3.5% p.a. in Australia and about 1.9% p.a. in New Zealand to 2050 (Australian Treasury, 2010; Bell *et al.*, 2010) but subject to significant shorter-term fluctuations.

The populations of Australia and New Zealand are projected to grow significantly over at least the next several decades (*very high confidence*; ABS, 2008; SNZ, 2012a); Australia's population from 22.3 million in 2011 to 31-43 million by 2056 and 34-62 million by 2101 (ABS, 2008, 2013); New Zealand's population from 4.4 million in 2011 to 5.1-7.1 million by 2061 (SNZ, 2012a). The number of people aged 65 and over is projected to almost double in the next two decades (ABS, 2008; SNZ, 2012a). More than 85% of the Australasian population lives in urban areas and their satellite communities, mostly in coastal areas (DCC, 2009; SNZ, 2010b; UN, 2012; see Box 25-9). Urban concentration and depletion of remote rural areas is expected to continue (Mendham and Curtis, 2010; SNZ, 2010c; Box 25-5), but some coastal non-urban spaces also face increasing development pressure (Freeman and Cheyne, 2008; Gurran, 2008; Box 25-1). More than 20% of Australasian residents were born overseas (OECD, 2013a).

Poverty rates and income inequality in Australia and New Zealand are in the upper half of OECD countries, and both measures increased significantly in both countries between the mid-1980s and the late-2000s (OECD, 2013a). Measurement of poverty and inequality, however, is highly contested, and it remains difficult to anticipate future changes and their effects on adaptive capacity (Peace, 2001; Scutella *et al.*, 2009; 25.3.2). Indigenous peoples constitute about 2.5% and 15% of the Australian and New Zealand populations, respectively, but in Australia, their national share is growing and they constitute a much higher percentage of the population in remote and very remote regions (ABS, 2009, 2010b; SNZ, 2010a). Indigenous peoples in both countries have lower than average life expectancy, income and education, implying that changes in socio-economic status and social inclusion could strongly influence their future adaptive capacity (see 25.8.2).

25.3.2. Use and Relevance of Socio-Economic Scenarios in Adaptive Capacity/Vulnerability Assessments

Demographic, economic and socio-cultural trends influence the vulnerability and adaptive capacity of individuals and communities (see Chapters 2, 11-13, 16, 20). A limited but growing number of studies in Australasia have attempted to incorporate such information, e.g. changes in the number of people and percentage of elderly people at risk (Preston *et al.*, 2008; Baum *et al.*, 2009; Preston and Stafford-Smith, 2009; Roiko *et al.*, 2012), the density of urban settlements and exposed infrastructure (Preston and Jones, 2008; Preston *et al.*, 2008; Baynes *et al.*, 2012), population-driven pressures on water demand (Jollands *et al.*, 2007; CSIRO, 2009), and economic and social factors affecting individual coping, planning and recovery capacity (Dwyer *et al.*, 2004; Khan, 2012; Roiko *et al.*, 2012).

Socio-economic considerations are used increasingly to understand adaptive capacity of communities (Preston *et al.*, 2008; Smith *et al.*, 2008; Fitzsimons *et al.*, 2010; Soste, 2010; Brunckhorst *et al.*, 2011) and to construct scenarios to help build regional planning capacity (Energy Futures Forum, 2006; Frame *et al.*, 2007; Pride *et al.*, 2010; Pettit *et* *al.*, 2011; Taylor *et al.*, 2011). Such scenarios, however, are only beginning to be used to quantify vulnerability to climate change (except e.g. Bohensky *et al.*, 2011; Baynes *et al.*, 2012; Low Choy *et al.*, 2012).

Apart from these emerging efforts, most vulnerability studies from Australasia make no or very limited use of socio-economic factors, consider only current conditions, and/or rely on postulated correlations between generic socio-economic indicators and climate change vulnerability. In many cases this limits confidence in conclusions regarding future vulnerability to climate change and adaptive capacity of human and mixed natural-human systems.

25.4. Cross-Sectoral Adaptation: Approaches, Effectiveness, and Constraints

25.4.1. Frameworks, Governance, and Institutional Arrangements

Adaptation responses depend heavily on institutional and governance arrangements (see Chapters 2, 14, 15, 16, 20). Responsibility for development and implementation of adaptation policy in Australasia is largely devolved to local governments and, in Australia, to State governments and Natural Resource Management bodies. Federal/central government supports adaptation mostly via provision of information, tools, legislation, policy guidance and (in Australia) support for pilot projects. A standard risk management paradigm has been promoted to embed adaptation into decision-making practices (AGO, 2006; MfE, 2008b; Standards Australia, 2013), but broader systems and resilience approaches are used increasingly for natural resource management (Clayton *et al.*, 2011; NRC, 2012).

The Council of Australian Governments agreed a national adaptation policy framework in 2007 (COAG, 2007). This included establishing the collaborative National Climate Change Adaptation Research Facility (NCCARF) in 2008, which complemented CSIRO's Climate Adaptation Flagship. The federal government supported a first-pass national coastal risk assessment (DCC, 2009; DCCEE, 2011), is developing indicators and criteria for assessing adaptation progress and outcomes (DIICCSRT, 2013), and commissioned targeted reports addressing impacts and management options for natural and managed landscapes (Campbell, 2008; Steffen *et al.*, 2009; Dunlop *et al.*, 2012), National and World Heritage areas (ANU, 2009; BMT WBM, 2011), and indigenous and urban communities (Green *et al.*, 2009; Norman, 2010). Most State and Territory governments have also developed adaptation plans (e.g. DSE, 2013).

In New Zealand, the central government updated and expanded tools to support impact assessments and adaptation responses consistent with regulatory requirements (MfE, 2008b, c, d, 2010b), and revised key directions for coastal management (Minister of Conservation, 2010). No cross-sectoral adaptation policy framework or national-level risk assessments exist, but some departments commissioned high-level impacts and adaptation assessments after the AR4 (e.g. on agriculture and on biodiversity; Wratt *et al.*, 2008; McGlone and Walker, 2011; Clark *et al.*, 2012).

Public and private sector organisations are potentially important adaptation actors but exhibit large differences in preparedness, linked to knowledge about climate change, economic opportunities, external connections, size, and scope for strategic planning (Gardner *et al.*, 2010; Taylor *et al.*, 2012a; Johnston *et al.*, 2013; Kuruppu *et al.*, 2013; see also Chapters 10, 16). This creates challenges for achieving holistic societal outcomes (see also 25.7-25.9).

Several recent policy initiatives in Australia, while responding to broader socio-economic and environmental pressures, include goals to reduce vulnerability to climate variability and change. These include establishing the Murray-Darling Basin Authority to address over-allocation of water resources (Connell and Grafton, 2011; MDBA, 2011), removal of the interest rate subsidy during exceptional droughts (Productivity Commission, 2009), and management of bush fire and flood risk (VBRC, 2010; QFCI, 2012). These may be seen as examples of mainstreaming adaptation (Dovers, 2009), but they also demonstrate lag times in policy design and implementation, windows of opportunity presented by crises (e.g. the Millennium Drought 1997-2009, the Victorian bushfires 2009 and Queensland floods of 2011), and the challenges arising from competing interests in managing finite and changing water resources (Botterill and Dovers, 2013; Pittock, 2013; Box 25-2).

25.4.2. Constraints on Adaptation and Emerging Leading Practice Models

A rapidly growing literature since the AR4 confirms, with *high confidence*, that while the adaptive capacity of society in Australasia is generally high, there are formidable environmental, economic, informational, social, attitudinal and political constraints, especially for local governments and small or highly fragmented industries. Reviews of public- and private-sector adaptation plans and strategies in Australia demonstrate strong efforts in institutional capacity building, but differences in assessment methods and weaknesses in translating goals into specific policies (White, 2009; Gardner *et al.*, 2010; Measham *et al.*, 2011; Preston *et al.*, 2011; Kay *et al.*, 2014). Similarly, local governments in New Zealand to date have focused mostly on impacts and climate-related hazards; some have developed adaptation plans, but few have committed to specific policies and steps to implementation (e.g. O'Donnell, 2007; Britton, 2010; Fitzharris, 2010; HRC, 2012; KCDC, 2012; Lawrence *et al.*, 2013b).

Table 25-2 summarises key constraints and corresponding enabling factors for effective institutional adaptation processes identified in Australia and New Zealand. Scientific uncertainty and resource limitations are reported consistently as important constraints, particularly for smaller councils. Ultimately more powerful constraints arise, however, from current governance and legislative arrangements and the lack of consistent tools to deal with dynamic risks and uncertainty or to evaluate the success of adaptation responses (*high agreement, robust evidence*; Britton, 2010; Barnett *et al.*, 2013; Lawrence *et al.*, 2013b; Mukheibir *et al.*, 2013; Webb *et al.*, 2013; see also Chapter 16).

[INSERT TABLE 25-2 HERE
Table 25-2: Constraints and enabling factors for institutional adaptation processes in Australasia.]

Some constraints exacerbate others. There is *high confidence* that the absence of a consistent information base and binding guidelines that clarify governing principles and liabilities is a challenge particularly for small and resource-limited local authorities, which need to balance special interest advocacy with longer term community resilience. This heightens reliance on individual leadership subject to short-term political change and can result in piecemeal and inconsistent risk assessments and responses between levels of government and locations, and over time (Smith *et al.*, 2008; Brown *et al.*, 2009; Norman, 2009; Britton, 2010; Rouse and Norton, 2010; Abel *et al.*, 2011; McDonald, 2011; Rive and Weeks, 2011; Corkhill, 2013; Macintosh *et al.*, 2013). In these situations, planners tend to rely more on single numbers for climate projections that can be argued in court (Reisinger *et al.*, 2011; Lawrence *et al.*, 2013b), which increases the risk of maladaptation given the uncertain and dynamic nature of climate risk (McDonald, 2010; Stafford-Smith *et al.*, 2011; Gorddard *et al.*, 2012; McDonald, 2013; Reisinger *et al.*, 2014).

Vulnerability assessments that take mid- to late-century impacts as their starting point can inhibit actors from implementing adaptation actions, as distant impacts are easily discounted and difficult to prioritise in competition with near-term non-climate change pressures (Productivity Commission, 2012). Emerging leading practice models in Australia (Balston, 2012; HCCREMS, 2012; SGS, 2012) and New Zealand (MfE, 2008a; Britton *et al.*, 2011) recommend a high-level scan of sectors and locations at risk and emphasise a focus on near-term decisions that influence current and future vulnerability (which could range from early warning systems to strategic and planning responses). More detailed assessment can then focus on this more tractable subset of issues, based on explicit and iterative framing of the adaptation issue (Webb *et al.*, 2013) and taking into account the full lifetime (lead- and consequence time) of the decision/asset in question (Stafford-Smith *et al.*, 2011).

Participatory processes help balance societal preferences with robust scientific information and ensure ownership by affected communities but rely on human capital and political commitment (*high confidence*; Hobson and Niemeyer, 2011; Rouse and Blackett, 2011; Weber *et al.*, 2011; Leitch and Robinson, 2012). Realising widespread and equitable participation is challenging where policies are complex, debates polarised, legitimacy of institutions contested and potential transformational changes threaten deeply held values (Gardner *et al.*, 2009a; Gorddard *et al.*, 2012; Burton and Mustelin, 2013; see also 25.4.3). Regional approaches that engage diverse stakeholders, government and science providers and support the co-production of knowledge can help overcome some of these problems but require long-term institutional and financial commitments (e.g. Britton *et al.*, 2011; DSEWPC, 2011; CSIRO, 2012; IOCI, 2012; Low Choy *et al.*, 2012; Webb and Beh, 2013).

There is active debate about the extent to which incremental adjustments of existing planning instruments, institutions and decision-making processes can deal adequately with the dynamic and uncertain nature of climate change and support transformational responses (Kennedy *et al.*, 2010; Preston *et al.*, 2011; Park *et al.*, 2012; Dovers, 2013; Lawrence *et al.*, 2013b; McDonald, 2013; Stafford-Smith, 2013). Recent studies suggest a greater focus on flexibility and matching decision-making frameworks to specific problems (Hertzler, 2007; Nelson *et al.*, 2008; Dobes, 2010; Howden and Stokes, 2010; Randall *et al.*, 2012). Limitations of mainstreamed and autonomous adaptation and the case for more proactive government intervention are being explored in Australia (Productivity Commission, 2012; Johnston *et al.*, 2013), but have not yet resulted in new policy frameworks.

_____ START BOX 25-1 HERE _____

Box 25-1. Coastal Adaptation – Planning and Legal Dimensions

Sea level rise is a significant risk for Australia and New Zealand (*very high confidence*) due to intensifying coastal development and the location of population centres and infrastructure (see 25.3). Under a high emissions scenario (RCP8.5), global mean sea level would *likely* rise by 0.53 to 0.97 m by 2100, relative to 1986-2005, whereas with stringent mitigation (RCP2.6), the *likely* rise by 2100 would be 0.28 to 0.6 m (*medium confidence*). Based on current understanding, only instability of the Antarctic Ice Sheet, if initiated, could lead to a rise substantially above the *likely* range; evidence remains insufficient to evaluate its probability, but there is *medium confidence* that this additional contribution would not exceed several tenths of a metre during the 21st century (AR5 WGI 13.5). Local case studies in New Zealand (Fitzharris, 2010; Reisinger *et al.*, 2014) and national reviews in Australia (DCC, 2009; DCCEE, 2011) demonstrate risks to large numbers of residential and commercial assets as well as key services, with widespread damages at the upper end of projected ranges (*high confidence*). In Australia, sea level rise of 1.1 m would affect over A$226 billion of assets, including up to 274,000 residential and 8,600 commercial buildings (DCCEE, 2011), with additional intangible costs related to stress, health effects and service disruption (HCCREMS, 2010) and ecosystems (DCC, 2009; BMT WBM, 2011). Under expected future settlement patterns, exposure of the Australian road and rail network will increase significantly once sea level rises above about 0.5 m (Baynes *et al.*, 2012). Even if temperatures peak and decline, sea level is projected to continue to rise beyond 2100 for many centuries, at a rate dependent on future emissions (AR5 WGI 13.5).

Responsibility for adapting to sea level rise in Australasia rests principally with local governments through spatial planning instruments. Western Australia, South Australia and Victoria have mandatory State planning benchmarks for 2100, with local governments determining how they should be implemented. Long-term benchmarks in New South Wales and Queensland have either been suspended or revoked, so local authorities now have broad discretion to develop their own adaptation plans. The New Zealand Coastal Policy Statement (Minister of Conservation, 2010) mandates a minimum 100-year planning horizon for assessing hazard risks, discourages hard protection of existing development and recommends avoidance of new development in vulnerable areas. Non-binding government guidance recommends a risk based approach, using a base value of 0.5 m sea level rise by the 2090s and considering the implications of at least 0.8 m and, for longer term planning, an additional 0.1 m per decade (MfE, 2008d).

The incorporation of climate change impacts into local planning has evolved considerably over the past 20 years, but remains piecemeal and shows a diversity of approaches (Gibbs and Hill, 2012; Kay *et al.*, 2014). Governments have invested in high-resolution digital elevation models of coastal and flood prone areas in some regions, but many local governments still lack the resources for hazard mapping and policy design. Political commitment is variable, and legitimacy of approaches and institutions is often strongly contested (Gorddard *et al.*, 2012), including pressure on State governments to modify adaptation policies and on local authorities to compensate developers for restrictions on current or future land uses (LGNZ, 2008; Berry and Vella, 2010; McDonald, 2010; Reisinger *et al.*, 2011). Incremental adaptation responses can entrench existing rights and expectations about on-going protection and development, which limit options for more transformational responses such as accommodation and retreat (*high agreement, medium evidence*; Gorddard *et al.*, 2012; Barnett *et al.*, 2013; Fletcher *et al.*, 2013; McDonald, 2013). Strategic regional-scale planning initiatives in rapidly growing regions, like south-east Queensland, allow climate change adaptation to be addressed in ways not typically achieved by locality- or sector-specific plans, but require effective coordination across different scales of governance (Serrao-Neumann *et al.*, 2013; Smith *et al.*, 2014).

Courts in both countries have played an important role in evaluating planning measures. Results of litigation have varied and, in the absence of clearer legislative guidance, more litigation is expected as rising sea levels affect existing properties and adaptation responses constrain development on coastal land (MfE, 2008d; Kenderdine, 2010; Rive and Weeks, 2011; Verschuuren and McDonald, 2012; Corkhill, 2013; Macintosh, 2013).

In addition to raising minimum floor levels and creating coastal set-backs to limit further development in areas at risk, several councils in Australia and New Zealand have consulted on or attempted to implement managed retreat policies (ECAN, 2005; BSC, 2010; HDC, 2012; KCDC, 2012). These policies remain largely untested in New Zealand, but experience in Australia has shown high litigation potential and opposing priorities at different levels of government, undermining retreat policies (SCCCWEA, 2009; DCCEE, 2010; Abel *et al.*, 2011). Mandatory disclosure of information about future risks, community engagement and policy stability are critical to support retreat, but existing-use rights, liability concerns, special interests, community resources, place attachment and divergent priorities at different levels of government present powerful constraints (*high confidence*; Hayward, 2008b; Berry and Vella, 2010; McDonald, 2010; Abel *et al.*, 2011; Alexander *et al.*, 2012; Leitch and Robinson, 2012; Macintosh *et al.*, 2013; Reisinger *et al.*, 2014).

_____ END BOX 25-1 HERE _____

25.4.3. Psychological and Socio-cultural Factors Influencing Impacts of and Adaptation to Climate Change

Adapting to climate change relies on individuals accepting and understanding changing risks and opportunities, and responding to these changes both psychologically and behaviourally (see Chapters 2, 16). The majority of Australasians accept the reality of climate change and less than 10% fundamentally deny its existence (*high confidence*; ShapeNZ, 2009; Leviston *et al.*, 2011; Lewandowsky, 2011; Milfont, 2012; Reser *et al.*, 2012b). Australians perceive themselves to be at higher risk from climate change than New Zealanders and citizens of many other countries, which may reflect recent experiences of climatic extremes (Gifford *et al.*, 2009; Agho *et al.*, 2010; Ashworth *et al.*, 2011; Milfont *et al.*, 2012; Reser *et al.*, 2012c). However, beliefs about climate change and its risks vary over time, are uneven across society and reflect media coverage and bias, political preferences and gender (ShapeNZ, 2009; Bacon, 2011; Leviston *et al.*, 2012; Milfont, 2012), which can influence attitudes to adaptation (Gardner *et al.*, 2010; Gifford, 2011; Reser *et al.*, 2011; Alexander *et al.*, 2012; Raymond and Spoehr, 2013).

Surveys in Australia between 2007 and 2011 show moderate to high levels of climate change concern, distress, frustration, resolve, psychological adaptation, and carbon-reducing behaviour (*high agreement, medium evidence*; Agho *et al.*, 2010; Reser *et al.*, 2012b, c). About two thirds of respondents expected global warming to worsen, with about half very or extremely concerned that they or their family would be affected directly. Direct experience with environmental changes or events attributed to climate change, reported by 45% of respondents, was particularly influential, but the extent to which resulting distress and concern translate into support for planned adaptation has not been fully assessed (Reser *et al.*, 2012a, b).

Perceived risks and potential losses from climate change depend on values associated by individuals with specific places, activities and objects. Examples from Australia include the value placed on snow cover in the Snowy Mountains (Gorman-Murray, 2008, 2010), risks to biodiversity and recreational values in coastal South Australia (Raymond and Brown, 2011), conflicts between human uses and environmental priorities in national parks (Wyborn, 2009; Roman *et al.*, 2010), and trade-offs between alternative water supplies and relocation in rural areas (Hurlimann and Dolnicar, 2011). These and additional studies in Australasia confirm that the more individuals identify with particular places and their natural features, the stronger the perceived potential loss but also the greater the motivation to address environmental threats (e.g. Rogan *et al.*, 2005; McCleave *et al.*, 2006; Collins and Kearns, 2010; Gosling and Williams, 2010; Raymond *et al.*, 2011; Russell *et al.*, 2013). This indicates that ecosystem-based climate change adaptation (see Box CC-EA) can provide co-benefits for subjective well-being and mental health, especially for disadvantaged and indigenous communities (Berry *et al.*, 2010; see also 25.8.2).

At the same time, social and cultural values and norms can constrain adaptation options for communities by limiting the range of acceptable responses and processes (e.g. place attachment, differing values relating to near- versus long-term, private versus public, and economic versus environmental or social costs and benefits, and perceived legitimacy of institutions). Examples of this are particularly prominent in Australasia in the coastal zone (e.g. Hayward, 2008a; King *et al.*, 2010; Gorddard *et al.*, 2012; Hofmeester *et al.*, 2012) and acceptance of water recycling or pricing (e.g. Pearce *et al.*, 2007; Kouvelis *et al.*, 2010; Mankad and Tapsuwan, 2011).

Overall, these studies give *high confidence* that the experience and threat of climate change and extreme climatic events are having appreciable psychological impacts, resulting in psychological and subsequent behavioural adaptations, reflected in high levels of acceptance and realistic concern, motivational resolve, self-reported changes in thinking, feeling and understanding of climate change and its implications, and behavioural engagement (Reser and Swim, 2011; Reser *et al.*, 2012a, b, c). However, adequate strategies and systems to monitor trends in psychological and social impacts, adaptation and vulnerability are lacking, and such perspectives remain poorly integrated with and dominated by bio-physical and economic characterisations of climate change impacts.

25.5. Freshwater Resources

25.5.1. Observed Impacts

Climate change impacts on water represent a cross-cutting issue affecting people, agriculture, industries and ecosystems. The challenge of satisfying multiple demands with a limited resource is exacerbated by the high inter-annual and inter-decadal variability of river flows (Chiew and McMahon, 2002; Peel *et al.*, 2004; Verdon *et al.*, 2004; McKerchar *et al.*, 2010) particularly in Australia. Declining river flows since the mid-1970s in far south-western Australia have led to changed water management (see Box 11.2 in Hennessy *et al.*, 2007). The unprecedented decline in river flows during the 1997-2009 ‘Millennium’ drought in south-eastern Australia resulted in low irrigation water allocations, severe water restrictions in urban centres, suspension of water sharing arrangements and major environmental impacts (Chiew and Prosser, 2011; Leblanc *et al.*, 2012).

25.5.2. Projected Impacts

Figure 25-4 shows estimated changes to mean annual runoff across Australia for a 1°C global average warming above current levels (Chiew and Prosser, 2011; Teng *et al.*, 2012). The range of estimates arises mainly from uncertainty in projected precipitation (Table 25-1). Hydrological modelling with CMIP3 future climate projections indicates that freshwater resources in far south-eastern and far south-west Australia will decline (*high confidence;* by 0-40% and 20-70%, respectively, for 2°C warming) due to the reduction in winter precipitation (Table 25-1) when most of the runoff in southern Australia occurs. The percent change in mean annual precipitation in Australia is generally amplified as a 2–3 times larger percent change in mean annual streamflow (Chiew, 2006; Jones *et al.*, 2006). This can vary, however, with unprecedented declines in flow in far south-eastern Australia in the 1997–2009 drought (Cai and Cowan, 2008; Potter and Chiew, 2011; Chiew *et al.*, 2013). Higher temperatures and associated evaporation, tree re-growth following more frequent bushfires (Kuczera, 1987; Cornish and Vertessy, 2001; Marcar *et al.*, 2006; Lucas *et al.*, 2007), interceptions from farm dams (van Dijk *et al.*, 2006; Lett *et al.*, 2009) and reduced surface-groundwater connectivity in long dry spells (Petrone *et al.*, 2010; Hughes *et al.*, 2012) can further accentuate declines. In the longer-term, water availability will also be affected by changes in vegetation and surface-atmosphere feedbacks in a warmer and higher CO_2 environment (Betts *et al.*, 2007; Donohue *et al.*, 2009; McVicar *et al.*, 2010).

[INSERT FIGURE 25-4 HERE
Figure 25-4: Estimated changes in mean annual runoff for 1°C global average warming above current levels. Maps show changes in annual runoff (percentage change; top row) and runoff depth (millimetres; bottom row), for dry, median and wet (10^{th} to 90^{th} percentile) range of estimates, based on hydrological modelling using 15 CMIP3 climate projections (Chiew *et al.*, 2009; CSIRO, 2009; Petheram *et al.*, 2012; Post *et al.*, 2012). Projections for 2°C global average warming are about twice that shown in the maps (Post *et al.*, 2011). (Figure adapted from Chiew and Prosser, 2011; Teng *et al.*, 2012).]

In New Zealand, precipitation changes (Table 25-1) are projected to lead to increased runoff in the west and south of the South Island and reduced runoff in the north-east of the South Island, and the east and north of the North Island (*medium confidence*). Annual flows of eastward flowing rivers with headwaters in the Southern Alps (Clutha, Waimakariri, Rangitata) are projected to increase by 5-10 % (median projection) by 2040 (Bright *et al.*, 2008; Poyck *et al.*, 2011; Zammit and Woods, 2011) in response to higher alpine precipitation. Most of the increases occur in winter and spring, as more precipitation falls as rain and snow melts earlier (Hendrikx *et al.*, 2013). In contrast, the Ashley River, slightly north of this region, is projected to have little change in annual flows, with the increase in winter flows offset by reduced summer flows (Woods *et al.*, 2008). The retreat of glaciers is expected to have only a minor impact on river flows in the first half of the century (Chinn, 2001; Anderson *et al.*, 2008).

Climate change will affect groundwater through changes in recharge rates and the relationship between surface waters and aquifers. Dryland diffuse recharge in most of western, central and southern Australia is projected to decrease because of the decline in precipitation, with increases in the north and some parts of the east because of projected increase in extreme rainfall intensity (*medium confidence*; Crosbie *et al.*, 2010; McCallum *et al.*, 2010; Crosbie *et al.*, 2012). In New Zealand, a single study projects groundwater recharge in the Canterbury Plains to decrease by about 10% by 2040 (Bright *et al.*, 2008). Climate change will also degrade water quality, particularly through increased material washoff following bushfires and floods (Box 25-6, Box 25-8).

25.5.3. Adaptation

The 1997–2009 drought in south-eastern Australia and projected declines in future water resources in southern Australia are already stimulating adaptation (Box 25-2). In New Zealand, there is little evidence of water resources adaptation specifically to climate change. Water in New Zealand is not as scarce generally and water policy reform is driven more by pressure to maintain water quality while expanding agricultural activities, with an increasing focus on collaborative management (Memon and Skelton, 2007; Memon *et al.*, 2010; Lennox *et al.*, 2011; Weber *et al.*, 2011) within national guidelines (LWF, 2010; MfE, 2011). Impacts of climate change on water supply, demand and infrastructure have been considered by several New Zealand local authorities and consultancy reports (Jollands *et al.*, 2007; Williams *et al.*, 2008; Kouvelis *et al.*, 2010), but no explicit management changes have yet resulted.

_____ START BOX 25-2 HERE _____

Box 25-2. Adaptation through Water Resources Policy and Management in Australia

Widespread drought and projections of a drier future in south-eastern and far south-west Australia (Bates *et al.*, 2010; CSIRO, 2010; Potter *et al.*, 2010; Chiew *et al.*, 2011) saw extensive policy and management change in both rural and urban water systems (Hussey and Dovers, 2007; Bates *et al.*, 2008; Melbourne Water, 2010; DSE, 2011; MDBA, 2011; NWC, 2011; Schofield, 2011). These management changes provide examples of adaptations, building on previous policy reforms (Botterill and Dovers, 2013). The broad policy framework is set out in the 2004 National Water Initiative and 2007 Commonwealth Water Act. The establishment of the National Water Commission (2004) and the Murray-Darling Basin Authority (2008) were major institutional reforms. The National Water Initiative explicitly recognises climate change as a constraint on future water allocations. Official assessments (NWC, 2009, 2011) and critiques (Connell, 2007; Grafton and Hussey, 2007; Byron, 2011; Crase, 2011; Pittock and Finlayson, 2011) have discussed progress and shortcomings of the initiative, but assessment of its overall success is made difficult by other factors such as on-going revisions to allocation plans and time lags to observable impacts.

Rural water reform in south-eastern Australia, focused on the Murray-Darling Basin, is currently being implemented. The Murray-Darling Basin Plan (MDBA, 2011, 2012) will return 2750 GL/year of consumptive water (about one fifth of current entitlements) to riverine ecosystems and develop flexible and adaptive water sharing mechanisms to cope with current and future climates. In 2012, the Australian Government committed more than A$12 billion nationally to upgrade water infrastructure, improve water use efficiency, and purchase water entitlements for environmental use. The Basin Plan also includes an environmental watering plan to optimise environmental outcomes for the Basin. Water markets are a key policy instrument, allowing water use patterns to adapt to shifting availability and water to move toward higher value uses (NWC, 2010; Kirby *et al.*, 2012). For example, the two-thirds reduction in irrigation water use over 2000–2009 in the Basin resulted in only 20% reduction in gross agricultural returns, mainly because water use shifted to more valuable enterprises (Kirby *et al.*, 2012). Elsewhere, catchment management authorities and state agencies throughout south-eastern Australia develop water management strategies to cope with prolonged droughts and climate change (e.g. DSE, 2011). Nevertheless, if the extreme dry end of future water projections is realised (25.5.2, Figure 25-4), agriculture and ecosystems across south-eastern and south-western Australia would be threatened even with comprehensive adaptation (see 25.6.1, 25.7.1, 25.7.2; Connor *et al.*, 2009; Kirby *et al.*, 2013).

Climate change and population growth are the two major factors that influence water planning in Australian capital cities. In Melbourne, for example, planning has centred on securing new supplies that are more resilient to major climate shocks; increasing use of alternative sources like sewage recycling and stormwater for non-potable water; programs to reduce demand; water sensitive urban design; and integrated planning that considers climate change impact on water supply, flood risk and stormwater and wastewater infrastructures (DSE, 2007; Skinner, 2010; DSE, 2011; Rhodes *et al.*, 2012). Melbourne's water augmentation program includes a desalinisation plant with a 150 GL/year capacity (about one third of the current demand), following the lead of Perth where a desalinisation plant was established in 2006 because of declining inflows since the mid-1970s (Rhodes *et al.*, 2012). Melbourne's water conservation strategies include water efficiency and rebate programs for business and industry, water smart gardens, dual flush toilets, grey water systems, rainwater tank rebates, free water-efficient showerheads and voluntary residential use targets. These conservation measures, together with water use restrictions since the early 2000s, have reduced Melbourne's total per capita water use by 40% (Fitzgerald, 2009; Rhodes *et al.*, 2012). Similar programs reduced Brisbane's per capita water use by about 50% (Shearer, 2011), while adoption of water recycling and rainwater harvesting resulted in up to 60% water savings in some parts of Adelaide (Barton and Argue, 2009).

The success of urban water reforms in the face of drought and climate change can be variously interpreted. Increasing supply through desalinisation plants and water reuse schemes reduces the risk of future water shortages and helps cities cope with increasing population. Uptake of household-scale adaptation options has been locally significant but their long-term sustainability or reversibility in response to changing drivers and societal attitudes needs further research (Troy, 2008; Brown and Farrelly, 2009; Mankad and Tapsuwan, 2011). Desalinisation plants can be maladaptive due to their energy demand, and the enhancement of mass supply could create a disincentive for reducing demand or increasing resilience through diversifying supply (Barnett and O'Neill, 2010; Taptiklis, 2011).

_____ END BOX 25-2 HERE _____

25.6. Natural Ecosystems

25.6.1. Inland Freshwater and Terrestrial Ecosystems

Terrestrial and freshwater ecosystems have suffered high rates of habitat loss and species extinctions since European settlement in both Australia and New Zealand (Kingsford *et al.*, 2009; Bradshaw *et al.*, 2010; McGlone *et al.*, 2010; Lundquist *et al.*, 2011; SoE, 2011); many reserves are small and isolated, and some key ecosystems and species under-represented (Sattler and Taylor, 2008; MfE, 2010a; SoE, 2011). Many freshwater ecosystems are pressured from over-allocation and pollution, especially in southern and eastern coastal regions in Australia (e.g. Ling, 2010). Additional stresses include erosion, changes in nutrients and fire regimes, mining, invasive species, grazing and salinity (Kingsford *et al.*, 2009; McGlone *et al.*, 2010; SoE, 2011). These increase vulnerability to rapid climate change and provide challenges for both autonomous and managed adaptation (Steffen *et al.*, 2009).

25.6.1.1. Observed Impacts

In Australian terrestrial systems, some recently observed changes in the distribution, genetics and phenology of individual species, and in the structure and composition of some ecological communities, can be attributed to recent climatic trends (*medium* to *high confidence*; see Box 25-3). Uncertainty remains regarding the role of non-climatic drivers, including changes in atmospheric CO_2, fire management, grazing and land-use. The 1997-2009 drought had severe impacts in freshwater systems in the eastern States and the Murray Darling Basin (Pittock and Finlayson, 2011) but in many freshwater systems, direct climate impacts are difficult to detect above the strong signal of over-allocation, pollution, sedimentation, exotic invasions and natural climate variability (Jenkins *et al.*, 2011). In New Zealand, few if any impacts on ecosystems have been directly attributed to climate change rather than variability (Box 25-3; McGlone *et al.*, 2010; McGlone and Walker, 2011). Alpine treelines in New Zealand have remained roughly stable for several hundred years (*high confidence*) despite 0.9°C average warming over the past century (McGlone and Walker, 2011; Harsch *et al.*, 2012).

25.6.1.2. Projected Impacts

Existing environmental stresses will interact with, and in many cases be exacerbated by, shifts in mean climatic conditions and associated change in the frequency or intensity of extreme events, especially fire, drought and floods (*high confidence*; Steffen *et al.*, 2009; Bradstock, 2010; Murphy *et al.*, 2012). Recent drought-related mortality has been observed for amphibians in south-east Australia (Mac Nally *et al.*, 2009), savannah trees in north-east Australia (Fensham *et al.*, 2009; Allen *et al.*, 2010), mediterranean-type eucalypt forest in southwest Western Australia (Matusik *et al.*, 2013), and, eucalypts in sub-alpine regions in Tasmania (Calder and Kirkpatrick, 2008). Mass die-offs of flying foxes and cockatoos have been observed during heatwaves (Welbergen *et al.*, 2008; Saunders *et al.*, 2011). These examples provide *high confidence* that extreme heat and reduced water availability, either singly or in combination, will be significant drivers of future population losses and will increase the risk of local species extinctions in many areas (e.g. McKechnie and Wolf, 2010; see also Figure 25-5).

Species distribution modelling (SDM) consistently indicates future range contractions for Australia's native species even assuming optimistic rates of dispersal, e.g. Western Australian *Banksia* spp. (Fitzpatrick *et al.*, 2008), koalas (Adams-Hosking *et al.*, 2011), northern macropods (Ritchie and Bolitho, 2008), native rats (Green *et al.*, 2008b), greater gliders (Kearney *et al.*, 2010b), quokkas (Gibson *et al.*, 2010), platypus (Klamt *et al.*, 2011), birds (Garnett *et al.*, 2013; van der Wal *et al.*, 2013), and fish (Bond *et al.*, 2011). In some studies, complete loss of climatically suitable habitat is projected for some species within a few decades, and therefore increased risk of local and, perhaps, global extinction (*medium confidence*). SDM has limitations (e.g. Elith *et al.*, 2010; McGlone and Walker, 2011) but is being improved through integration with physiological (Kearney *et al.*, 2010b) and demographic models (Keith *et al.*, 2008; Harris *et al.*, 2012), genetic estimates of dispersal capacity (Duckett *et al.*, 2013), and incorporation into broader risk assessments (e.g. Williams *et al.*, 2008; Crossman *et al.*, 2012).

In Australia, assessments of ecosystem vulnerability have been based on observed changes, coupled with projections of future climate in relation to known biological thresholds and assumptions about adaptive capacity (e.g. Laurance *et al.*, 2011; Murphy *et al.*, 2012). There is *very high confidence* that one of the most vulnerable Australian ecosystems is the alpine zone due to loss of snow cover, invasions by exotic species, and changed species interactions (reviewed in Pickering *et al.*, 2008). There is also *high confidence* in substantial risks to coastal wetlands such as Kakadu National Park subject to saline intrusion (BMT WBM, 2011); tropical savannas subject to changed fire regimes (Laurance *et al.*, 2011); inland freshwater and groundwater systems subject to drought, over-allocation and altered timing of floods (Pittock *et al.*, 2008; Jenkins *et al.*, 2011; Pratchett *et al.*, 2011); peat-forming wetlands along the east coast subject to drying (Keith *et al.*, 2010); and biodiversity-rich regions such as southwest Western Australia (Yates *et al.*, 2010a; Yates *et al.*, 2010b) and tropical and sub-tropical rainforests in Queensland subject to drying and warming (Stork *et al.*, 2007; Shoo *et al.*, 2011; Murphy *et al.*, 2012; Hagger *et al.*, 2013).

The very few studies of climate change impacts on biodiversity in New Zealand suggest that on-going impacts of invasive species (Box 25-4) and habitat loss will dominate climate change signals in the short- to medium-term (McGlone *et al.*, 2010), but that climate change has the potential to exacerbate existing stresses (McGlone and Walker, 2011). There is *limited evidence but high agreement* that the rich biota of the alpine zone is at risk through increasing shrubby growth and loss of herbs, especially if combined with increased establishment of invasive species (McGlone *et al.*, 2010; McGlone and Walker, 2011). Some cold water-adapted freshwater fish and invertebrates are vulnerable to warming (August and Hicks, 2008; Winterbourn *et al.*, 2008; Hitchings, 2009; McGlone and Walker, 2011) and increased spring flooding may increase risks for braided-river bird species (MfE, 2008b). For some restricted native species, suitable habitat may increase with warming (e.g. native frogs; Fouquet *et* *al.*, 2010) although limited dispersal ability will limit range expansion. Tuatara populations are at risk as warming increases the ratio of males to females (Mitchell *et al.*, 2010), although the lineage has persisted during higher temperatures in the geological past (McGlone and Walker, 2011).

25.6.1.3. Adaptation

High levels of endemism in both countries (Lindenmayer, 2007; Lundquist *et al.*, 2011) are associated with narrow geographic ranges and associated climatic vulnerability, although there is greater scope for adaptive dispersal to higher elevations in New Zealand than in Australia. Anticipated rates of climate change, together with fragmentation of remaining habitat and limited migration options in many regions (Steffen *et al.*, 2009; Morrongiello *et al.*, 2011), will limit *in situ* adaptive capacity and distributional shifts to more climatically suitable areas for many species (*high confidence*). Significant local and global losses of species, functional diversity, and ecosystem services, and large scale changes in ecological communities, are anticipated (e.g. Dunlop *et al.*, 2012; Gallagher *et al.*, 2012b; Murphy *et al.*, 2012).

There is increasing recognition in Australia that rapid climate change has fundamental implications for traditional conservation objectives (e.g. Steffen *et al.*, 2009; Prober and Dunlop, 2011; Dunlop *et al.*, 2012; Murphy *et al.*, 2012). Research on impacts and adaptation in terrestrial and freshwater systems has been guided by the National Adaptation Research Plans (Hughes *et al.*, 2010; Bates *et al.*, 2011) and by research undertaken within the CSIRO Climate Adaptation Flagship. Climate change adaptation plans developed by many levels of government and Natural Resource Management (NRM) bodies, supported by substantial Australian government funding, have identified priorities that include: identification and protection of climatic refugia (Davis *et al.*, 2013; Reside *et al.*, 2013); restoration of riparian zones to reduce stream temperatures (Davies, 2010; Jenkins *et al.*, 2011); construction of levees to protect wetlands from saltwater intrusion (Jenkins *et al.*, 2011); reduction of non-climatic threats such as invasive species to increase ecosystem resilience (Kingsford *et al.*, 2009); ecologically-appropriate fire regimes (Driscoll *et al.*, 2010); restoration of environmental flows in major rivers (Kingsford and Watson, 2011; Pittock and Finlayson, 2011); protecting and restoring habitat connectivity in association with expansion of the protected area network (Dunlop and Brown, 2008; Mackey *et al.*, 2008; Taylor and Philp, 2010; Prowse and Brook, 2011; Maggini *et al.*, 2013); and, active interventionist strategies such as assisted colonisation to reduce probability of species extinctions (Burbidge *et al.*, 2011; McIntyre, 2011) or restore ecosystem services (Lunt *et al.*, 2013). Few specific measures have been implemented and thus their effectiveness cannot yet be assessed. Biodiversity research and management in New Zealand to date has taken little account of climate change-related pressures and continues to focus largely on managing pressures from invasive species and predators, freshwater pollution, exotic diseases, and halting the decline in native vegetation, although a number of specific recommendations have been made to improve ecosystem resilience to future climate threats (McGlone *et al.*, 2010; McGlone and Walker, 2011).

Climate change responses in other sectors may have beneficial as well as adverse impacts on biodiversity, but few tools to assess risks from an integrated perspective have been developed (25.9.1, Box 25-10). Assessments of the impacts of climate change on the provision of ecosystem services (such as pollination and erosion control) via impacts on terrestrial and freshwater ecosystems are generally lacking. Similarly, the concept of Ecosystem-based Adaptation, the role of healthy, well-functioning ecosystems in increasing the resilience of human sectors to the impacts of climate change (see Chapters 4 and 5, and Box CC-EA), is relatively unexplored.

25.6.2. Coastal and Ocean Ecosystems

Australia's 60,000 km coastline spans tropical waters in the north to cool temperate waters off Tasmania and the sub-Antarctic islands with sovereign rights over ~8.1 million km^2, excluding the Australian Antarctic Territory (Richardson and Poloczanska, 2009). New Zealand has ~18,000 km of coastline, spanning subtropical to sub-Antarctic waters, and the world's fifth largest Exclusive Economic Zone at 4.2 million km^2 (Gordon *et al.*, 2010). The marine ecosystems of both countries are considered hotspots of global marine biodiversity with many rare, endemic and commercially important species (Hoegh-Guldberg *et al.*, 2007; Blanchette *et al.*, 2009; Gordon *et al.*, 2010; Gillanders *et al.*, 2011; Lundquist *et al.*, 2011). The increasing density of coastal populations (see 25.3) and stressors such as pollution and sedimentation from settlements and agriculture will intensify non-climate stressors in coastal areas (*high confidence*; e.g. Russell *et al.*, 2009). Coastal habitats provide many ecosystem services including coastal protection (Arkema *et al.*, 2013) and carbon storage, particularly in seagrass, saltmarsh and mangroves, which could become increasingly important for mitigation (e.g. Irving *et al.*, 2011). Coastal ecosystems occupy <1% of the land mass but may account for 39% of Australia's average national annual carbon burial (estimated total: 466 millions tonnes CO_2-eq per year; Lawrence *et al.*, 2012).

25.6.2.1. Observed Impacts

There is *high confidence* that climate change is already affecting the oceans around Australia (Pearce and Feng, 2007; Poloczanska *et al.*, 2007; Lough and Hobday, 2011) and warming the Tasman sea in northern New Zealand (Sutton *et al.*, 2005; Lundquist *et al.*, 2011); average climate zones have shifted south by more than 200 km along the northeast and about 100 km along the northwest Australian coasts since 1950 (Lough, 2008). The rate of warming is even faster in southeast Australia, with a poleward advance of the East Australia Current of ~350 km over the past 60 years (Ridgway, 2007). Based on elevated rates of ocean warming, southwest and southeast Australia are recognized as global warming hotspots (Wernberg *et al.*, 2011). It is *virtually certain* that the increased storage of carbon by the ocean will increase acidification in the future, continuing the observed trends of the past decades in Australia as elsewhere (Howard *et al.*, 2012; see also WGI 3.8, 6.44).

Recently observed changes in marine systems around Australia are consistent with warming oceans (*high confidence*; Box 25-3). Examples include changes in phytoplankton productivity (Thompson *et al.*, 2009; Johnson *et al.*, 2011); species abundance of macroalgae (Johnson *et al.*, 2011); growth rates of abalone (Johnson *et al.*, 2011), southern rock lobster (Pecl *et al.*, 2009; Johnson *et al.*, 2011), coastal fish (Neuheimer *et al.*, 2011) and coral (De'ath *et al.*, 2009); life cycles of southern rock lobster (Pecl *et al.*, 2009) and seabirds (Cullen *et al.*, 2009; Chambers *et al.*, 2011); and, distribution of subtidal seaweeds (Johnson *et al.*, 2011; Wernberg *et al.*, 2011; Smale and Wernberg, 2013), plankton (Mcleod *et al.*, 2012), fish (Figueira *et al.*, 2009; Figueira and Booth, 2010; Last *et al.*, 2011; Madin *et al.*, 2012), sea urchins (Ling *et al.*, 2009) and intertidal invertebrates (Pitt *et al.*, 2010).

Habitat-related impacts are more prevalent in northern Australia (Pratchett *et al.*, 2011), while distribution changes are reported more often in southern waters (Madin *et al.*, 2012), particularly south-east Australia, where warming has been greatest. The 2011 marine heat wave in Western Australia caused the first-ever reported bleaching at Ningaloo reef (Abdo *et al.*, 2012; Feng *et al.*, 2013) resulting in coral mortality (Moore *et al.*, 2012; Depczynski *et al.*, 2013) and changes in community structure and composition (Smale and Wernberg, 2013; Wernberg *et al.*, 2013). About 10% of the observed 50% decline in coral cover on the Great Barrier Reef since 1985 has been attributed to bleaching, the remainder to cyclones and predators (De'ath *et al.*, 2012). Changes in distribution and abundance of marine species in New Zealand are primarily linked to ENSO-related variability that dominates in many time series (Clucas, 2011; Lundquist *et al.*, 2011; McGlone and Walker, 2011; Schiel, 2011), although water temperature is also important (e.g. Beentjes and Renwick, 2001). New Zealand fisheries exported over $1.5 billion worth of product in 2012 (SNZ, 2013) and variability in ocean circulation and temperature plays an important role in local fish abundance (e.g. Chiswell and Booth, 2005; Dunn *et al.*, 2009); no climate change impacts have been reported at this stage (Dunn *et al.*, 2009), although this may be due to insufficient monitoring.

25.6.2.2. Projected Impacts

Even though evidence of climate impacts on coastal habitats is limited to date, *confidence* is *high* that negative impacts will arise with continued climate change (Lovelock *et al.*, 2009; McGlone and Walker, 2011; Traill *et al.*, 2011; Chapter 6). Some coastal habitats such as mangroves are projected to expand further landward, driven by sea-level rise and exacerbated by soil subsidence if rainfall declines (*medium confidence*; Traill *et al.*, 2011), although this may be at the expense of saltmarsh and constrained in many regions by the built environment (DCC, 2009; Lovelock *et al.*, 2009; Rogers *et al.*, 2012). Estuarine habitats will be affected by changing rainfall or sediment discharges, as well as connectivity to the ocean (*high confidence*; Gillanders *et al.*, 2011). Loss of coastal habitats and declines in iconic species will result in substantial impacts on coastal settlements and infrastructure from direct impacts such as storm surge, and will affect tourism (*medium confidence*; 25.7.5).

Changes in temperature and rainfall, and sea level rise, are expected to lead to secondary effects, including erosion, landslips, and flooding, affecting coastal habitats and their dependent species, e.g. loss of habitat for nesting birds (*high confidence*; Chambers *et al.*, 2011). Increasing ocean acidification is expected to affect many taxa (*medium confidence*; see also Box CC-OA, Chapters 6, 30) including corals (Fabricius *et al.*, 2011), coralline algae (Anthony *et al.*, 2008), calcareous plankton (Richardson *et al.*, 2009; Thompson *et al.*, 2009; Hallegraeff, 2010), reef fishes (Munday *et al.*, 2009; Nilsson *et al.*, 2012), bryozoans, and other benthic calcifiers (Fabricius *et al.*, 2011). Deep-sea scleractinian corals are also expected to decline with ocean acidification (Miller *et al.*, 2011).

The AR4 identified the Great Barrier Reef (GBR) as highly vulnerable to both warming and acidification (Hennessy *et al.*, 2007). Recent observations of bleaching (GBRMPA, 2009a) and reduced calcification in both the GBR and other reef systems (Cooper *et al.*, 2008; De'ath *et al.*, 2009; Cooper *et al.*, 2012), along with model and experimental studies (Hoegh-Guldberg *et al.*, 2007; Anthony *et al.*, 2008; Veron *et al.*, 2009) confirm this vulnerability (see also Box CC-CR). The combined impacts of warming and acidification associated with atmospheric CO_2 concentrations in excess of 450-500 ppm are projected to be associated with increased frequency and severity of coral bleaching, disease incidence and mortality, in turn leading to changes in community composition and structure including increasing dominance by macroalgae (*high confidence*; Hoegh-Guldberg *et al.*, 2007; Veron *et al.*, 2009). Other stresses, including rising sea levels, increased cyclone intensity, and nutrient-enriched and freshwater runoff, will exacerbate these impacts (*high confidence*; Hoegh-Guldberg *et al.*, 2007; Veron *et al.*, 2009; GBRMPA, 2011). Thermal thresholds and the ability to recover from bleaching events vary geographically and between species (e.g. Diaz-Pulido *et al.*, 2009) but evidence of the ability of corals to adapt to rising temperatures and acidification is limited and appears insufficient to offset the detrimental effects of warming and acidification (*robust evidence, medium agreement*; Hoegh-Guldberg, 2012; Howells *et al.*, 2013; Box CC-CR).

Under all SRES scenarios and a range of CMIP3 models, pelagic fishes such as sharks, tuna and billfish are projected to move further south on the east and west coasts of Australia (*high confidence*; Hobday, 2010). These changes depend on sensitivity to water temperature, and may lead to shifts in species-overlap with implications for by-catch management (Hartog *et al.*, 2011). Poleward movements are also projected for coastal fish species in Western Australia (Cheung *et al.*, 2012) and a complex suite of impacts are expected for marine mammals (Schumann *et al.*, 2013). A strengthening East Auckland Current in northern New Zealand is expected to promote establishment of tropical or sub-tropical species that currently occur as vagrants in warm La Niña years (Willis *et al.*, 2007). Such shifts suggest potentially substantial changes in production and profit of both wild fisheries (Norman-Lopez *et al.*, 2011) and aquaculture species such as salmon, mussels and oysters (*medium confidence*; Hobday *et al.*, 2008; Hobday and Poloczanska, 2010). Ecosystem models also project changes to habitat and fisheries production (*low confidence*; Fulton, 2011; Watson *et al.*, 2012).

25.6.2.3. Adaptation

In Australia, research on marine impacts and adaptation has been guided by the National Adaptation Research Plan for Marine Biodiversity and Resources (Mapstone *et al.*, 2010), programs within the CSIRO Climate Adaptation Flagship and the Great Barrier Reef Marine Park Authority (GBRMPA, 2007). Limits to autonomous adaptation are unknown for almost all species, although limited experiments suggests capacity for response on a scale comparable to projected warming for some species (e.g. coral reef fish; Miller *et al.*, 2012) and not others (e.g. Antarctic krill; Kawaguchi *et al.*, 2013). Planned adaptation options include removal of human barriers to landward migration of species, beach nourishment, management of environmental flows to maintain estuaries (Jenkins *et al.*, 2010), habitat provision (Hobday and Poloczanska, 2010), assisted colonisation of seagrass and species such as turtles (e.g. Fuentes *et al.*, 2009) and burrow modification for nesting seabirds (Chambers *et al.*, 2011). For southern species on the continental shelf, options are more limited because suitable habitat will not be present – the next shallow water to the south is Macquarie Island. There is *low confidence* about the adequacy of autonomous rates of adaptation by species, although recent experiments with coral reef fish suggest that some species may adapt to the projected climate changes (Miller *et al.*, 2012).

Management actions to increase coral reef resilience include reducing fishing pressure on herbivorous fish, protecting top predators, managing runoff quality, and minimizing other human disturbances, especially through marine protected areas (Hughes *et al.*, 2007; Veron *et al.*, 2009; Wooldridge *et al.*, 2012). Such actions will slow, but not prevent, long-term degradation of reef systems once critical thresholds of ocean temperature and acidity are exceeded (*high confidence*), and so novel options, including assisted colonisation and shading critical reefs, have been proposed but remain untested at scale (Rau *et al.*, 2012). Seasonal forecasting can also prepare managers for bleaching events (Spillman, 2011).

Adaptation by the fishing industry to shifting distributions of target species is considered possible by most stakeholders (e.g. southern rock lobster fishery; Pecl *et al.*, 2009). Assisted colonisation to maintain production in the face of declining recruitment may also be possible for some high value species, and has been trialled for the southern rock lobster (Green *et al.*, 2010a). Options for aquaculture include disease management, alternative site selection, and selective breeding (Battaglene *et al.*, 2008), but implementation is only preliminary. Marine protected area planning is not explicitly considering climate change in either country, but reserve performance will be affected by projected environment shifts and novel combinations of species, habitats and human pressures (Hobday, 2011).

_____ START BOX 25-3 HERE _____

Box 25-3. Impacts of a Changing Climate in Natural and Managed Ecosystems

Observed changes in species, and in natural and managed ecosystems (25.6.1, 25.6.2, 25.7.2) provide multiple lines of evidence of the impacts of a changing climate[1]. Examples of observations published since the AR4 are shown in Table 25-3.

[INSERT TABLE 25-3 HERE
Table 25-3: Examples of detected changes in species, natural and managed ecosystems, consistent with a climate change[1] signal, published since the AR4. Confidence in detection of change is based on the length of study, and the type, amount and quality of data in relation to the natural variability in the particular species or system. Confidence in the role of climate as a major driver of the change is based on the extent to which the detected change is consistent with that expected under climate change, and to which other confounding or interacting non-climate factors have been considered and been found insufficient to explain the observed change.]

[FOOTNOTE 1: Consistent with the IPCC definition, a change in climate refers to any statistically detectable signal; it does not necessarily imply a human cause. See Glossary, Table 25-1 and 25.2.]

_____ END BOX 25-3 HERE _____

25.7. Major Industries

25.7.1. Production Forestry

Australia has about 149 Mha forests, including woodlands. Two Mha are plantations and 9.4 Mha multiple-use native forests, and forestry contributes around $7 billion annually to GDP (ABARES, 2012). New Zealand's plantation estate in production forests comprises about 1.7 Mha (90% *Pinus radiata*), with recent contractions due to increased profitability of dairying (FOA and MPI, 2012; MfE, 2013).

25.7.1.1. Observed and Projected Impacts

Existing climate variability and other confounding factors have so far prevented the detection of climate change impacts on forests. Modelled projections are based on ecophysiological responses of forests to CO_2, water and temperatures. In Australia, potential changes in water availability will be most important (*very high confidence*; e.g.

reviews by Battaglia *et al.*, 2009; Medlyn *et al.*, 2011b). Modelling future distributions or growth rates indicate that plantations in south-west Western Australia are most at risk due to declining rainfall, and there is *high confidence* that plantation growth will be reduced by temperature increases in hotter regions, especially where species are grown at the upper range of their temperature tolerances (Medlyn *et al.*, 2011a). Moderate reductions in rainfall and increased temperature could be offset by fertilisation from increasing CO_2 (*limited evidence, medium agreement*; Simioni *et al.*, 2009). In cool regions where water is not limiting, higher temperatures could benefit production (Battaglia *et al.*, 2009). In New Zealand, temperatures are mostly sub-optimal for growth of *P. radiata* and water relations are generally less limiting (Kirschbaum and Watt, 2011). Warming is expected to increase *P. radiata* growth in the cooler south (*very high confidence*), whereas in the warmer north, temperature increases can reduce productivity, but CO_2 fertilisation may offset this (*medium confidence*; Kirschbaum *et al.*, 2012).

Modelling studies are limited by their reliance on key assumptions which are difficult to verify experimentally, e.g. the degree to which photosynthesis remains stimulated under elevated CO_2 (Battaglia *et al.*, 2009). Most studies also exclude impacts of pests, diseases, weeds, fire and wind damage that may change adversely with climate. Fire, for instance, poses a significant threat in Australia and is expected to worsen with climate change (see Box 25-6), especially for the commercial forestry plantations in the southern winter-rainfall regions (Williams *et al.*, 2009; Clarke *et al.*, 2011). In New Zealand, changes in biotic factors are particularly important as they already affect plantation productivity. *Dothistroma* blight, for instance, is a serious pine disease with a temperature optimum that coincides with New Zealand's warmer, but not warmest, pine-growing regions; under climate change, its severity is, therefore, expected to reduce in the warm central North Island but increase in the cooler South Island (*high confidence*) where it could offset temperature-driven improved plantation growth (Watt *et al.*, 2011a). There is *medium evidence* and *high agreement* of similar future southward shifts in the distribution of existing plantation weed, insect pest and disease species in Australia (see review in Medlyn *et al.*, 2011b).

25.7.1.2. Adaptation

Depending on the extent of climate changes and plant responses to increasing CO_2, the above studies provide *limited evidence* but *high agreement* of potential net increased productivity in many areas, but only where soil nutrients are not limiting. Adaptation strategies include changes to species or provenance selection towards trees better adapted to warmer conditions, or adopting different silvicultural options to increase resilience to climatic or biotic stresses, such as pest challenges (White *et al.*, 2009; Booth *et al.*, 2010; Singh *et al.*, 2010; Wilson and Turton, 2011a). The greatest barriers to long-term adaptation planning are incomplete knowledge of plant responses to increased CO_2 and uncertainty in regional climate scenarios (*medium evidence, high agreement*; Medlyn *et al.*, 2011b). The rotation time of plantation forests of about 30 years or more makes proactive adaptation important but also challenging.

25.7.2. Agriculture

Australia produces 93% of its domestic food requirements and exports 76% of agricultural production (PMSEIC, 2010a). New Zealand agriculture contributes about 56% of total export value and dairy products 27%; 95% of dairy products are exported (SNZ, 2012b). Agricultural production is sensitive to climate (especially drought; Box 25-5) but also to many non-climate factors such as management, which thus far has limited both detection and attribution of climate-related changes (see Chapters 7 and 18; Webb *et al.*, 2012a; Darbyshire *et al.*, 2013). Because the region is a major exporter – providing, for example, over 40% of the world trade in dairy products – changes in production conditions in the region have a major influence on world supply (OECD, 2011). This implies that climate change impacts could have consequences for food security not just locally but even globally (Qureshi *et al.*, 2013a).

25.7.2.1. Projected Impacts and Adaptation – Livestock Systems

Livestock grazing dominates land use by area in the region. At the Australian national level, the net effect of a 3°C temperature increase (from a 1980-99 baseline) is expected to be a 4% reduction in gross value of the beef, sheep and wool sector (McKeon et al., 2008). Dairy output is projected to decline in all regions of Australia other than

Tasmania under a 1°C increase by 2030 (Hanslow *et al.*, 2013). Projected changes in national pasture production for dairy, sheep and beef pastures in New Zealand range from an average reduction of 4% across climate scenarios for the 2030s (Wratt et al., 2008) to increases of up to 4% for two scenarios in the 2050s (Baisden *et al.*, 2010) when the models included CO_2 fertilisation and nitrogen feedbacks.

Studies modelling seasonal changes in fodder supply show greater sensitivity in animal production to climate change and elevated CO_2 than models using annual average production, with some impacts expected even under modest warming (*high confidence*) in both New Zealand (Lieffering *et al.*, 2012) and Australia (Moore and Ghahramani, 2013). Across 25 sites in southern Australia (an area that produces 85% of sheep and 40% of beef production by value) modelled profitability declined at most sites by the 2050s because of a shorter growing season due to changes in both rainfall and temperature (Moore and Ghahramani, 2013). In New Zealand, projected changes in seasonal pasture growth drove changes in animal production at four sites representing the main areas of sheep production (Lieffering *et al.*, 2012). In Hawke's Bay, changes in stock number and the timing of grazing were able to maintain farm income for a period in the face of variable forage supply but not in the longer term. In Southland and Waikato, projected increases in early spring pasture growth posed management problems in maintaining pasture quality, yet, if these were met, animal production could be maintained or increased. The temperature-humidity index (THI), an indicator of potential heat stress for animals, increased from 1960-2008 in the Murray Dairy region of Australia and further increases and reductions in milk production are projected (Nidumolu *et al.*, 2011). Shading can substantially reduce, but not avoid, the temperature and humidity effects that produce a high THI (Nidumolu *et al.*, 2011).

Rainfall is a key determinant of inter-annual variability in production and profitability of pastures and rangelands (Radcliffe and Baars, 1987; Steffen *et al.*, 2011) yet remains the most uncertain change. In northern Australia, incremental adaptation may be adequate to manage risks of climate change to the grazing industry but an increasing frequency of droughts and reduced summer rainfall will potentially drive the requirement for transformational change (Cobon *et al.*, 2009). Rangelands that are currently water-limited are expected to show greater sensitivity to temperature and rainfall changes than nitrogen-limited ones (Webb *et al.*, 2012b). The 'water-sparing' effect of elevated CO_2 (offsetting reduced water availability from reduced rainfall and increased temperatures) is invoked in many impact studies but does not always translate into production benefits (Kamman *et al.*, 2005; Newton *et al.*, 2006; Stokes and Ash, 2007; Wan *et al.*, 2007). The impacts of elevated CO_2 on forage production, quality, nutrient cycling and water availability remains the major uncertainty in modelling system responses (McKeon *et al.*, 2009; Finger *et al.*, 2010); recent findings of grazing impacts on plant species composition (Newton *et al.*, 2013) and nitrogen fixation (Watanabe *et al.*, 2013) under elevated CO_2 have added to this uncertainty. New Zealand agro-ecosystems are subject to erosion processes strongly driven by climate; greater certainty in projections of rainfall, particularly storm frequency, are needed to better understand climate change impacts on erosion and consequent changes in the ecosystem services provided by soils (Basher *et al.*, 2012).

25.7.2.2. Projected Impacts and Adaptation – Cropping

Experiments with elevated CO_2 at two sites with different temperatures have shown a wide range in the response of current wheat cultivars (Fitzgerald *et al.*, 2010). Modelling suggests there is the potential to increase New Zealand wheat yields under climate change with appropriate choices of cultivars and sowing dates (*high confidence*; Teixeira *et al.*, 2012). In Australia, the selection of appropriate cultivars and sowing times are projected to result in increased wheat yields in high rainfall areas such as southern Victoria under climate change and maintenance of current yields in some areas expected to be drier (e.g. north-western Victoria; O'Leary *et al.*, 2010). However, if extreme low rainfall scenarios are realized in areas such as South Australia then changes in cultivars and fertilizer applications are not expected to maintain current yields by 2080 (Luo *et al.*, 2009). Under the more severe climate scenarios and without adaptation, Australia could become a net importer of wheat (Howden *et al.*, 2010). One caveat to modelling studies is that an intercomparison of 27 wheat models found large differences between model outputs for already dry and hot Australian sites in response to increasing CO_2 and temperature (Asseng *et al.*, 2013; Carter, 2013).

Rice production in Australia is largely dependent on irrigation and climate change impacts will strongly depend on water availability and price (Gaydon *et al.*, 2010). Sugarcane is also strongly water dependent (Carr and Knox, 2011); yields may increase where rainfall is unchanged or increased, but rising temperatures could drive up evapotranspiration and increase water use (*medium confidence*; Park *et al.*, 2010).

Observed trends and modelling for wine-grapes suggest that climate change will lead to earlier budburst, ripening and harvest for most regions and scenarios (*high confidence*; Grace *et al.*, 2009; Sadras and Petrie, 2011; Webb *et al.*, 2012a). Without adaptation, reduced quality is expected in all Australian regions (*high confidence*; Webb *et al.*, 2008). Change in cultivar suitability in specific regions is expected (Clothier *et al.*, 2012), with potential for development of cooler or more elevated sites within some regions (Tait, 2008; Hall and Jones, 2009) and/or expansion to new regions, with some growers in Australia already relocating (e.g. to Tasmania; Smart, 2010).

Climate change and elevated CO_2 impacts on weeds, pests and diseases are highly uncertain (see Box 25.4). Future performance of currently effective plant resistance mechanisms under elevated CO_2 and temperature is particularly important (Melloy *et al.*, 2010; Chakraborty *et al.*, 2011) as is the future efficacy of widely used biocontrol, i.e. the introduction or stimulation of natural enemies to control pests (Gerard *et al.*, 2012). Australia is ranked second and New Zealand fourth in the world in the number of biological control agent introductions (Cock *et al.*, 2010).

25.7.2.3. Integrated Adaptation Perspectives

Future water demand by the sector is critical for planning (Box 25-2). Irrigated agriculture occupies less than 1% of agricultural land in Australia but accounted for 28% of gross agricultural production value in 2010/11; almost half of this was produced the Murray Darling Basin, which used 68% of all irrigation water (ABS, 2012b; DAFF, 2012). Reduced inflow under dry climate scenarios is predicted to reduce substantially the value of agricultural production in the Basin (*high agreement*, *robust evidence*; Garnaut, 2008; Quiggin *et al.*, 2010; Qureshi *et al.*, 2013b), e.g. in one study by 12-44% to 2030 and 49-72% to 2050 (A1F1; Garnaut, 2008).Water availability also constrains agricultural expansion: 17 Mha in northern Australia could support cropping but only 1% has appropriate water availability (Webster *et al.*, 2009). In New Zealand, the irrigated area has risen by 82% since 1999 to over 1 Mha; 76% is on pasture (Rajanayaka *et al.*, 2010). The New Zealand dairy herd doubled between 1980-2009 expanding from high rainfall zones (>2000 mm annual) into drier, irrigation-dependent areas (600-1000 mm annual); this dependence will increase with further expansion (Robertson, 2010), which is being supported by the Government’s Irrigation Acceleration Fund.

Many adaptation options such as flexible water allocation, irrigation and seasonal forecasting support managing risk in the current climate (Howden *et al.*, 2008; Botterill and Dovers, 2013) and adoption is often high (Hogan *et al.*, 2011a; Kenny, 2011). However, incremental on-farm adaptation has limits (Park *et al.*, 2012) and may hinder transformational change such as diversification of land use or relocation (see Box 25-5) if it encourages persistence where climate change may take current systems beyond their response capacity (Marshall, 2010; Park *et al.*, 2012; Rickards and Howden, 2012). In many cases, transformational change requires a greater level of commitment, access to more resources, and greater integration across all levels of decision-making that encompass both on- and off-farm knowledge, processes and values (Marshall, 2010; Rickards and Howden, 2012).

_____ START BOX 25-4 HERE _____

Box 25-4. Biosecurity

Biosecurity is a high priority for Australia and New Zealand given the economic importance of biologically-based industries and risks to endemic species and iconic ecosystems. The biology and potential risk from invasive and native pathogenic species will be altered by climate change (*high confidence*; Roura-Pascual *et al.*, 2011), but impacts may be positive or negative depending on the particular system.

[INSERT TABLE 25-4 HERE
Table 25-4: Examples of potential consequences of climate change for invasive and pathogenic species relevant to Australia and New Zealand, with consequence categories based on Hellman et al. (2008).]

_____ END BOX 25-4 HERE _____

_____ START BOX 25-5 HERE _____

Box 25-5. Climate Change Vulnerability and Adaptation in Rural Areas

Rural communities in Australasia have higher proportions of older and unemployed people than urban populations (Mulet-Marquis and Fairweather, 2008). Employment and economic prospects depend heavily on the physical environment and hence are highly exposed to climate (averages, variability and extremes) as well as changing commodity prices. These interact with other economic, social and environmental pressures, such as changing government policies (e.g. on drought, carbon pricing; Productivity Commission, 2009; Nelson *et al.*, 2010) and access to water resources. The vulnerability of rural communities differs within and between countries reflecting differences in financial security, environmental awareness, policy and social support, strategic skills and capacity for diversification (Bi and Parton, 2008; Marshall, 2010; Nelson *et al.*, 2010; Hogan *et al.*, 2011b; Kenny, 2011).

Climate change will affect rural industries and communities through impacts on resource availability and distribution, particularly water. Decreased availability and/or increased demand, or price, in response to climate change will increase tensions among agricultural, mining, urban and environmental water users (*very high confidence*), with implications for governance and participatory adaptation processes to resolve conflicts (see 25.4.2, 25.6.1, 25.7.2, 25.7.3, Box 25-2, Box 25-10). Communities will also be affected through direct impacts on primary production, extraction activities, critical infrastructure, population health and recreational and culturally significant sites (see 25.7, 25.8; Kouvelis *et al.*, 2010; Balston *et al.*, 2012).

Altered production and profitability risks and/or land use will translate into complex and interconnected effects on rural communities, particularly income, employment, service provision, and reduced volunteerism (Stehlik *et al.*, 2000; Bevin, 2007; Kerr and Zhang, 2009). The prolonged drought in Australia during the early 2000s, for example, had many interrelated negative social impacts in rural communities, including farm closures, increased poverty, increased off-farm work and, hence, involuntary separation of families, increased social isolation, rising stress and associated health impacts, including suicide (especially of male farmers), accelerated rural depopulation and closure of key services (*high agreement, robust evidence*; Alston, 2007; Edwards and Gray, 2009; Alston, 2010, 2012; Hanigan *et al.*, 2012; see also Box CC-GC). Positive social change also occurred, however, including increased social capital through interaction with community organisations (Edwards and Gray, 2009). While social and cultural changes have the potential to undermine the adaptive capacity of communities (Smith *et al.*, 2011), robust ongoing engagement between farmers and the local community can contribute to a strong sense of community and enhance potential for resilience (McManus *et al.*, 2012; see also 25.4.3).

The economic impact of droughts on rural communities and the entire economy can be substantial. The most recent drought in Australia (2006/7-2008/9), for example, is estimated to have reduced national GDP by about 0.75% (RBA, 2006) and regional GDP in the southern Murray Darling Basin was about 5.7% below forecast in 2007/08, along with the temporary loss of 6000 jobs (Wittwer and Griffith, 2011). Widespread drought in New Zealand during 2007-2009 reduced direct and off-farm output by about NZ$3.6 billion (Butcher, 2009). The 2012-13 drought in New Zealand is estimated to have reduced national GDP by 0.3-0.6% and contributed to a significant rise in global dairy prices, which tempered even greater domestic economic losses (Kamber *et al.*, 2013). Drought frequency and severity are projected to increase in many parts of the region (Table 25-1).

The decisions of rural enterprise managers have significant consequences for and beyond rural communities (Pomeroy, 1996; Clark and Tait, 2008). Many current responses are incremental, responding to existing climate variability (Kenny, 2011). Transformational change has occurred where industries and individuals are relocating part of their operations in response to recent and/or expectations of future climate or policy change (Kenny, 2011; see also Box 25-10), e.g. rice (Gaydon *et al.*, 2010), wine-grapes (Park *et al.*, 2012), peanuts (Thorburn *et al.*, 2012) or changing and diversifying land use *in situ* (e.g. the recent switch from grazing to cropping in South Australia; Howden *et al.*, 2010). Such transformational changes are expected to become more frequent and widespread with a changing climate (*high confidence*; 25.7.2), with positive or negative implications for the wider communities in origin and destination regions (Kiem and Austin, 2012).

Although stakeholders within rural communities differ in their vulnerabilities and adaptive capacities, they are bound by similar dependence upon critical infrastructure and resources, economic conditions, government policy direction, and societal expectations (Loechel *et al.*, 2013). Consequently, adaptation to climate change will require an approach that devolves decision-making to the level where the knowledge for effective adaptations resides, using open communication, interaction and joint-planning (Nelson *et al.*, 2008; Kiem and Austin, 2013).

_____ END BOX 25-5 HERE _____

_____ START BOX 25-6 HERE _____

Box 25-6. Climate Change and Fire

Fire during hot, dry and windy summers in southern Australia can cause loss of life and substantial property damage (Cary *et al.*, 2003; Adams and Attiwill, 2011). The 'Black Saturday' bushfires in Victoria in February 2009, for example, burnt over 3,500 km^2, caused 173 deaths, destroyed over 2,000 buildings and caused damages of A$4 billion (Cameron *et al.*, 2009; VBRC, 2010). This fire occurred toward the end of a 13-year drought (CSIRO, 2010) and after an extended period of consecutive days over 30°C (Tolhurst, 2009).

Climate change is expected to increase the number of days with very high and extreme fire weather (Table 25-1), with greater changes where fire is weather-constrained (most of southern Australia; many, in particular eastern and northern, parts of New Zealand) than where it is constrained by fuel load and ignitions (tropical savannas in Australia). Fire season length will be extended in many already high-risk areas (*high confidence*) and so reduce opportunities for controlled burning (Lucas *et al.*, 2007). Higher CO_2 may also enhance fuel loads by increasing vegetation productivity in some regions (Donohue *et al.*, 2009; Williams *et al.*, 2009; Bradstock, 2010; Hovenden and Williams, 2010; King *et al.*, 2011).

Climate change and fire will have complex impacts on vegetation communities and biodiversity (Williams *et al.*, 2009). Greatest impacts in Australia are expected in sclerophyll forests of the south-east and south-west (Williams *et al.*, 2009). Most New Zealand native ecosystems have limited exposure but also limited adaptations to fire (Ogden *et al.*, 1998; McGlone and Walker, 2011). There is *high confidence* that increased fire incidence will increase risk in southern Australia to people, property and infrastructure such as electricity transmission lines (Parsons Brinkerhoff, 2009; O'Neill and Handmer, 2012; Whittaker *et al.*, 2013) and in parts of New Zealand where urban margins expand into rural areas (Jakes *et al.*, 2010; Jakes and Langer, 2012); exacerbate some respiratory conditions such as asthma (Johnston *et al.*, 2002; Beggs and Bennett, 2011); and increase economic risks to plantation forestry (Watt *et al.*, 2008; Pearce *et al.*, 2011). Forest regeneration following wildfires also reduces water yields (Brown *et al.*, 2005; MDBC, 2007), while reduced vegetation cover increases erosion risk and material washoff to waterways with implications for water quality (Shakesby *et al.*, 2007; Wilkinson *et al.*, 2009; Smith *et al.*, 2011a).

In Australia, fire management will become increasingly challenging under climate change, potentially exacerbating conflicting management objectives for biodiversity conservation versus protection of property (*high confidence*; O'Neill and Handmer, 2012; Whittaker *et al.*, 2013). Current initiatives centre on planning and regulations, building design to reduce flammability, fuel management, early warning systems, and fire detection and suppression (Handmer and Haynes, 2008; Preston *et al.*, 2009; VBRC, 2010; O'Neill and Handmer, 2012). Some Australian authorities are taking climate change into account when rethinking approaches to managing fire to restore ecosystems while protecting human life and properties (Preston *et al.*, 2009; Adams and Attiwill, 2011). Improved understanding of climate drivers of fire risk is assisting fire management agencies, landowners and communities in New Zealand (Pearce *et al.*, 2008; Pearce *et al.*, 2011), although changes in management to date show little evidence of being driven by climate change.

_____ END BOX 25-6 HERE _____

25.7.3. Mining

Australia is the world's largest exporter of coking coal and iron ore and has the world's largest resources of brown coal, nickel, uranium, lead and zinc (ABS, 2012c). Recent events demonstrated significant vulnerability to climate extremes: the 2011 floods reduced coal exports by 25-54 million tonnes and led to A$5-9bn revenue lost in that year (ABARES, 2011; RBA, 2011), and tropical cyclones regularly disrupted mining operations over the past decade (McBride, 2012; Sharma *et al.*, 2013). Flood impacts were exacerbated by regulatory constraints on mine discharges, highlighting tensions among industry, social and ecological management objectives (QRC, 2011), and by flooding affecting road and rail transport to major shipping ports (QRC, 2011; Sharma *et al.*, 2013).

Projected changes in climate extremes imply increasing sector vulnerability without adaptation (*high confidence*; Hodgkinson *et al.*, 2010a; Hodgkinson *et al.*, 2010b). Stakeholders have conducted initial climate risk assessments (Mills, 2009) and perceive the adaptive capacity of the industry to be high (Hodgkinson *et al.*, 2010a; Loechel *et al.*, 2010; QRC, 2011), but costs and broader benefits are yet to be explored along the value-chain and evaluated for community support. On-going challenges include competition for energy and water, climate change scepticism, dealing with contrasting extremes, avoiding maladaptation, and mining-community relations regarding response options, acceptable mine discharges and post-mining rehabilitation (Loechel *et al.*, 2013; Sharma *et al.*, 2013).

25.7.4. Energy Supply, Demand, and Transmission

Energy demand is projected to grow by 0.5-1.3% per annum in Australasia over the next few decades in the absence of major new policies (MED, 2011; Syed, 2012). Australia's predominantly thermal power generation is vulnerable to drought-induced water restrictions, which could require dry-cooling and increased water use efficiency where rainfall declines (Graham *et al.*, 2008; Smart and Aspinall, 2009). Depending on carbon price and technology costs, renewable electricity generation in Australia is projected to increase from 10% in 2010/11 to ~33-50% by 2030 (Hayward *et al.*, 2011; Stark *et al.*, 2012; Syed, 2012), but few studies have explored the vulnerability of these new energy sources to climate change (Bryan *et al.*, 2010; Crook *et al.*, 2011; Odeh *et al.*, 2011).

New Zealand's predominantly hydroelectric power generation is vulnerable to precipitation variability. Increasing winter precipitation and snow melt, and a shift from snowfall to rainfall will reduce this vulnerability (*medium confidence*) as winter/spring inflows to main hydro lakes are projected to increase by 5-10% over the next few decades (McKerchar and Mullan, 2004; Poyck *et al.*, 2011). Further reductions in seasonal snow and glacial melt as glaciers diminish, however, would compromise this benefit (Chinn, 2001; Renwick *et al.*, 2009; Srinivasan *et al.*, 2011). Increasing wind power generation (MED, 2011) would benefit from projected increases in mean westerly winds but face increased risk of damages and shut-down during extreme winds (Renwick *et al.*, 2009).

Climate warming would reduce annual average peak electricity demands by 1-2% per °C across New Zealand and 2(±1)% in New South Wales, but increase by 1.1(±1.4)% and 4.6(±2.7)% in Queensland and South Australia due to air conditioning demand (Stroombergen *et al.*, 2006; Jollands *et al.*, 2007; Thatcher, 2007; Nguyen *et al.*, 2010). Increased summer peak demand, particularly in Australia (see also Figure 25-5), will place additional stress on networks and can result in black-outs (*very high confidence*; Jollands *et al.*, 2007; Thatcher, 2007; Howden and Crimp, 2008; Wang *et al.*, 2010a). During the 2009 Victorian heat wave demand rose by 24% but electrical losses from transmission lines increased by 53% due to higher peak currents (Nguyen *et al.*, 2010), and successive failures of the overloaded network temporarily left more than 500,000 people without power (QUT, 2010). Various adaptation options to limit increasing urban energy demand exist and some are being implemented (see Box 25-9).

There is *limited evidence* but *high agreement* that without additional adaptation, distribution networks in most Australian states will be at high risk of failure by 2031-2070 under non-mitigation scenarios due to increased bushfire risk and potential strengthening and southward shift of severe cyclones in tropical regions (Maunsell and CSIRO, 2008; Parsons Brinkerhoff, 2009). Adaptation costs have been estimated at A$2.5 billion to 2015, with more than half to meet increasing demand for air conditioning and the remainder to increase resilience to climate-related hazards; underground cabling would reduce bushfire risk but has large investment costs that are not included above (Parsons Brinkerhoff, 2009). Decentralised ownership of assets constitutes a significant adaptation constraint

(ATSE, 2008; Parsons Brinkerhoff, 2009). In New Zealand, increasing high winds and temperatures have been identified qualitatively as the most relevant risks to transmission (Jollands *et al.*, 2007; Renwick *et al.*, 2009).

25.7.5. Tourism

Tourism contributes 2.6-4% of GDP to the economies of Australia and New Zealand (ABS, 2010a; SNZ, 2011). The net present value of the Great Barrier Reef alone over the next 100 years has been estimated at A$51.4 billion (Oxford Economics, 2009). Most Australasian tourism is exposed to climate variability and change (see 25.2 for projected trends), and some destinations are highly sensitive to extreme events (Hopkins *et al.*, 2012). The 2011 floods and Tropical Cyclone Yasi, for example, cost the Queensland tourism industry about A$590 million, mainly due to cancellations and damage to the Great Barrier Reef (PWC, 2011); and drought in the Murray-Darling Basin caused an estimated A$70 million loss in 2008 due to reduced visitor days (TRA, 2010).

25.7.5.1. Projected Impacts

Future impacts on tourism have been modelled for several Australian destinations. The Great Barrier Reef is expected to degrade under all climate change scenarios (25.6.2, 30.5, Box CC-CR), reducing its attractiveness (Marshall and Johnson, 2007; Bohensky *et al.*, 2011; Wilson and Turton, 2011b). Ski tourism is expected to decline in the Australian Alps due to snow cover reducing more rapidly than in New Zealand (Pickering *et al.*, 2010; Hendrikx *et al.*, 2013) and greater perceived attractiveness of New Zealand (Hopkins *et al.*, 2012). Higher temperature extremes in the Northern Territory are projected with *high confidence* to increase heat stress and incur higher costs for air conditioning (Turton *et al.*, 2009). Sea level rise places pressures on shorelines and long-lived infrastructure but implications for tourist resorts have not been quantified (Buckley, 2008).

Economic modelling suggests that the Australian alpine region would be most negatively affected in relative terms due to limited alternative activities (Pham *et al.*, 2010), whereas the competitiveness of some destinations (e.g. Margaret River in Western Australia) could be enhanced by higher temperatures and lower rainfall (Jones *et al.*, 2010; Pham *et al.*, 2010). An analogue-based study suggests that, in New Zealand, warmer and drier conditions mostly benefit but wetter conditions and extreme climate events undermine tourism (Wilson and Becken, 2011). *Confidence* in outcomes is *low*, however, due to uncertain future tourist behaviour (Scott *et al.*, 2012; also 25.9.2).

25.7.5.2. Adaptation

Both New Zealand and Australia have formalised adaptation strategies for tourism (Becken and Clapcott, 2011; Zeppel and Beaumont, 2011). In Australia, institutions at various levels also promote preparation for extreme events (Tourism Queensland, 2007, 2010; Tourism Victoria, 2010) and strengthening ecosystem resilience to maintain destination attractiveness (GBRMPA, 2009b). Snow-making is already broadly adopted to increase reliability of skiing (Bicknell and McManus, 2006; Hennessy *et al.*, 2008b), but its future effectiveness depends on location. In New Zealand, even though warming will significantly reduce the number of days suitable for snow-making (Hendrikx and Hreinsson, 2012), sufficient snow could be made in all years until the end of the 21st century to maintain current minimum operational skiing conditions. Options for resorts in Australia's Snowy Mountains are far more limited (Hendrikx *et al.*, 2013), where maintaining skiing conditions until at least 2020 would require A$100 million in capital investment into 700 snow guns and 2.5-3.3 GL of water per month (Pickering and Buckley, 2010).

Short investment horizons, high substitutability and a high proportion of human capital compared with built assets give *high confidence* that the adaptive capacity of the tourism industry is high overall, except for destinations where climate change is projected to degrade core natural assets and diversification opportunities are limited (Evans *et al.*, 2011; Morrison and Pickering, 2011). Strategic adaptation decisions are constrained by uncertainties in regional climatic changes (Turton *et al.*, 2010), limited concern (Bicknell and McManus, 2006), lack of leadership and limited coordinated forward planning (Sanders *et al.*, 2008; Turton *et al.*, 2009; Roman *et al.*, 2010; White and Buultjens, 2012). An integrated assessment of tourism vulnerability in Australasia is not yet possible due to limited understanding of future changes in tourism and community preferences (Scott *et al.*, 2012), including the flow-on effects of changing travel behaviour and tourism preferences in other world regions (see 25.9.2).

25.8.1. Human Health

25.8.1.1. Observed Impacts

Life expectancy in Australasia is high, but shows substantial ethnic and socio-economic inequalities (Anderson *et al.*, 2006). Mortality increases in hot weather in Australia (*high agreement*, *robust evidence*; Bi and Parton, 2008; Vaneckova *et al.*, 2008) with air pollution exacerbating this association. The last four decades have seen a steady increase in the ratio of summer to winter mortality in Australia, indicating a health effect from climatic warming (Bennett *et al.*, 2013). Exceptional heatwave conditions in Australia have been associated with substantial increases in mortality and hospital admissions in several regional towns and capital cities (*high confidence*; Khalaj *et al.*, 2010; Loughnan *et al.*, 2010; Tong *et al.*, 2010a; Tong *et al.*, 2010b). For example, during the heatwave in January and February 2009 in south-eastern Australia (BoM, 2009), total emergency cases increased by 46% over the three hottest days. Direct heat-related health problems increased 34-fold, 61% of these being in people aged 75 years or older, and there were an estimated 374 excess deaths, a 62% increase in all-cause mortality (Victorian Government, 2009a). Mental health admissions increased across all age groups by 7.3% in metropolitan South Australia during heatwaves (1993-2006; Hansen *et al.*, 2008). Mortality attributed to mental and behavioural disorders increased in the 65 to 74-year age group and in persons with existing mental health problems (Hansen *et al.*, 2008). Experience of extreme events also strongly affects psychological well-being (see 25.4.3).

25.8.1.2. Projected Impacts

Projected increases in heatwaves (Figure 25-5) will increase heat-related deaths and hospitalizations, especially among the elderly, compounded by population growth and ageing (*high confidence*; Bambrick *et al.*, 2008; Gosling *et al.*, 2009; Huang *et al.*, 2012). In the southern states of Australia and parts of New Zealand, this may be partly offset by reduced deaths from cold at least for modest rises in temperature (*low confidence*; Bambrick *et al.*, 2008; Kinney, 2012). With strong mitigation, climate change is projected to result in 11% fewer temperature-related deaths in both 2050 and 2100 in Australia, but 14% and 100% more deaths in 2050 and 2100, respectively, without mitigation under a hot, dry A1FI scenario (Bambrick *et al.*, 2008; see Chapter 11 for details on temperature-related health trade-offs). Net results were driven almost entirely by increased mortality in the north, especially Queensland, consistent with Huang *et al.* (2012). In a separate study that accounted for increased daily temperature variability, a threefold increase in heat-related deaths is projected for Sydney by 2100 for the A2 scenario, assuming no adaptation (Gosling *et al.*, 2009). The number of hot days when physical labor in the sun becomes dangerous is also projected to increase substantially in Australia by 2070, leading to economic costs from lost productivity, increased hospitalisations and occasional deaths (*medium confidence*; Hanna *et al.*, 2011; Maloney and Forbes, 2011).

Water- and food-borne diseases are projected to increase, but the complexity of their relationship to climate and non-climate drivers means there is *low confidence* in specific projections. For Australia, 205,000-335,000 new cases of bacterial gastroenteritis by 2050, and 239,000-870,000 cases by 2100, are projected under a range of emission scenarios (Bambrick *et al.*, 2008; Harley *et al.*, 2011). Based on their observed positive relationship with temperature, notifications of salmonellosis notifications are projected to increase 15% for every 1°C increase in average monthly temperatures (Britton *et al.*, 2010a). Water-borne zoonotic diseases such as cryptosporidiosis and giardiasis have more complex relationships with climate and are amenable to various adaptations, making future projections more difficult (Britton *et al.*, 2010b; Lal *et al.*, 2012).

Understanding of the combined effects of climate change and socio-economic development on the distribution of vector-borne diseases has improved since the AR4. Australasia is projected to remain malaria free under the A1B emission scenario until at least 2050 (Béguin *et al.*, 2011) and sporadic cases could be treated effectively. The area climatically suitable for transmission of dengue will expand in Australasia (*high confidence*; Bambrick *et al.*, 2008; Åström *et al.*, 2012), but changes in socio-economic factors, especially domestic water-storage may have a more important influence on disease incidence than climate (Beebe *et al.*, 2009; Kearney *et al.*, 2009). Impacts of climate change on Barmah Forest Virus in Queensland depend on complex interactions between rainfall and temperature changes, together with tidal and socio-economic factors, and thus will vary substantially among different coastal regions (Naish *et al.*, 2013). The effects of climate change combined with frequent travel within and outside the region, and recent incursions of exotic mosquito species, could expand the geographic range of other important arboviruses such as Ross River Virus (*medium confidence*; Derraik and Slaney, 2007; Derraik *et al.*, 2010).

A growing literature since the AR4 has focused on the psychological impacts of climate change, based on impacts of recent climate variability and extremes (Doherty and Clayton, 2011; 25.4.3). These studies indicate significant mental health risks associated with climate-related disasters, in particular persistent and severe drought, floods and storms; climate impacts may be especially acute in rural communities where climate change places additional stresses on livelihoods (*high confidence*; Edwards *et al.*, 2011; see also Box 25-5). Projected population growth and urbanization could further increase health risks indirectly via climate-related stress on housing, transport and energy infrastructure and water supplies (*low confidence*; Howden-Chapman, 2010; see also Box 25-9).

[INSERT FIGURE 25-5 HERE
Figure 25-5: Projected changes in exposure to heat under a high emissions scenario (A1FI). Maps show the average number of days with peak temperatures >40°C, for ~1990 (based on available meteorological station data for the period 1975-2004), ~2050 and ~2100. Bar charts show the change in population heat exposure, expressed as person-days exposed to peak temperatures >40°C, aggregated by State/Territory and including projected population growth for a default scenario. Future temperatures are based on simulations by the GFDL-CM2 global climate model (Meehl *et al.*, 2007), re-scaled to the A1FI scenario; simulations based on other climate models could give higher or lower results. Data from Baynes *et al*. (2012).]

25.8.1.3. Adaptation

Research since the AR4 has mainly focused on climate change impacts, although some adaptation strategies have received attention in Australia. These include improving healthcare services, social support for those most at risk, improving community awareness to reduce adverse exposures, developing early warning and emergency response plans (Wang and McAllister, 2011), and understanding perceptions of climatic risks to health as they affect adaptive behaviours (Akompad *et al.*, 2013). In New Zealand, central Government health policies do not identify specific measures to adapt to climate change (Wilson, 2011). In both countries, policies to reduce risks from extreme events such as floods and fires will have co-benefits for health (see Box 25-6, Box 25-8).

A review of the southern Australian heatwave of 2009 identified a range of issues including communication failures with no clear public information or warning strategy, and no clear thresholds for initiating public information campaigns (Kiem *et al.*, 2010). Emergency services were underprepared and relied on reactive solutions (QUT, 2010). The Victorian government has since developed a heatwave plan to coordinate a state-wide response, maintain consistent community-wide understanding through a Heat Health alert system, build capacity of councils to support communities most at risk, support a Heat Health Intelligence surveillance system, and distribute public health information (Victorian Government, 2009b).

25.8.2. Indigenous Peoples

25.8.2.1. Aboriginal and Torres Strait Islanders

Work since the AR4 includes a national Indigenous adaptation research action plan (Langton *et al.*, 2012), regional risk studies (Green *et al.*, 2009; DNP, 2010; TSRA, 2010; Nursey-Bray *et al.*, 2013) and scrutiny from an Indigenous rights perspective (ATSISJC 2009). Socio-economic disadvantage and poor health (SCRGSP 2011) indicate a disproportionate climate change vulnerability of Indigenous Australians (McMichael *et al.*, 2009) although there are no detailed assessments. In urban and regional areas, where 75% of the Indigenous population lives, assessments have not specifically addressed risks to Indigenous people (e.g. Guillaume *et al.*, 2010). In other regions, all remote, there is limited empirical evidence of vulnerability (Maru *et al.*, 2012). However, there is *high agreement* and *medium evidence* for significant future impacts from increasing heat stress, extreme events and increased disease (Campbell *et al.*, 2008; Spickett *et al.*, 2008; Green *et al.*, 2009).

The Indigenous estate comprises more than 25% of the Australian land area (Altman *et al.*, 2007; NNTT, 2013). There is *high agreement* but *limited evidence* that natural resource dependence (e.g. Bird *et al.*, 2005; Gray *et al.*, 2005a; Kwan *et al.*, 2006; Buultjens *et al.*, 2010) increases Indigenous exposure and sensitivity to climate change (Green *et al.*, 2009); climate change-induced dislocation, attenuation of cultural attachment to place and loss of agency will disadvantage Indigenous mental health and community identity (Fritze *et al.*, 2008; Hunter, 2009; McIntyre-Tamwoy and Buhrich, 2011); and, housing, infrastructure, services and transport, often already inadequate for Indigenous needs especially in remote Australia (ABS 2010c), will be further stressed (Taylor and Philp, 2010). Torres Strait island communities and livelihoods are vulnerable to major impacts from even small sea level rises (*high confidence*; DCC, 2009; Green *et al.*, 2010b; TSRA 2010).

Little adaptation of Indigenous communities to climate change is apparent to date (but see Burroughs, 2010; GETF 2011; Nursey-Bray *et al.*, 2013; Zander *et al.*, 2013). Plans and policies that are imposed on Indigenous communities can constrain their adaptive capacity (Ellemor, 2005; Petheram *et al.*, 2010; Veland *et al.*, 2010; Langton *et al.*, 2012) but participatory development of adaptation strategies is challenged by multiple stressors and uncertainty about causes of observed changes (Leonard *et al.*, 2013b; Nursey-Bray *et al.*, 2013). Adaptation planning would benefit from a robust typology (Maru *et al.*, 2011) across the diversity of Indigenous life experience (McMichael *et al.*, 2009). Indigenous re-engagement with environmental management (e. g. Hunt *et al.*, 2009; Ross *et al.*, 2009) can promote health (Burgess *et al.*, 2009) and may increase adaptive capacity (Berry *et al.*, 2010; Davies *et al.*, 2011). There is emerging interest in integrating Indigenous observations of climate change (Green *et al.*, 2010c; Petheram *et al.*, 2010) and developing inter-cultural communication tools (Woodward *et al.*, 2012; Leonard *et al.*, 2013b). Extensive land ownership in northern and inland Australia and land management traditions mean that Indigenous people are well situated to provide greenhouse gas abatement and carbon sequestration services that may also support their livelihood aspirations (Whitehead *et al.*, 2009; Heckbert *et al.*, 2012).

25.8.2.2. New Zealand Māori

The projected impacts of climate change on Māori society are expected to be highly differentiated, reflecting complex economic, social, cultural, environmental and political factors (*high confidence*). Since the AR4, studies have been either sector-specific (e.g. Insley, 2007; Insley and Meade, 2008; Harmsworth *et al.*, 2010; King *et al.*, 2012) or more general, inferring risk and vulnerability based on exploratory engagements with varied stakeholders and existing social, economic, political and ecological conditions (e.g. MfE, 2007b; Te Aho, 2007; King *et al.*, 2010).

The Māori economy depends on climate-sensitive primary industries with vulnerabilities to climate conditions (*high confidence*; Packman *et al.*, 2001; NZIER, 2003; Cottrell *et al.*, 2004; TPK, 2007; Tait *et al.*, 2008b; Harmsworth *et al.*, 2010; King *et al.*, 2010; Nana *et al.*, 2011a). Much of Māori-owned land is steep (>60%) and susceptible to damage from high intensity rainstorms, while many lowland areas are vulnerable to flooding and sedimentation (Harmsworth and Raynor, 2005; King *et al.*, 2010). Land in the east and north is also drought prone, and this increases uncertainties for future agricultural performance, product quality and investment (*medium confidence*; Cottrell *et al.*, 2004; Harmsworth *et al.*, 2010; King *et al.*, 2010). The fisheries and aquaculture sector faces substantial risks (and uncertainties) from changes in ocean temperature and chemistry, potential changes in species composition, condition and productivity levels (*medium confidence*; King *et al.*, 2010; see also 25.6.2). At the community and individual level, Māori regularly utilize the natural environment for hunting and fishing, recreation, the maintenance of traditional skills and identity, and collection of cultural resources (King and Penny, 2006; King *et al.*, 2012). Many of these activities are already compromised due to resource-competition, degradation and modification (Woodward *et al.*, 2001; King *et al.*, 2012). Climate change driven shifts in natural ecosystems will further challenge the capacities of some Māori to cope and adapt (*medium confidence*; King *et al.*, 2012).

Māori organizations have sophisticated business structures, governance (e.g. trusts, incorporations) and networks (e.g. Iwi leadership groups) across the state and private sectors (Harmsworth *et al.*, 2010; Insley, 2010; Nana *et al.*, 2011b), critical for managing and adapting to climate change risks (Harmsworth *et al.*, 2010; King *et al.*, 2012). Future opportunities will depend on partnerships in business, science, research and government (*high confidence*; Harmsworth *et al.*, 2010; King *et al.*, 2010) as well as innovative technologies and new land management practices to better suit future climates and use opportunities from climate policy, especially in forestry (Carswell *et al.*, 2002; Harmsworth, 2003; Funk and Kerr, 2007; Insley and Meade, 2008; Tait *et al.*, 2008b; Penny and King, 2010).

Māori knowledge of environmental processes and hazards (King *et al.*, 2005; King *et al.*, 2007) as well as strong social-cultural networks are vital for adaptation and on-going risk management (King *et al.*, 2008); however, choices and actions continue to be constrained by insufficient resourcing, shortages in social capital, and competing values (King *et al.*, 2012). Combining traditional ways and knowledge with new and untried policies and strategies will be key to the long-term sustainability of climate-sensitive Māori communities, groups and activities (*high confidence*; Harmsworth *et al.*, 2010; King *et al.*, 2012).

_____ START BOX 25-7 HERE _____

Box 25-7. Insurance as a Climate Risk Management Tool

Insurance helps spread the risk from extreme events across communities and over time and therefore enhances the resilience of society to disasters (see 10.7). In Australia, insured losses are dominated by meteorological hazards, including the 2011 Queensland floods and the 1999 Sydney hailstorm (ICA, 2012) with estimated claims of A$3 billion p.a. (IAA, 2011b). In New Zealand, floods and storms are the second most costly natural hazards after earthquakes (ICNZ, 2013). The number of damaging insured events (up to a certain loss value) has increased significantly in the Oceania region since 1980 (Schuster, 2013). Normalised insured losses in Australia show no significant trend from 1967 to 2006 (Crompton and McAneney, 2008; Crompton *et al.*, 2010; Table 10.4), though this conclusion rests on a simplified accounting of population growth and may also reflect improved building codes and early warning systems (Nicholls, 2011; IPCC, 2012).

There is *high confidence* that without adaptive measures, projected increases in extremes (Table 25-1) and uncertainties in these projections will lead to increased insurance premiums, exclusions and non-coverage in some locations (IAG, 2011), which will reshape the distribution of vulnerability, e.g., through unaffordability or unavailability of cover in areas at highest risk (IAA, 2011b, a; NDIR, 2011; Booth and Williams, 2012). Restriction of cover occurred in some locations following the 2011 flood events in Queensland (Suncorp, 2013).

Insurance can contribute positively to risk reduction by providing incentives to policy holders to reduce their risk profile (O'Neill and Handmer, 2012), e.g. through resilience ratings given to buildings (TGA, 2009; Edge Environment, 2011; IAG, 2011). Apart from constituting an autonomous private sector response to extreme events, insurance can also be framed as a form of social policy to manage climate risks, similar to New Zealand’s government insurance scheme (Glavovic *et al.*, 2010); government measures to reduce or avoid risks also interact with insurance companies’ willingness to provide cover (Booth and Williams, 2012). Yet insurance can also act as a constraint on adaptation, if those living in climate-risk prone localities pay discounted or cross-subsidised premiums or policies fail to encourage betterment after damaging events by requiring replacement of ‘like for like’, constituting a missed opportunity for risk reduction (NDIR, 2011; QFCI, 2012; Reisinger *et al.*, 2014; see also 10.7). The effectiveness of insurance thus depends on the extent to which it is linked to a broader national resilience approach to disaster mitigation and response (Mortimer *et al.*, 2011).

_____ END BOX 25-7 HERE _____

_____ START BOX 25-8 HERE _____

Box 25-8. Changes in Flood Risk and Management Responses

Flood damages across eastern Australia and both main islands of New Zealand in 2010 and 2011 revealed a significant adaptation deficit (ICA, 2012; ICNZ, 2013). For example, the Queensland floods in January 2011 resulted in 35 deaths, three quarters of the State including Brisbane declared a disaster zone, and damages to public infrastructure of AUD$5-6 billion (Queensland Government, 2011). These floods were associated with a strong monsoon and the strongest La Niña on record (Cai *et al.*, 2012; CSIRO and BoM, 2012; Evans and Boyer-Souchet, 2012). Flood frequency and severity exhibit strong decadal variability with no significant long-term trend in Australasia to date (Kiem *et al.*, 2003; Smart and McKerchar, 2010; Ishak *et al.*, 2013).

Flood risk is projected to increase in many regions due to more intense extreme rainfall events driven by a warmer and wetter atmosphere (*medium confidence*; Table 25-1). High resolution downscaling (Carey-Smith *et al.*, 2010), and dynamic catchment hydrological and river hydraulic modelling in New Zealand (Gray *et al.*, 2005b; McMillan *et al.*, 2010; MfE, 2010b; Ballinger *et al.*, 2011; Duncan and Smart, 2011; McMillan *et al.*, 2012) indicate that the 50-year and 100-year flood peaks for rivers in many parts of the country will increase by 5–10% by 2050 and more by 2100 (with large variation between models and emissions scenarios), with a corresponding decrease in return periods for specific flood levels. Studies for Queensland show similar results (DERM *et al.*, 2010). In Australia, flood risk is expected to increase more in the north (driven by convective rainfall systems) than in the south (where more intense extreme rainfall may be compensated by drier antecedent moisture conditions), consistent with confidence in heavy rainfall projections (Table 25-1; Alexander and Arblaster, 2009; Rafter and Abbs, 2009).

Flood risk near river mouths will be exacerbated by storm surge associated with higher sea level and potential change in wind speeds (McInnes *et al.*, 2005; MfE, 2010b; Wang *et al.*, 2010b). Higher rainfall intensity and peak flow will also increase erosion and sediment loads in waterways (Prosser *et al.*, 2001; Nearing *et al.*, 2004) and exacerbate problems from aging stormwater and wastewater infrastructure in cities (Howe *et al.*, 2005; Jollands *et al.*, 2007; CCC, 2010; WCC, 2010; see also Box 25-9). However, moderate flooding also has benefits through filling reservoirs, recharging groundwater and replenishing natural environments (Hughes, 2003; Chiew and Prosser, 2011; Oliver and Webster, 2011).

Adaptation to increased flood risk from climate change is starting to happen (Wilby and Keenan, 2012) through updating guidelines for design flood estimation (MfE, 2010b; Westra, 2012), improving flood risk management (O'Connell and Hargreaves, 2004; NFRAG, 2008; Queensland Government, 2011), accommodating risk in flood prone areas (options include raising floor levels, using strong piled foundations, using water-resistant insulation materials and ensuring weather tightness), and risk reduction and avoidance through spatial planning and managed relocation (Trotman, 2008; Glavovic *et al.*, 2010; LVRC, 2012; QFCI, 2012). Adaptation options in urban areas also include ecosystem-based approaches such as retaining floodplains and floodways, restoring wetlands, and retrofitting existing systems to attenuate flows (Box 25.9; Howe *et al.*, 2005; Skinner, 2010; WCC, 2010).

The recent flooding in eastern Australia and the projected increase in future flood risk have resulted in changes to reservoir operations to mitigate floods (van den Honert and McAneney, 2011; QFCI, 2012) and insurance practice to cover flood damages (NDIR, 2011; Phelan, 2011; Box 25-7). However, the magnitude of potential future changes in flood risk and limits to incremental adaptation responses in urban areas suggest that more transformative approaches based on altering land-use and avoidance of exposure to future flooding may be needed in some locations, especially if changes in the upper range of projections are realised (*high confidence*; Lawrence and Allan, 2009; DERM *et al.*, 2010; Glavovic *et al.*, 2010; Wilby and Keenan, 2012; Lawrence *et al.*, 2013a).

_____ END BOX 25-8 HERE _____

25.9. Interactions among Impacts, Adaptation, and Mitigation Responses

The AR4 found that individual adaptation responses can entail synergies or trade-offs with other adaptation responses and with mitigation, but that integrated assessment tools were lacking in Australasia (Hennessy *et al.*, 2007). Subsequent studies provide detail on such interactions and can inform a balanced portfolio of climate change responses, but evaluation tools remain limited, especially for local decision-making (Park *et al.*, 2011). A review of 25 specific climate change-associated land-use plans from Australia, for example, found that 14 exhibited potential for conflict between mitigation and adaptation (Hamin and Gurran, 2009).

_____ START BOX 25-9 HERE _____

Box 25-9. Opportunities, Constraints, and Challenges to Adaptation in Urban Areas

Considerable opportunities exist for Australasian cities and towns to reduce climate change impacts and, in some regions, benefit from projected changes such as warmer winters and more secure water supply (Fitzharris, 2010; Australian Government, 2012). Many tools and practices developed for sustainable resource management or disaster risk reduction in urban areas are co-beneficial for climate change adaptation, and vice versa, and can be integrated with mitigation objectives (Hamin and Gurran, 2009). Despite the abundance of potential adaptation options, however, social, cultural, institutional and economic factors frequently constrain their implementation (*high confidence*; see also 25.4.2). The form and longevity of cities and towns, with their concentration of hard and critical infrastructure such as housing, transport, energy, stormwater and wastewater systems, telecommunications and public facilities provide additional challenges (see also Chapters 8 and 10, 25.7.4, 25.8.1, Boxes 25-1, 25-2, 25-8). Transport infrastructure is vulnerable to extreme heat and flooding (QUT, 2010; Taylor and Philp, 2010) but quantification of future risks remains limited (Gardiner *et al.*, 2009; Balston *et al.*, 2012; Baynes *et al.*, 2012). Table 25-5 summarises some adaptation options, co-benefits and constraints on their adoption in Australasia.

Overall, the implementation of climate change adaptation policy for urban settlements in Australia and New Zealand has been mixed. The Australian National Urban Policy encourages adaptation, and many urban plans include significant adaptation policies (e.g. City of Melbourne, 2009; City of Port Phillip, 2010; ACT Government, 2012; City of Adelaide, 2012). New Zealand also promotes urban adaptation through strategies, plans and guidance documents (MfE, 2008b; CCC, 2010; WCC, 2010; Auckland Council, 2012; NIWA *et al.*, 2012). Many examples of incremental urban adaptation exist (Box 25-2, Table 25-5), particularly where these include co-benefits and respond to other stressors, like prolonged drought in southern Australia and recurrent floods. Experience is much scarcer with more flexible land-uses, managed relocation and ecosystem-based adaptation that could transform existing settlement patterns and development trends, and where maintaining flexibility to address long-term climate risks can run against near-term development pressures (see Boxes 25-1, 25-2, 25-8, CC-EA). Decision-making models that support such adaptive and transformative changes (25.4.2, Box 25-1) have not yet been implemented widely in urban contexts; increased coordination among different levels of government may be required to spread costs and balance public and private, near- and long-term and local and regional benefits (Norman, 2009; Britton, 2010; Norman, 2010; Abel *et al.*, 2011; Lawrence *et al.*, 2013a; McDonald, 2013; Palutikof *et al.*, 2013; Reisinger *et al.*, 2014).

[INSERT TABLE 25-5 HERE
Table 25-5: Examples of co-beneficial climate change adaptation options for urban areas and barriers to their adoption. Options in italics are already widely implemented in Australia and New Zealand urban areas.]

_____ END BOX 25-9 HERE _____

25.9.1. Interactions among Local-Level Impacts, Adaptation, and Mitigation Responses

Table 25-6 shows examples of adaptation responses that are either synergistic or entail trade-offs with other impacts and/or adaptation responses and goals. Adapting proactively to projected climate changes, particularly extremes such as floods or drought, can increase near-term resilience to climate variability and be a motivation for adopting adaptation measures (Productivity Commission, 2012). However, exclusive reliance on near-term benefits can increase trade-offs and result in long-term maladaptation (*high confidence*). For example, enhancing protection measures after major flood events, combined with rapid re-building, accumulates fixed assets that can become increasingly costly to protect as climate change continues, with attendant loss of amenity and environmental values (Glavovic *et al.*, 2010; Gorddard *et al.*, 2012; McDonald, 2013). Similarly, deferring adoption of increased design wind speeds in cyclone-prone areas delays near-term investment costs but also reduces the long-term benefit/cost ratio of the strategy (Stewart and Wang, 2011).

[INSERT TABLE 25-6 HERE
Table 25-6: Examples of interactions between impacts and adaptation measures in different sectors. In each case, impacts or responses in one sector have the potential to cause negative impacts or have co-benefits with impacts or responses in another sector, or with another type of response in the same sector.]

Mitigation actions can contribute to but also counteract local adaptation goals. Energy efficient buildings, for example, reduce network and health risks during heat waves, but urban densification to reduce transport energy demand intensifies urban heat islands and, hence, heat-related health risks (25.7.4, 25.8.1). Specific adaptations can also make achievement of mitigation targets harder or easier. Increased use of air conditioning, for example, increases energy demand, but energy efficiency and building design can reduce heat exposure as well as energy demand (25.7.4, Box 25-9). Table 25-7 gives further examples, and Box 25-10 explores the multiple and complex benefits and trade-offs in changing land-use to simultaneously adapt to and mitigate climate change.

[INSERT TABLE 25-7 HERE
Table 25-7: Examples of interactions between adaptation and mitigation measures (green rows denote synergies where multiple benefits may be realized, orange rows denote potential tradeoffs and conflicts; grey row gives an example of complex, mixed interactions). The primary goal may be adaptation or mitigation.]

_____ START BOX 25-10 HERE _____

Box 25-10. Land-based Interactions Among Climate, Energy, Water, and Biodiversity

Climate, water, biodiversity, food and energy production and use are intertwined through complex feedbacks and trade-offs (see also Box CC-WE). This could make alternative uses of natural resources within rural landscapes increasingly contested, yet decision support tools to manage competing objectives are limited (PMSEIC, 2010b).

Various policies in Australasia support increased biofuel production and biological carbon sequestration via, for example, mandatory renewable energy targets and incentives to increase carbon storage. Impacts of increased biological sequestration activities on biodiversity depend on their implementation. Benefits arise from reduced erosion, additional habitat, and enhanced ecosystem connectivity, while risks or lost opportunities are associated with large-scale monocultures especially if replacing more diverse landscapes (Brockerhoff *et al.*, 2008; Giltrap *et al.*, 2009; Steffen *et al.*, 2009; Todd *et al.*, 2009; Bradshaw *et al.*, 2013).

Photosynthesis transfers water to the atmosphere, so increased sequestration is projected to reduce catchment yields particularly in southern Australia and affect water quality negatively (CSIRO, 2008; Schrobback *et al.*, 2011; Bradshaw *et al.*, 2013). Accounting for this water use in water allocations for sequestration activities would increase their cost and limit the potential of sequestration-driven land-use change (Polglase *et al.*, 2011; Stewart *et al.*, 2011). Large-scale land-cover changes also affect local and regional climates and soil moisture through changing albedo, evaporation, plant transpiration and surface roughness (McAlpine *et al.*, 2009; Kirschbaum *et al.*, 2011b), but these feedbacks have rarely been included in analyses of changing water demands and availability.

Biological carbon sequestration in New Zealand is less water-challenged than in Australia, except where catchments are projected to become drier and/or are already completely allocated (MfE, 2007a; Rutledge *et al.*, 2011), and would mostly improve water quality through reduced erosion (Giltrap *et al.*, 2009). Policies to protect water quality by limiting nitrogen discharge from agriculture have reduced livestock production and greenhouse gas emissions in the Lake Taupo and Rotorua catchments and supported land-use change towards sequestration (OECD, 2013b).

Trade-offs between biofuel and food production and ecosystem services depend strongly on the type of sequestration activity and their management relies on the use of consistent principles to evaluate externalities and benefits of alternative land-uses (PMSEIC, 2010b). First-generation biofuels have been modelled in Australia as directly competing with agricultural production (Bryan *et al.*, 2010). In contrast, production of woody biofuels in New Zealand is projected to occur on marginal land, not where the most intense agriculture occurs (Todd *et al.*, 2009). Falling costs and increasing efficiency of solar energy may limit future biofuel demand, given the limited efficiency of plants in converting solar energy into usable fuel (e.g. Reijnders and Huijbregts, 2007).

_____ END BOX 25-10 HERE _____

25.9.2. Intra- and Inter-Regional Flow-On Effects Among Impacts, Adaptation and Mitigation

Recent studies strengthen conclusions from the AR4 (Hennessy *et al.*, 2007) that flow-on effects from climate change impacts occurring in other world regions can exacerbate or counteract projected impacts in Australasia. Modelling suggests Australia's terms of trade would deteriorate by about 0.23% in 2050 and 2.95% in 2100 as climate change impacts without mitigation reduce economic activity and demand for coal, minerals and agricultural products in other world regions (A1FI scenario; Harman *et al.*, 2008). As a result, Australian Gross National Product (GNP) is expected to decline more strongly than GDP due to climate change, especially towards the end of the 21^{st} century (Gunasekera *et al.*, 2008). These conclusions, however, merit only *medium confidence*, because they rely on simplified assumptions about global climate change impacts, economic effects and policy responses.

For New Zealand, there is *limited evidence* but *high agreement* that higher global food prices driven by adverse climate change impacts on global agriculture and some international climate policies would increase commodity prices and hence producer returns. Agriculture and forestry producer returns, for example, are estimated to increase by 14.6% under the A2 scenario by 2070 (Saunders *et al.*, 2010) and real gross national disposable income by 0.6-2.3% under a range of non-mitigation scenarios (Stroombergen, 2010) relative to baseline projections in the absence of global climate change. Some climate policies such as biofuel targets and agricultural mitigation in other regions would also increase global commodity prices and hence returns to New Zealand farmers (Saunders *et al.*, 2009; Reisinger *et al.*, 2012). Depending on global implementation, these could more than offset projected average domestic climate change impacts on agriculture (Tait *et al.*, 2008a). In contrast, higher international agricultural commodity prices appear insufficient to compensate for the more severe effects of climate change on agriculture in Australia (see 25.7.2; Gunasekera *et al.*, 2007; Garnaut, 2008).

Climate change could affect international tourism to Australasia through international destination and activity preferences (Kulendran and Dwyer, 2010; Rosselló-Nadal *et al.*, 2011; Scott *et al.*, 2012), climate policies, and oil prices (Mayor and Tol, 2007; Becken, 2011; Schiff and Becken, 2011). These potentially significant effects remain poorly quantified, however, and are not well integrated into local vulnerability studies (Hopkins *et al.*, 2012).

Climate change has the potential to change migration flows within Australasia, particularly due to coastal changes (e.g. from the Torres Straits islands to mainland Australia), although reliable estimates of such movements do not yet exist (see 12.4; Green *et al.*, 2010b; McNamara *et al.*, 2011; Hugo, 2012). Migration within countries, and from New Zealand to Australia, is largely economically driven and sustained by transnational networks, though the perceived more attractive current climate in Australia is reportedly a factor in migration from New Zealand (Goss and Lindquist, 2000; Green *et al.*, 2008a; Poot, 2009). The impacts of climate change in the Pacific may contribute to an increase in the number of people seeking to move to nearby countries (Bedford and Bedford, 2010; Hugo, 2010; McAdam, 2010; Farbotko and Lazrus, 2012; Bedford and Campbell, 2013) and affect political stability and geopolitical rivalry within the Asia-Pacific region, although there is no clear evidence of this to date and causal theories are scarce (see 12.4, 12.5; Dupont, 2008; Pearman, 2009). Increasing climate-driven disasters, disease and border control will stimulate operations other than war for Australasia's armed forces; integration of security into adaptation and development assistance for Pacific island countries can therefore play a key role in moderating the influence of climate change on forced migration and conflict (*high agreement, robust evidence*; Dupont and Pearman, 2006; Bergin and Townsend, 2007; Dupont, 2008; Sinclair, 2008; Barnett, 2009; Rolfe, 2009).

25.10. Synthesis and Regional Key Risks

25.10.1. Economy-wide Impacts and the Potential of Mitigation to Reduce Risks

Globally effective mitigation could reduce or delay some of the risks associated with climate change and make adaptation more feasible beyond about 2050, when projected climates begin to diverge substantially between mitigation and non-mitigation scenarios (see also 19.7). Literature quantifying these benefits for Australasia has increased since the AR4 but remains very sparse. Economy-wide net costs for Australia are modelled to be substantially greater in 2100 under unmitigated climate change (A1FI; GNP loss 7.6%) than under globally effective mitigation (GNP loss less than 2% for stabilization at 450 or 550 ppm CO2-eq, including costs of mitigation and residual impacts; Garnaut, 2008). These estimates, however, are highly uncertain and depend strongly on valuation of non-market impacts, treatment of potentially catastrophic outcomes, and assumptions about adaptation, global changes and flow-on effects for Australia, and effectiveness and implementation of global mitigation efforts (Garnaut, 2008). No estimates of climate change costs across the entire economy exist for New Zealand.

The benefits of mitigation in terms of reduced risks have been quantified for some individual sectors in Australia, e.g. for irrigated agriculture in the Murray-Darling Basin (Quiggin *et al.*, 2008; Quiggin *et al.*, 2010; Valenzuela and Anderson, 2011; Scealy *et al.*, 2012) and for net health outcomes (Bambrick *et al.*, 2008). Although quantitative estimates from individual studies are highly assumption-dependent, multiple lines of evidence (see 25.7, 25.8) give *very high confidence* that globally effective mitigation would significantly reduce many long-term risks from climate change to Australia. Benefits differ, however, between States for some issues, e.g. heat and cold mortality (Bambrick *et al.*, 2008). Few studies consider mitigation benefits explicitly for New Zealand, but scenario-based studies give *high confidence* that if global emissions were reduced from a high (A2) to a medium-low (B1) emissions scenario, this would markedly lower the projected increase in flood risks (Ballinger *et al.*, 2011; McMillan *et al.*, 2012) and reduce risks to livestock production in the most drought prone regions (Tait *et al.*, 2008a; Clark *et al.*, 2011). Mitigation would also reduce the projected benefits to production forestry, however, though amounts depend on the response to CO_2 fertilization (Kirschbaum *et al.*, 2011a; 25.7.1).

25.10.2. Regional Key Risks as a Function of Mitigation and Adaptation

The Australia/New Zealand Chapter of the AR4 (Hennessy *et al.*, 2007) concluded with an assessment of aggregated vulnerability for a range of sectors as a function of global average temperature. Building on recent additional insights, Table 25-8 shows eight key risks within those sectors that can be identified with *high confidence* for the 21st century, based on the multiple lines of evidence presented in the preceding sections and selected using the framework for identifying key risks set out in Chapter 19 (see also Box CC-KR). This combines consideration of biophysical impacts, their likelihood, timing and persistence, with vulnerability of the affected system, based on exposure, magnitude of harm, significance of the system and its ability to cope with or adapt to projected biophysical changes. These key risks differ in the extent to which they can be managed through adaptation and mitigation and their evolution over time, and some are more likely than others, but all warrant attention from a risk-management perspective.

[INSERT TABLE 25-8 HERE
Table 25-8: Key regional risks from climate change and the potential for reducing risk through mitigation and adaptation. Key risks are identified based on assessment of the literature and expert judgments by chapter authors, with evaluation of evidence and agreement in the supporting chapter sections. Each key risk is characterized on a scale from very low to very high and presented in three timeframes: the present, near-term (2030-2040), and long-term (2080-2100). For the near-term era of committed climate change (here, for 2030-2040), projected levels of global mean temperature increase do not diverge substantially across emissions scenarios. For the longer-term era of climate options (here, for 2080-2100), risk levels are presented for global mean temperature increase of 2°C and 4°C above preindustrial levels. For each timeframe, risk levels are estimated for a continuation of current adaptation and for a hypothetical highly adapted state. Relevant climate variables are indicated by icons. For a given key risk, change in risk level through time and across magnitudes of climate change is illustrated, but because the assessment considers potential impacts on different physical, biological, and human systems, risk levels should not necessarily be used to evaluate relative risk across key risks, sectors, or regions.]

One set of key risks comprises damages to natural ecosystems (significant change in community structure of coral reefs and loss of some montane ecosystems) that can be moderated by globally effective mitigation but to which some damage now seems inevitable. For some species and ecosystems, climatically constrained ecological niches, fragmented habitats and limited adaptive movement collectively present hard limits to adaptation to further climate change (*high confidence*). A second set of key risks (increase in flood risk, water scarcity, heat waves and wild fire) comprises damages that could be severe but can be reduced substantially by globally effective mitigation combined with adaptation, with the need for transformational adaptation increasing with the rate and amount of climate change. A third set of key risks (coastal damages from sea level rise, and loss of agriculture production from severe drying) comprises potential impacts whose scale remains highly uncertain within the 21st century, even for a given global temperature change, and where alternative scenarios materially affect levels of concern, adaptation needs and strategies. Even though scenarios of severe drying (see 25.5.2) or rapid sea level rise approaching 1 m or more by 2100 (see Box 25-2 and WGI 13.5) have low or currently unknown probabilities, the associated impacts would so severely challenge adaptive capacity, including transformational changes, that they constitute important risks.

A first comparative assessment for Australia of exposure and damages from different hazards up to 2100 indicates that river flooding will continue to be the most costly source of direct damages to infrastructure, even though the largest value of assets is exposed to bush fire. Exposure to and damages from coastal inundation are currently smaller, but would rise most rapidly beyond mid-century if sea level rise exceeds 0.5 m (Baynes *et al.*, 2012).

An *emerging risk* is the compounding of extreme events, none of which would constitute a *key* risk in its own right, but that collectively and cumulatively across space and time could stretch emergency response and recovery capacity and hamper regional economic development, including through impacts on insurance markets or multiple concurrent needs for major infrastructure upgrades (NDIR, 2011; Phelan, 2011; Baynes *et al.*, 2012; Booth and Williams, 2012; Karoly and Boulter, 2013). Efforts are underway to better understand the potential importance of cumulative impacts and responses, including the challenges arising from impacts and responses across different levels of government (CSIRO, 2011; Leonard *et al.*, 2013a), but evidence is as yet too limited to identify this as a *key risk* consistent with the definitions adopted in this report (see Chapter 19).

Climate change is projected to bring benefits to some sectors and parts of Australasia, at least under limited warming scenarios associated with globally effective mitigation (*high confidence*). Examples include an extended growing season for agriculture and forestry in cooler parts of New Zealand and Tasmania, reduced winter mortality (*low confidence*) and reduced winter energy demand in most of New Zealand and southern States of Australia, and increased winter hydropower potential in New Zealand's South Island (25.7.1, 25.7.2, 25.7.4, 25.8.1).

The literature supporting this assessment of key risks is uneven among sectors and between Australia and New Zealand; for the latter, conclusions in many sectors are based on limited studies that often use a narrow set of assumptions, models, and data and which, accordingly, have not explored the full range of potential outcomes.

25.10.3. Challenges to Adaptation in Managing Key Risks, and Limits to Adaptation

Two key and related challenges for regional adaptation are apparent: to identify when and where adaptation may imply transformational rather than incremental changes; and, where specific interventions are needed to overcome adaptation constraints, in particular to support transformational responses that require coordination across different spheres of governance and decision-making (Productivity Commission, 2012; Palutikof *et al.*, 2013). The magnitude of climate change, especially under scenarios of limited mitigation, and constraints to adaptation suggest that incremental and autonomous responses will not deliver the full range of available adaptation options nor ensure the continued function of natural and human systems if some key risks are realized (*high confidence*; see also 25.4).

Most incremental adaptation measures in natural ecosystems focus on reducing other non-climate stresses but, even with scaled-up efforts, conserving the current state and composition of the ecosystems most at risk appears increasingly infeasible (25.6.1, 25.6.2). Maintenance of key ecosystem functions and services requires a radical reassessment of conservation values and practices related to assisted colonisation and the values placed on 'introduced' species (Steffen *et al.*, 2009). Divergent views regarding intrinsic and service values of species and ecosystems imply the need for a proactive discussion to enable effective decision-making and resource allocation.

In human systems, incremental adjustments of current risk management tools, planning approaches and early warning systems for floods, fire, drought, water resources and coastal hazards can increase resilience to climate variability and change especially in the near term (IPCC, 2012; Productivity Commission, 2012; Dovers, 2013). A purely incremental approach, however, which generally aims to preserve current management objectives, governance and institutional arrangements, can make later transformational changes increasingly difficult and costly (*high agreement, medium evidence*; e.g. Howden *et al.*, 2010; Park *et al.*, 2012; McDonald, 2013; Stafford-Smith, 2013). Examples of transformational changes include: shifting emphasis from protection to accommodation or avoidance of flood risk, including managed retreat from eroding coasts; the translocation of industries in response to increasing drought, flood and fire risks or water scarcity; and the associated transformation of the economic and social base and governance of some rural communities (Boxes 25-1, -2, 5-9; Nelson *et al.*, 2010; Linnenluecke *et al.*, 2011; Kiem and Austin, 2012; O'Neill and Handmer, 2012; McDonald, 2013; Palutikof *et al.*, 2013).

Consideration of transformational adaptation becomes critical where long life- or lead-times are involved, and where high up-front costs or multiple interdependent actors create constraints that require coordinated and proactive interventions (Stafford-Smith *et al.*, 2011; Productivity Commission, 2012; Palutikof *et al.*, 2013). Deferring such adaptation decisions due to uncertainty about the future will not necessarily minimize costs or ensure adequate flexibility for future responses, although up-front investment and opportunity costs of adaptation can present powerful arguments for delayed or staged responses (Stewart and Wang, 2011; Gorddard *et al.*, 2012; Productivity Commission, 2012; McDonald, 2013). Whether transformational responses are seen as success or failure of adaptation depends on the extent to which actors accept a change in, or wish to maintain current activities and management objectives, and the degree to which the values and institutions underpinning the transformation are shared or contested across stakeholders (Park *et al.*, 2012; Stafford-Smith, 2013). These views will differ not only between communities and industries but also from person to person depending on their individual value systems, perceptions of and attitude to risk, and ability to capitalize on opportunities (see also 25.4.3).

25.11. Filling Knowledge Gaps to Improve Management of Climate Risks

The wide range of projected rainfall changes (averages and extremes) and their hydrological amplification are key uncertainties affecting the scale and urgency of adaptation in agriculture, forestry, water resources, some ecosystems, and wildfire and flood risks. For ecosystems, agriculture and forestry, these uncertainties are compounded by limited knowledge of responses of vegetation to elevated CO_2, changes in ocean pH, and interactions with changing climatic conditions. The uncertainties in future impacts are most critical for decisions with long lifetimes, such as capital infrastructure investment or large-scale changes in land- and water-use. Uncertainties about the rate of sea level rise, and changes in storm paths and intensity, add to challenges for infrastructure design. The use of multi-model means and a narrow set of emissions scenarios in many past studies implies that the full set of climate-related risks and management options remains incompletely explored.

Understanding of ecological and physiological thresholds that, once exceeded, would result in rapid changes in species, ecosystems and their services, is still very limited. The literature is noticeably sparse in New Zealand and for arid Australia. These knowledge gaps are compounded by limited information about the effect of global climate change on patterns of natural climate variability, such as ENSO. Better understanding the effect of evolving natural climate variability and long-term trends, along with rising CO_2 concentrations, on pests, invasive species and native and managed ecosystems could support more robust ecosystem-based adaptation strategies.

Vulnerability of human and managed systems depends critically on future socio-economic characteristics. Research into psychological, economic, social and cultural dimensions of vulnerability, adaptive capacity and underpinning values remains limited and poorly integrated with bio-physical studies. This limits the level of confidence in conclusions regarding future vulnerabilities and the feasibility and effectiveness of adaptation strategies.

These multiple, persistent and structural uncertainties imply that, in most cases, adaptation requires an iterative risk management process. While decision-support frameworks are being developed, it remains unclear to what extent existing governance and institutional arrangements will be able to support more transformational responses, particularly where competing public and private interests and particularly vulnerable groups are involved. The enabling or constraining influences on adaptation from interactions among market forces, institutions, governance, policy and regulatory environments have only recently begun to attract research attention, mostly in Australia.

Climate change impacts, adaptation and mitigation responses in other world regions will affect Australasia, but our understanding of this remains very limited. Existing studies suggest that transboundary effects, mediated mostly via trade but potentially also migration, can be of similar if not larger scale than direct domestic impacts of climate change for economically important sectors such as agriculture and tourism. However, scenarios used in such studies tend to be highly simplified. Effective management of risks and opportunities in these sectors would benefit from better integration of relevant global scenarios of climatic and socio-economic changes into studies of local vulnerability and adaptation options.

Frequently Asked Questions

FAQ 25-1: How can we adapt to climate change if projected future changes remain uncertain?

[to be inserted at end of Section 25.4.2]

Many existing climate change impact assessments in Australia and New Zealand focus on the distant future (2050 to 2100). When contrasted with more near-term non-climate pressures, the inevitable uncertainty of distant climate impacts can impede effective adaptation. Emerging best practice in Australasia recognises this challenge and instead focuses on those decisions that can and will be made in the near future in any case, along with the 'lifetime' of those decisions, and the risk from climate change during that lifetime. Thus, for example, the choice of next year's annual crop, even though it is greatly affected by climate, only matters for a year or two and can be adjusted relatively quickly. Even land-use change among cropping, grazing and forestry industries has demonstrated significant flexibility in Australasia over the space of a decade. When the adaptation challenge is reframed as *implications for near-term decisions*, uncertainty about the distant future becomes less problematic and adaptation responses can be better integrated into existing decision-making processes and early warning systems.

Some decisions, such as those about long-lived infrastructure and spatial planning and of a public good nature, must take a long-term view and deal with significant uncertainties and trade-offs between short- and long-term goals and values. Even then, widely used techniques can help reduce challenges for decision-making – including the 'precautionary principle', 'real options', 'adaptive management', 'no regrets strategies', or 'risk hedging'. These can be matched to the type of uncertainty but depend on a regulatory framework and institutions that can support such approaches, including the capacity of practitioners to implement them robustly.

Adaptation is not a one-off action but will take place along an evolving pathway, in which decisions will be revisited repeatedly as the future unfolds and more information comes to hand (see Figure 25-3). Although this creates learning opportunities, successive short-term decisions need to be monitored to avoid unwittingly creating an adaptation path that is not sustainable as climate change continues, or which would cope only with a limited sub-set of possible climate futures. This is sometimes referred to as maladaptation. Changing pathways – for example, shifting from on-going coastal protection to gradual retreat from the most exposed areas – can be challenging and may require new types of interactions among governments, industry and communities.

[INSERT FIGURE 25-3 HERE
Adaptation as an iterative risk management process. Individual adaptation decisions comprise well known aspects of risk assessment and management (top left panel). Each decision occurs within and exerts its own sphere of influence, determined by the lead- and consequence time of the decision, and the broader regulatory and societal influences on the decision (top right panel). A sequence of adaptation decisions creates an adaptation pathway (bottom panel). There is no single 'correct' adaptation pathway, although some decisions, and sequences of decisions, are more likely to result in long-term maladaptive outcomes than others, but the judgment of outcomes depends strongly on societal values, expectations and goals.]

FAQ 25-2: What are the key risks from climate change to Australia and New Zealand?

[to be inserted at end of Section 25.10.3]

Our assessment identifies eight key regional risks from climate change. Some impacts, especially on ecosystems, are by now difficult to avoid entirely. Coral reef systems have a limited ability to adapt naturally to further warming and an increasingly acidic ocean. Similarly, the habitat for some mountain or high elevation ecosystems and their associated species is shrinking inexorably with rising temperatures. This implies substantial impacts and some losses even under scenarios of limited warming. Other risks, however, can be reduced substantially by adaptation, combined with globally effective mitigation. These include potential flood damages from more extreme rainfall in most parts of Australia and New Zealand; constraints on water resources from reducing rainfall in southern Australia; increased health risks and infrastructure damages from heat waves in Australia; and, increased economic losses, risks to human life and ecosystem damage from wildfires in southern Australia and many parts of New Zealand. A third set of risks is particularly challenging to manage robustly because the severity of potential impacts varies widely across the range of climate projections, even for a given temperature increase. These concern damages to coastal infrastructure and low-lying ecosystems from continuing sea level rise, where damages would be widespread if sea level turns out to be at the upper end of current scenarios; and, threats to agricultural production in both far south-eastern and far south-western Australia, which would affect ecosystems and rural communities severely at the dry end of projected rainfall changes. Even though some of these key risks are more likely to materialise than others, and they differ in the extent that they can be managed by adaptation and mitigation, they all warrant attention from a risk management perspective, given their potential major consequences for the region.

Table 25-1: Observed and projected changes in key climate variables, and (where assessed) the contribution of human activities to observed changes. For further relevant information see WGI Chapters 3, 6 (ocean changes, including acidification), 11, 12 (projections), 13 (sea level), and 14 (regional climate phenomena). (*) *medium confidence*, (**) *high confidence*, (***) *very high confidence*, (****) *virtually certain*

Climate variable	*Observed change*	*Direction of projected change*	*Examples of projected magnitude of change (relative to ~1990, unless otherwise stated)*	*Additional comments*
Mean air temperature	***Aus:*** Increased by 0.09 ± 0.03°C per decade since 1911[1] (***) ***NZ:*** Increased by 0.09 ± 0.03°C per decade since 1909[2] (***)	***Aus and NZ:*** Increase[3-8] (****); greatest over inland Aus and least in coastal areas and NZ[5-8] (***)	***Aus:*** 0.6-1.5°C (2030 A1B), 1.0-2.5°C (2070 B1), 2.2-5.0°C (2070 A1FI)[3] ***NZ:*** 0.3-1.4°C (2040 A1B), 0.7-2.3°C (2090 B1), 1.6-5.1°C (2090 A1FI)[5] *CMIP5 RCP4.5, rel. to ~1995[9]:* ***N Aus:*** 0.3-1.6°C (2016-2035), 0.7-2.6°C (2046-2065) ***S Aus & NZ:*** 0.1-1.0°C (2016-2035), 0.6-1.7°C (2046-2065)	***Aus****:* A significant contribution to observed change attributed to anthropogenic climate change[10] (**) with some regional variations attributed to atmospheric circulation variations[11,12] ***NZ:*** Observed change partially attributed to anthropogenic climate change[13] (*)
Sea surface temperature	***Aus:*** Increased by about 0.12°C per decade for NW&NE Aus and by about 0.2°C per decade for SE Aus since 1950[14,15] (***) ***NZ:*** Increased by about 0.07°C per decade over 1909-2009[2] (***)	**Aus and NZ:** Increase[3,7,8] (***) with greater increase in the Tasman sea region (*) [3,7]	***Aus:*** 0.6-1.0°C (2070 B1) and 1.6-2.0°C (2070 A1FI) for southern coastal and 1.2-1.5°C (2070 B1) and 2.2-2.5°C (2070 A1FI) elsewhere[3] ***NZ:*** Similar to projected changes in mean air temperature for coastal waters[5]	
Air temperature extremes	***Aus and NZ:*** Significant trend since 1950: cool extremes have become rarer and hot extremes more frequent and intense[16-19] (**).The Australian heatwave of 2012/13 was exceptional in heat, duration and spatial extent [20].	***Aus and NZ:*** Hot days and nights more frequent and cold days and cold nights less frequent during the 21st century[3,5,21-24] (**)	***Aus:*** Hot days in Melbourne (>35°C max.) increase by 20-40% (2030 A1B), 30-90% (2070 B1) and 70-190% (2070 A1FI)[3] ***NZ:*** Spring and autumn frost-free land to at least triple by 2080s[24]; up to 60 more hot days (>25°C max.) for northern areas by 2090[5]	***Aus****:* Observed trends partly attributable to anthropogenic climate change (**) as they are consistent with mean warming and historical simulations[18,19,21,25], although other factors may have contributed to high extremes during droughts[26-28]
Precipitation	***Aus:*** Late autumn/winter decreases in SW Aus since the 1970s and in SE Aus since the mid 1990s, and annual increases in NW Aus since the 1950s[29-31] (***) ***NZ:*** Mean annual rainfall increased over 1950-2004 in the south and west of the South Island and west of the North Island, and decreased in the north-east of the South Island and east and north of the North Island[32] (***)	***Aus:*** Annual decline in SW Aus (**), elsewhere on most of the southern (*) and NE (*low confidence*) continental edges, with reductions strongest in the winter half year[3,4,9,33-35] (**). Direction of annual change elsewhere is uncertain[3,35,36] (Figure 25.1) (**) ***NZ:*** In the South Island, annual increase in the west and south and decrease in north-east. In the North Island, increase in the west and decrease in eastern and northern regions [5,34,37] (Figure 25.1) (*)	***Aus:*** For 2030 A1B, annual changes of-10% to +5% (N Aus) and -10% to 0% (S Aus), for 2070 B1, -15% to +7.5% (N&E Aus) and -15% to 0% (S Aus), and for 2070 A1FI, -30% to +20% (N&E Aus) and -30% to +5% (S Aus), with larger changes seasonally[3] ***NZ:*** For 2040 A1B, annual changes of -5% to +15% (S&W) and -15% to +10% (N&E) and for 2090 A1B, -10% to +25% (S&W) and -20% to +15% (N&E) based on downscaled projections with larger changes seasonally[5,37]	***Aus:*** Observed decline in SW is related to atmospheric circulation changes[38-40] (***), other factors[41], and partly attributable to anthropogenic climate change[40-43] (**). The recent SE rainfall decline is also related to circulation changes[31,44-46] (**), with some evidence of an anthropogenic component[47] ***NZ:*** Observed trends related to increased westerly winds[32]. Projected annual trends dominated by winter and spring trends related to increased westerlies[5]
Precipitation extremes	***Aus:*** Indices of annual daily extremes (e.g. 95th and 99th percentile rainfalls) show mixed or insignificant trends[21,48], but significant increase is evident in recent decades for shorter duration (sub-daily) events[49,50] (**) ***NZ:*** Extreme annual 1-day rainfall decrease in north and east and increase in west since 1930[32] (*)	***Aus and NZ:*** Increase in most regions in the intensity of rare daily rainfall extremes (i.e. current 20 year return period events) and in short duration (sub-daily) extremes (*) and an increase in the intensity of 99 percentile daily extremes (*low confidence*)[5,8,21,51-56]	***Aus:*** For 2090 A2, CMIP3 give increases in the intensity of the 20 year daily extreme of around +200% to -25% depending on region and model[52] ***NZ:*** Increases of daily extreme rainfalls of around 8% per degree C are projected but with significant regional variations[5,56]	***Aus and NZ:*** The sign of observed trends mostly reflects trends in mean rainfall (e.g. there is a decrease in mean and daily extremes in SW Aus)[21,32,49]. Similarly, future increases in intensity of extreme daily rainfall are more likely where mean rainfall is projected to increase[3,5]

Drought	***Aus:*** Defined using rainfall only, drought occurrence over the period 1900-2007 has not changed significantly[57] (**) ***NZ:*** Defined using a soil water balance model, there has been no trend in drought occurrence since 1972[58] (*)	***Aus and NZ:*** Drought frequency is projected to increase in southern Australia [8,54,57,59,60] (*) and in many regions of New Zealand[58,61] (*)	***Aus:*** Occurrence under 2070 A1B and A2 ranges from a halving to 3 times more frequent in N. Aus, and 0-5 times more frequent in southern Aus[60] ***NZ:*** Time spent in drought in eastern and northern New Zealand is projected to double or triple by 2040[61]	***Aus:*** Regional warming may have led to an increase in hydrological drought (*low confidence*)[62,63]
Winds	***Aus:*** Significant decline in storminess over SE Aus since 1885[64] (*), but inconsistent trends in wind observations since 1975[65,66] ***NZ:*** Mean westerly flow increased during the late 20th century (1978–1998), associated with the positive phase of the IPO[67,68]	***Aus:*** Increases in winds in 20-30°S band, with little change to decrease elsewhere, except for winter increases over Tasmania. Decrease to little change in extremes (99th percentile) over most of Australia except Tasmania in winter[69] (*) ***NZ:*** Mean westerly winds and extreme winds (based on projected changes in circulation patterns) are projected to increase, especially in winter[5,70] (*)	***Aus:*** Magnitude of simulated mean changes may exceed 10% under A1B for 2081-2100 relative to 1981-2000 [69] ***NZ:*** Mean westerly flow to increase by around 20% in spring and around 70% in winter, and to decrease by around 20% in summer and autumn, by 2090[5]	***Aus and NZ:*** Many of past and projected changes in mean wind speed can be related to changes in atmospheric circulation[43,67,68] ***NZ:*** Extreme westerlies and southerlies have slightly increased while extreme easterlies have decreased since 1960[13,71]
Mean sea level	***Aus:*** From 1900-2011 the average rate of relative sea level rise (SLR) was 1.4±0.6 mm/yr[72] (***) ***NZ:*** The average rate of relative SLR was 1.7±0.1 mm/yr over 1900-2009[73] (***)	***Aus and NZ:*** Regional sea level rise will *very likely* exceed the 1971-2000 historical rate, consistent with global mean trends[74]. Mean sea level will continue to rise for at least several more centuries[74] (***)	***Aus:*** Off shore regional sea level rise may exceed 10% more than global SLR, see AR5 WGI Chap13, Figure 13.21[74] ***NZ***: Off shore regional sea level rise may be up to 10% more than global SLR[75]	***Aus and NZ**:* Satellite estimates of regional SLR for 1993-2009 are significantly higher than those for 1920-2000, partly reflecting climatic variability[72,73,76,77] ***NZ:*** Allowing for glacial isostatic adjustment, absolute observed SLR is around 2.0mm/yr[73,78]
Extreme sea level	***Aus and NZ:*** Extreme sea levels have risen at a similar rate to global SLR[79]	***Aus and NZ:*** Projected mean SLR will lead to large increases in the frequency of extreme sea level events (***), with other changes in storm surges playing a lesser role[80-83]	***Aus:*** An increase of mean sea level by 0.1m increases the frequency of an extreme sea level event by a factor of between 2 and 10 over southeastern Australia depending on location [80-82],	
Fire weather	***Aus:*** Increased since 1973(**) with 24 out of 38 sites showing increases in the 90th percentile of the McArthur Forest Fire Danger index[84]	***Aus:*** Fire weather is expected to increase in most of southern Australia due to hotter and drier conditions (**), based on explicit model studies carried out for SE Australia [85-88], and change little or decrease in NE[88] (*) ***NZ:*** Fire danger index is projected to increase in many areas[89] (*)	***Aus:*** Increase in days with very high and extreme fire danger index by 2-30% (2020), 5-100% (2050) (using B1 and A2 and two climate models, and 1973-2007 base)[85] ***NZ:*** Increase in days with very high and extreme fire danger index from around 0 to 400% (2040) and 0 to 700% (2090) (using A1B,16 CMIP3 GCMs)[89]	***Aus:*** For the example of Canberra, the projected changes represent the current 17 days per year increasing to 18-23 days in 2020 and 20-33 days in 2050[85]
Tropical cyclones and other severe storms	***Aus:*** No regional change in the number of tropical cyclones (TCs) or in the proportion of intense TCs over 1981-2007[90] (*), but frequency of severe landfalling TCs in NE Aus has declined significantly since the late 19th Century[91] and east-west distribution changed since 1980.[92] There has been no trend in environments suitable for severe thunderstorms[93]	***Aus:*** Tropical cyclones are projected to increase in intensity and stay similar or decrease in numbers[9,94], and occur further south[94] (*low confidence*) ***NZ:*** Projected increase in the average intensity of cyclones in the south during winter, but a decrease elsewhere[70] (*)	***Aus:*** Modelling study shows a 50% reduction in TC occurrence for 2051-2090 relative to 1971-2000, increases in intensity of the modelled storms, and occur around 100km further south[94] ***NZ:*** Occurrence of conditions conducive to convective storm development is projected to increase by 3–6% by 2070-2100 (A2), relative to 1970-2000, with the largest increases over the South Island[70]	***Aus:*** Regional research on convective storms is limited but studies have shown a projected decrease in the frequency of cool-season tornadoes[95], and hail[3] in southern Australia, and increases in the frequency and intensity of hail in the Sydney region[3,96]

Snow and ice	***Aus:*** Late season significant snow depth decline at three out of four Snowy mountain sites over 1957-2002[97] (**) ***NZ:*** Ice volume declined by 36-61% from the mid-late 1800s to the late 1900s[98-100], with glacier volume reducing by 15% between 1976 and 2008[101] (**)	***Aus:*** Both snow depth and area are projected to decline[97] (***) ***NZ:*** Snowline elevations are projected to rise, and winter snow volume and days with low elevation snow cover are projected to decrease[5,102,103] (***)	***Aus:*** Area with at least 30 days cover annually projected to decline 14-54% (2020) and 30-93% (2050)[97] ***NZ:*** By 2090, peak snow accumulation is projected to decline by 32-79% at 1000m and by 6-51% at 2000 m[103]	***NZ:*** Atmospheric circulation variations can enhance or outweigh multi-decadal trends in ice volume over time scales of up to two decades[104,105]

Table 25-2: Constraints and enabling factors for institutional adaptation processes in Australasia.*

Constraint	**Enabling factors**
Uncertainty of projections	Improved guidance and tools to manage uncertainty and support adaptive management [1-8] Increased focus on lead and consequence time of decisions and link with current climate variability and related risks [9-13] Increased communication between practitioners and scientists to identify and provide decision-relevant data and context [2,3,11,13-17]
Availability and cost of data and models	Central provision of relevant core climate and non-climate data, including regional scenarios of projected changes [4,5,7,9,18,19] National first-pass risk assessments [4,5,7,8,18,20-24]
Limited financial and human capability and capacity; time lag in developing expertise	Support for pilot projects [4,8,15,18,24,25] Building capacity through institutional commitment and learning [3,5,11,17,23,26-28] Central databases on guidance, tools, methodologies, case studies [4,5,7,18,24] Regional partnerships and collaborations, knowledge networks [3,4,8,13,15,17,26,28-30]
Unclear problem definition and goals; unclear standards for risk assessment methodologies and decision support tools; limited monitoring and evaluation	Explicit but iterative framing and scoping of adaptation challenge, to reflect alternative entry points for stakeholders while meeting expectations of project sponsors to ensure long-term support [3,11,17,31-34] Tailoring decision-making frameworks to specific problems [1,2,6,17,35,36] Criteria and tools to monitor and evaluate adaptation success [7,18,37-39]
Unclear or contradictory legislative frameworks and responsibilities, unclear liabilities	Clear and coordinated legislative frameworks [5,8,9,15,24,40-45] Defined responsibilities for public and private actors, including liabilities from acting and failure to act [8,9,11,24,41,44,46] Legally binding guidance on the incorporation of climate change in planning mechanisms [5,7,8,15,38,40]
Static planning mechanisms and practice; competing mandates and fragmentation of policies; disciplinary voids or single approaches	Whole-of-council approach to climate adaptation to break up institutional and professional silos [15,33,47] Long-term policy commitments and implementation support [5,18,26,33,48] Increased policy coherence across sectors, regulations and levels of government [9,26,28,40,42,43,47] Enabling risk-based flexible land-use decisions [4,5,9,49] Strengthening multi-disciplinarity across professional fields [14,29,48]
Lack of political leadership; short election cycles; limited community support, participation and awareness for adaptation	Legally binding guidance and clarification of liabilities and duty of care to reduce dependence on individual leadership [5,7-9,15,24,38,40,46,49] Consistent but audience-specific communication of current and potential future vulnerability and implications for community values [4,5,7,26,42,43,50] Comprehensible communication of and access to response options, and their consistency with wider development plans [7,26,28,33,39,42,43] Clearly identified entry points for public participation [17,34,38,39,42,48,51-53]

* Note: The relevance of each constraint varies among organisations, sectors and location. Some enabling factors are only beginning to be implemented or have only been suggested in the literature, hence their effectiveness cannot yet be evaluated. Entries for enabling factors exclude generic mechanisms, such as insurance (see Box 25-7), emergency management and early warning systems, and funding for pilot studies, capital infrastructure upgrades or retreat schemes.

Table 25-3: Examples of detected changes in species, natural and managed ecosystems, consistent with a climate change[1] signal, published since the AR4. Confidence in detection of change is based on the length of study, and the type, amount and quality of data in relation to the natural variability in the particular species or system. Confidence in the role of climate being a major driver of the change is based on the extent to which the detected change is consistent with that expected under climate change, and to which other confounding or interacting non-climate factors have been considered and been found insufficient to explain the observed change.

Type of change and nature of evidence	**Examples**	**Time scale of observations**	**Confidence in the detection of biological change**	**Potential climate change driver(s) [1]**	**Confidence in the role of climate vs other drivers**
Morphology *Limited evidence* (1 study)	Declining body size of southeast Australian passerine birds, equivalent to ~7° latitudinal shift (Gardner *et al.*, 2009)	~100 years	***medium*** trend significant for 4 out of 8 species, two other species show same trend but not statistically significant	Warming air temperatures ~1.0ºC over same period	***medium*** Nutritional cause discounted
Geographic distribution *High agreement, robust evidence* for many marine species & mobile terrestrial species	Southerly range extension of the barrens-forming sea urchin *Centrostephanus rodgersii* from the New South Wales coast to Tasmania; flow on impacts to marine communities including lobster fishery; shift of 160 km per decade over 30 years (Ling, 2008; Ling *et al.*, 2008; Ling *et al.*, 2009; Banks *et al.*, 2010)	~30-50 years (first recorded in Tasmania late 1970s)	***high***	Increased sea surface temperature (SST), Ocean warming in SE Australia, increased southerly penetration of the East Australian Current (EAC), 350 km over 60 years	***high***
	Forty-five fish species, representing 27 families (about 30% of the inshore fish families occurring in the region), exhibited major distributional shifts in Tasmania (Last *et al.*, 2011)	distributions from late 1880s, 1980s and present (1995-now)	***high***	Increased SST SE Australia, increased southerly penetration of EAC	***medium*** Changed fishing practices have potentially contributed to trends
	Southward range shift of intertidal species (average minimum distance 116 km) off west coast of Tasmania; 55% species recorded at more southerly sites, only 3% species expanded to more northerly sites (Pitt *et al.*, 2010)	~50 years Sites resampled 2007-2008, compared with 1950s	***medium***	Increased SST in SE Australia (average 0.22ºC per decade), increased southerly penetration of the EAC, 350 km over 60 years	***medium***

Life cycles *Robust evidence, medium agreement*; increasing documentation of advances in phenology in some species (mainly migration and reproduction in birds, emergence in butterflies, flowering in plants) but also significant trends towards later life cycle events in some taxa (see meta-analysis for Southern Hemisphere phenology (Chambers *et al.*, 2013a)	Significant advance in mean emergence date of 1.5 days per decade (1941-2005) in the Common Brown butterfly *Heteronympha merope* in Australia (Kearney *et al.*, 2010)	65 years	***high***	Increase in local air temperatures of 0.16°C per decade (1945-2007)	***high*** Advance consistent with physiologically based model of temperature influence on development
	Advances in spring phenology of migratory birds, and both advances and delays in phenology in other seasons at multiple Australian sites: meta-analysis of 52 species and 145 datasets (Chambers *et al.*, 2013b)	Multiple time periods from 1960s, all included 1990s and 2000s	***high***	Local climate trends (increasing air temperature, decreased raindays) were more important than broad-scale drivers such as the Southern Oscillation Index. Strongest associations were with decreased raindays.	***high*** *No other potential confounding facotrs identified*
	Earlier wine-grape ripening at 9 of 10 sites in Australia (Webb *et al.*, 2012)	Multiple time periods up to 64 years (average 41 years)	***high***	Increased length of growing season, increased average temperature and reduced soil moisture	***medium*** Changed husbandry techniques, resulting in lower crop yields, may have contributed to trend
	Timing of migration of glass eels, *Anguilla* spp. advanced by several weeks in Waikato River, North island, New Zealand (Jellyman *et al.*, 2009)	30 years (2004-2005 compared to 1970s)	***medium***	Warming water temperatures in spawning grounds	***low*** Changes in discharge discounted as contributing factor
Marine productivity *Limited evidence, medium agreement*	Otolith (“ear stone”) analyses in long-lived Pacific fish indicates significantly increased growth rates for shallow-water species (<250 m) (3 of 3 species), reduced growth rates of deep-water (>1000 m) species (3 of 3 species); no change observed in the 2 intermediate-depth species (Thresher *et al.*, 2007)	Birth years ranged 1861-1993 (fish 2-128 years old)	***high***	Increasing growth rates in species in top 250m associated with warming SST, declining growth rates in species >1000m associated with long-term cooling (as indicated by Mg/Ca ratios and delta^{18}O in deep water corals)	***medium*** Changed fishing pressure may have contributed to trend
	~50% decline in growth rate and biomass of spring phytoplankton bloom in western Tasman Sea (Thompson *et al.*, 2009)	60 year dataset; decline recorded over period 1997-2007	***high***	Increased SST and extension EAC associated with reduced nutrient availability	***medium***

Vegetation change *Limited agreement & evidence*; interacting impacts of changed land practices, altered fire regimes, increasing atmospheric CO_2 concentration and climate trends difficult to disentangle	Expansion of monsoon rainforest at expense of eucalypt savanna and grassland in Northern Territory, Australia (Banfai and Bowman, 2007; Bowman *et al.*, 2010)	~40 years	***medium***	Increases in rainfall and atmospheric CO_2	***medium*** Changes in fire regimes and land management practices may have contributed to trend
	Net increase in mire wetland extent (10.2%) and corresponding contraction of adjacent eucalypt woodland in seven sub-catchments in south east Australia (Keith *et al.*, 2010)	Weather data covers >40 years (depending on parameter); vegetation mapping from 1961-1998	***medium***	Decline in evapo-transpiration	***low*** Resource exploitation, fire history and autogenic mire development discounted
Freshwater communities *Limited evidence* (1 study)	Decline in families of macroinvertebrates that favour cooler, faster-flowing habitats in New South Wales streams and increase in families favouring warmer and more lentic conditions (Chessman, 2009)	13 years (1994-2007)	***medium***	Increasing water temperatures and declining flows	***low*** Variation in sampling, changes in water quality, impacts of impoundment and water extraction may have contributed to trends
Disease *Limited evidence, robust agreement*	Emergence and increased incidence of coral diseases including white syndrome (since 1998), and black band disease (since 1993-4) (Bruno *et al.*, 2007; Sato *et al.*, 2009; Dalton *et al.*, 2010)	1998 onwards	***medium***	Increasing SST	***high***
Coral reefs *Robust evidence & high agreement*	Multiple mass bleaching events since 1979 (see 25.6.2, 30.5)	1979 onwards	***high***	Increasing SST	***high***
	Calcification of *Porites* on GBR declined 21% (1971-2003, 4 reefs; Cooper *et al.*, 2008); about 11% (1990-2005, 69 reefs; De'ath *et al.*, 2009)	1971-2003; 1990-2005	***high***	Increasing SST	***high*** Changes in water quality discounted

Table 25-4: Examples of potential consequences of climate change for invasive and pathogenic species relevant to Australia and New Zealand, with consequence categories based on Hellman et al. (2008).

Consequence	Projected change	Organism/Ecosystem affected
altered mechanisms of transport and introduction	Increased risk of introduction of Asiatic Citrus Psyllid, (*Diaphorina citri*), vector of the disease huanglongbing [1]	Australian citrus industry and native citrus and other rutaceaous species and endemic psyllid fauna
altered distribution of existing invasive & pathogenic species	*Nassella neesiana* (Chilean needle grass): increased droughts favour establishment [2]	Managed pasture in New Zealand
	Warming and drying may encourage the spread of existing invasives such as *Pheidole megacephala* in New Zealand and provide suitable conditions for other exotic ant species if they invade [3]	Human health and potentially agricultural and natural ecosystems
	Reduced climatic suitability for exotic invasive grasses in Australia (11 species including *Nassella* sp.) [4]	Australian rangeland
	Range of the invasive weed *Lantana camara* (lantana) projected to extend from Northern Australia to Victoria, South Australia and Tasmania [5]	Multiple
	Projected increases in the range of three recently naturalised sub-tropical plants (*Archontophoenix cunninghamiana*, *Psidium guajava*, *Schefflera actinophylla*) [6]	Native ecosystems in New Zealand
altered climatic constraints on invasive & pathogenic species	Queensland fruit fly (*Bactrocera tryoni*) moving southwards [7]	Australian horticulture
	Significant association between amphibian declines in upland rainforests of north Queensland and three consecutive years of warm weather suggests future warming could increase the vulnerability of frogs to chytridiomycosis caused by the chytrid fungus *Batrachochytrium dendrobatadis* [8]	Native frogs
altered impact of existing invasive & pathogenic species	*Fusarium pseudograminearum* causing crown rot increases under elevated CO_2 [9]	Australian wheat
	Increased abundance of the root-feeding nematode *Longidorus elongatus* under elevated CO_2 [10]	New Zealand pasture
	Increased severity of Swiss needle cast disease caused by *Phaeocryptopus gaeumannii* [11]	Douglas fir plantations in New Zealand, impact more severe in North Island
altered effectiveness of management strategies	Light brown apple moth, *Epiphyas postvittana* (Walker) (*Lepidoptera:Tortricidae*) reduction in natural enemies due to asynchrony and loss of host species [12]	Australian horticulture
	Projected changes in the efficacy of five biological control systems demonstrating a range of potential disruption mechanisms [13]	Pastoral and horticultural systems in New Zealand

References: [1] Finlay *et al.* (2009); [2] Bourdôt *et al.* (2012); [3] Harris and Barker (2007); [4] Gallagher *et al.* (2012a); [5] Taylor *et al.* (2012b); [6] Sheppard (2012); [7] Sutherst *et al.* (2000); [8] Laurance (2008); [9] Melloy *et al.* (2010); [10] Yeates and Newton (2009); [11] Watt *et al.* (2011b); [12] Thomson *et al.* (2010); [13] Gerard *et al.* (2012).

Table 25-5: Examples of co-beneficial climate change adaptation options for urban areas and barriers to their adoption. Options in italics are already widely implemented in Australia and New Zealand urban areas.

Climate impact	**Adaptation options**	**Co-benefits**	**Barriers to adoption**
Hot days and heatwaves [1-8]	Greening cities/roofs; *more green spaces*; *well-designed energy efficient buildings*; occupant behavioral change; standards for new and retrofitting of existing infrastructure and assets; new methods and material for transport infrastructure to withstand higher extreme temperature	Energy efficiency; reduced risk of blackouts; fewer health impacts; resilient infrastructure and assets; resilient community	Lack of standards; high installation costs; limited understanding of benefits; high individual discount rate; split of private costs and public benefits
Decreased water supply and drought [See Box 25-2 for more]	Supply augmentation (*water recycling*, *rainwater harvesting*, *increased storage*, desalinisation); *demand management*; *infrastructure upgrades*; *integrated urban sensitive design*	Water self-sufficiency for current and future demand/population; less pipe/storage leakage; reduced environmental impacts from abstraction	Potential health impacts of recycled water; lower than expected uptake of demand options and relaxation after crises; trade-offs between supply and demand management; cost and environmental impacts of some augmentation options
River and local flooding, coastal erosion and inundation [See Boxes 25-1 and 25-8 for more]	New standards and improvements to *building, water infrastructure (e.g. drainage and sewerage)* and transport infrastructure; *upgrades of protection systems*; *retaining floodplains/floodways*; restoring wetlands; buffers from hazard-prone areas; *raising minimum floor levels*; rezoning/ relocation	Reduced damages to homes and infrastructure and loss of life; decreased insurance premiums; habitat protection	High implementation cost especially if retrospective on existing stock; rezoning/ relocation can affect property prices and are highly contested
Severe storms and tropical cyclones [9-12]	New building design to withstand higher wind pressures; rezoning/relocation	Reduced damages to homes and infrastructure and loss of life; decreased insurance premiums	High implementation cost; rezoning/ relocation can affect property prices and are highly contested
Corrosion from increased atmospheric CO_2 levels [13,14]	Improved standards for construction using concrete; application of coatings for existing building stock	Reduced rates of carbonation-induced corrosion of concrete	Effectiveness of coatings varies with age and condition of concrete

References: [1] BRANZ (2007); [2] Coutts *et al.* (2010); [3] Moon and Han (2011); [4] Stephenson *et al.* (2010); [5] Williams *et al.* (2010); [6] CSIRO *et al.* (2007); [7] Taylor and Philp (2010); [8] QUT (2010); [9] Mason and Haynes (2010); [10] Wang *et al.* (2010b); [11] Stewart and Wang (2011); [12] Mason *et al.* (2013); [13] Stewart *et al.* (2012); [14] Wang *et al.* (2012).

Table 25-6: Examples of interactions between impacts and adaptation measures in different sectors. In each case, impacts or responses in one sector have the potential to conflict (cause negative impacts) or be synergistic (have co-benefits) with impacts or responses in another sector, or with another type of response in the same sector.

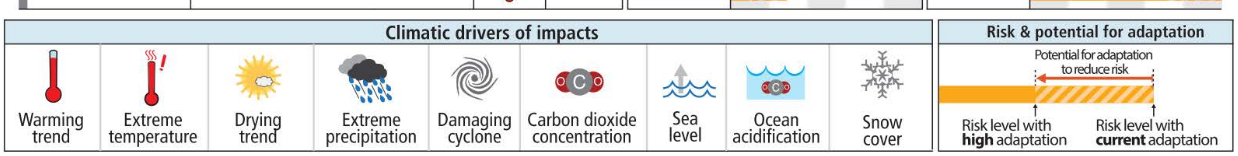
Primary goal	Sector(s) affected	Examples of interactions between impacts and adaptation responses
Reduction of bushfire risk in natural landscapes	Biodiversity, tourism	Potential for greater conflict between conservation managers and other park users in Kosciuszko National Park if increasing fire incidence causes park closures, either to reduce risk, or to rehabilitate vegetation after fires (Wyborn, 2009), e.g. Objectives of the Wildfire Management Overlay (WMO) in Victoria conflicts with vegetation conservation (Hughes and Mercer, 2009).
Reduction of risk to energy transmission from bushfires	Biodiversity, energy	Underground cabling would reduce both the susceptibility of transmission networks to fire and ignition sources for wild fires, thus reducing risks to ecosystems and settlements; constraints include significant investment cost, diverse ownership of assets and lack of an overarching national strategy (ATSE, 2008; Parsons Brinkerhoff, 2009; Linnenluecke *et al.*, 2011).
Protection of coastal infrastructure	Biodiversity, tourism	Seawalls may provide habitat but these communities have different diversity and structure to those developing on natural substrates (Jackson *et al.*, 2008); groynes potentially alter beach fauna diversity and community structure (Walker *et al.*, 2008); continuing hard protection against sea level rise results in long-term loss of coastal amenities (Gorddard *et al.*, 2012).
Avoidance of risks from sea level rise via relocation	Indigenous communities	Relocation can avoid increasing local pressures on communities from sea level rise but raises complex cultural, land rights, legal and economic issues, e.g. potential relocation of Torres Strait islander communities (Green *et al.*, 2010b; McNamara *et al.*, 2011).
Allocating scarce water resources via market instruments	Rural areas, agriculture, mining	Market based instruments such as water trading help allocation of scarce water resources to the highest value uses. The negative implications of this include potential loss of access to lower value users, which in some areas includes agriculture and drinking water supplies, with potentially significant social, environmental and wider economic consequences (Kiem and Austin, 2012).
Increased water security via augmentation of supply for urban and agricultural systems	Biodiversity, water demand management	Water storage can buffer urban settlements and agricultural systems against high variability in river flows, but altered flow regimes can have significant negative impacts on freshwater ecosystems (Bond *et al.*, 2008; Pittock *et al.*, 2008; Kingsford, 2011). Discharge from desalination plants (e.g. in Perth and Sydney) can lead to substantial local increases in salinity and temperature, and the accumulation of metals, hydrocarbons and toxic anti-fouling compounds in receiving waters (Roberts *et al.*, 2010); increasing supply can reduce the effectiveness of demand-side measures (Barnett and O'Neill, 2010; Taptiklis, 2011; Box 25-2).

Table 25-7: Examples of interactions between adaptation and mitigation measures (green rows denote synergies where multiple benefits may be realized, orange rows denote potential tradeoffs and conflicts; grey row gives an example of complex, mixed interactions). The primary goal may be adaptation or mitigation.

Primary goal	Sector(s) affected	Examples of interactions between adaptation and mitigation responses
Adaptation to decreasing snowfall	Biodiversity, energy use, water use	Snowmaking in the Australian Alps would require large additional energy and water resources by 2020 of 2500-3300 ML of water per month, more than half the average monthly water consumption by Canberra in 2004-05. Increased snowmaking negatively affects vegetation, soils and hydrology of subalpine-alpine areas (Pickering and Buckley, 2010; Morrison and Pickering, 2011; ABS, 2012a).
Air conditioning for heat stress	Health, energy use	Rising temperatures degrade building energy efficiency (Wang *et al.*, 2010a) and increase energy demand and associated CO_2 emissions if summer cooling needs are met by increased air conditioning (Stroombergen *et al.*, 2006; Thatcher, 2007; Wang *et al.*, 2010a).
Renewable wind energy production	Biodiversity	Wind-farms can have localised negative effects on bats and birds. However, risk assessment of the potential negative impacts of wind turbines on threatened bird species in Australia indicated low to negligible impacts on all species modelled (Smales, 2006).
Urban densification	Biodiversity, water, health	Higher urban density to reduce energy consumption from transport and infrastructure can result in loss of permeable surfaces and tree cover, intensify flood risks, and exacerbate discomfort and health impacts of hotter summers (Hamin and Gurran, 2009).
Water supply from desalination	Energy demand	Meeting increasing urban water demand via desalination plants increases energy demand and CO_2 emissions if this demand is met by increased fossil fuel energy generation (Barnett and O'Neill, 2010; Stamatov and Stamatov, 2010).
Secure food production in a warming climate	Nitrous oxide and methane emissions	Net greenhouse gas emissions intensity from dairy systems in southern Australia have been estimated to increase in future in several locations due to a changing climate and management responses (Cullen and Eckard, 2011; Eckard and Cullen, 2011). A shift towards perennial C4 grasses would increase methane emissions from grazing ruminants due to lower feed quality, but studies in south-west Australia suggest this could be more than offset by increased soil carbon storage (Thomas *et al.*, 2012; Bradshaw *et al.*, 2013).
Housing design to reduce peak energy demand	Energy use, infrastructure, health	Reducing peak energy demand through building design and demand management reduces vulnerability of electricity networks and transmission losses during heat waves (Parsons Brinkerhoff, 2009; Nguyen *et al.*, 2010), reduces heat stress during summer and provides health benefits during winter (Strengers, 2008; Howden-Chapman, 2010; Strengers and Maller, 2011; Ren *et al.*, 2012).
Energy from second-generation biofuels	Biodiversity, rural areas, agriculture	New crops such as oil mallees or other eucalypts may provide multiple benefits, especially in marginal areas, displacing fossil fuels or sequestering carbon, generating income for landholders (essential oils, charcoal, bio-char, biofuels), and providing ecosystem services including reducing erosion (Cocklin and Dibden, 2009; Giltrap *et al.*, 2009; McHenry, 2009).
Reduced emissions from fires	Biodiversity, livelihoods	Improved management of savanna fires to reduce the extent of high intensity late season fires could substantially reduce emissions as well as having significant benefits for biodiversity and indigenous employment (Russell-Smith *et al.*, 2009; Bradshaw *et al.*, 2013).
Reduce methane emissions from feral camels	Biodiversity, agriculture	Feral camels in Australia are projected to double from 1 to 2 million by 2020. Controlling their numbers to reduce methane emissions could have significant biodiversity benefits (NRMMC, 2010; Bradshaw *et al.*, 2013). Economic benefits of reduced grazing competition, infrastructure damage and greenhouse gases could outweigh costs of camel reductions (Drucker *et al.*, 2010).

Table 25-8: Key regional risks from climate change and the potential for reducing risk through mitigation and adaptation. Key risks are identified based on assessment of the literature and expert judgments by chapter authors, with evaluation of evidence and agreement in the supporting chapter sections. Each key risk is characterized on a scale from very low to very high and presented in three timeframes: the present, near-term (2030-2040), and long-term (2080-2100). For the near-term era of committed climate change (here, for 2030-2040), projected levels of global mean temperature increase do not diverge substantially across emissions scenarios. For the longer-term era of climate options (here, for 2080-2100), risk levels are presented for global mean temperature increase of 2°C and 4°C above preindustrial levels. For each timeframe, risk levels are estimated for a continuation of current adaptation and for a hypothetical highly adapted state. Relevant climate variables are indicated by icons. For a given key risk, change in risk level through time and across magnitudes of climate change is illustrated, but because the assessment considers potential impacts on different physical, biological, and human systems, risk levels should not necessarily be used to evaluate relative risk across key risks, sectors, or regions.

Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
Impacts can be delayed but now appear very difficult to avoid entirely, even with combined globally effective mitigation and planned adaptation					
Significant change in community composition and structure of coral reef systems in Australia (*high confidence*)	Ability of corals to adapt naturally appears limited and insufficient to offset the detrimental effects of rising temperatures and acidification. Other options are mostly limited to reducing other stresses (water quality, tourism, fishing) and early warning systems; direct interventions such as assisted colonisation and shading have been proposed but remain untested at scale.		25.6.2, 30.5, Box CC-CR Box CC-OA	Present Near-term (2030-2040) 1.5°C Long-term (2080-2100) 2°C 4°C	Very low – Medium – Very high
Loss of montane ecosystems and some native species in Australia (*high confidence*)	Direct adaptation options are limited, but reducing other stresses such as pests and diseases, predator control and enhancing connectivity of habitats provides immediate co-benefits; need to consider facilitating migration and assisted colonisation.		25.6.1	Present Near-term (2030-2040) 1.5°C Long-term (2080-2100) 2°C 4°C	Very low – Medium – Very high
Impacts have the potential to be severe but can be reduced substantially by globally effective mitigation combined with adaptation					
Increased frequency and intensity of flood damage to infrastructure and settlements in Australia and New Zealand (*high confidence*)	Significant adaptation deficit in some regions to current flood risk; effective adaptation includes land-use controls and relocation as well as protection and accommodation of increased risk to ensure flexibility.		25.2, Table 25-1, Box 25-8, 25-9	Present Near-term (2030-2040) 1.5°C Long-term (2080-2100) 2°C 4°C	Very low – Medium – Very high
Constraints on water resources in southern Australia (*high confidence*)	Water resources already struggling to meet unrestrained demand in many locations and exacerbated by projected population growth; effective adaptation relies on combination of demand and supply mechanisms.		25.5.1, Box 25-2, 25-9	Present Near-term (2030-2040) 1.5°C Long-term (2080-2100) 2°C 4°C	Very low – Medium – Very high
Increased morbidity, mortality and infrastructure damages during heat waves in Australia (*high confidence*)	Vulnerability is exacerbated by population growth and ageing; transport and power infrastructure already severely stressed during heat waves in many regions, with significant financial costs from future upgrades.		25.7.4, 25.8.1	Present Near-term (2030-2040) 1.5°C Long-term (2080-2100) 2°C 4°C	Very low – Medium – Very high
Wild fire damages to ecosystems and settlements and risks to human life in southern Australia and many parts of New Zealand (*high confidence*)	Part of integrated landscape management; trade-offs between different management objectives and settlement patterns and goals (biodiversity versus protection of human life and property).		Table 25-1, Box 25-6	Present Near-term (2030-2040) 1.5°C Long-term (2080-2100) 2°C 4°C	Very low – Medium – Very high
Impacts whose severity depends on changes in climate variables that span a particularly large range; the most severe end would present major challenges					
Widespread damages to coastal infrastructure and low-lying ecosystems in Australia and New Zealand (*high confidence*)	Adaptation deficit in some locations to current coastal erosion and flood risk; successive building and protection cycles constrain flexible responses; effective adaptation includes land-use controls and ultimately relocation as well as protection and accommodation.		Table 25-1, 25.6.1, 25.6.2, Box 25-2, 25-9	Moderate sea level rise (AR5 WGI 13.5; Box 25-2) High sea level rise (>1m by 2100): Present Near-term (2030-2040) 1.5°C Long-term (2080-2100) 2°C 4°C	Very low – Medium – Very high
Significant reduction in agriculture production in the Murray-Darling Basin and far south-eastern and south-western Australia (*high confidence*)	Immediate co-benefits from improved management of over-allocated water resources and balancing competing demands, but the extreme dry end would threaten agricultural production as well as ecosystems and some rural communities.		25.2, 25.6.1, 25.7.2, Table 25-1, Box 25-2, 25-5	Wet end of scenario (25.2, 25.5.2, Figure 25-4) Dry end of scenario: Present Near-term (2030-2040) 1.5°C Long-term (2080-2100) 2°C 4°C	Very low – Medium – Very high



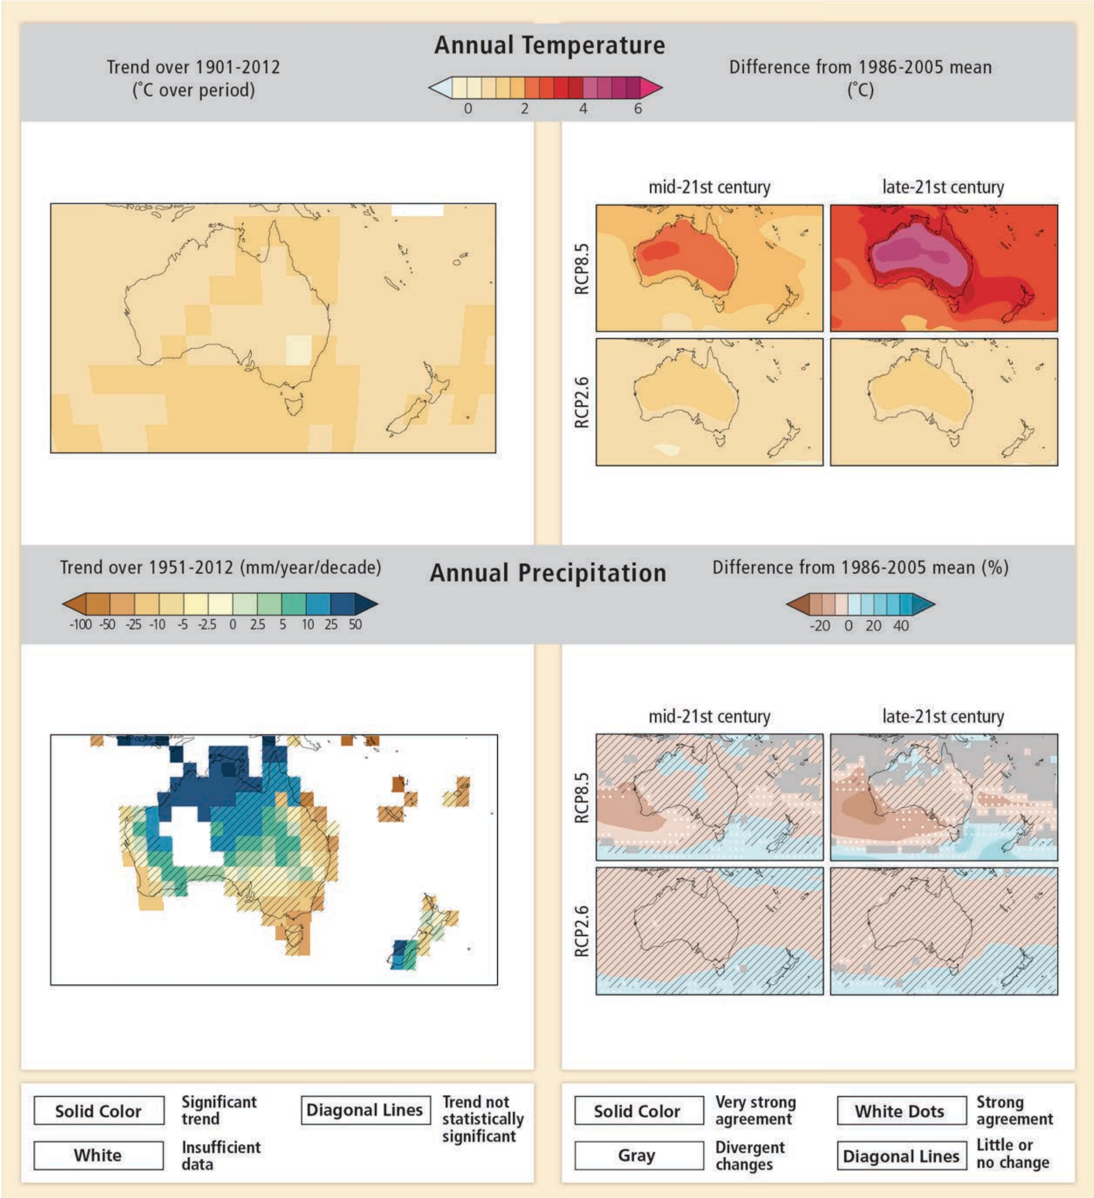


Figure 25-1: Observed and projected changes in annual average temperature and precipitation. (Top panel, left) Observed temperature trends from 1901-2012 determined by linear regression [WGI AR5 Figures SPM.1 and 2.21]. (Bottom panel, left) Observed precipitation change from 1951-2010 determined by linear regression [WGI AR5 Figure SPM.2]. For observed temperature and precipitation, trends have been calculated where sufficient data permits a robust estimate (i.e., only for grid boxes with greater than 70% complete records and more than 20% data availability in the first and last 10% of the time period). Other areas are white. Solid colors indicate areas where change is significant at the 10% level. Diagonal lines indicate areas where change is not significant. (Top and bottom panel, right) CMIP5 multi-model mean projections of annual average temperature changes and average percent change in annual mean precipitation for 2046-2065 and 2081-2100 under RCP2.6 and 8.5. Solid colors indicate areas with very strong agreement, where the multi-model mean change is greater than twice the baseline variability, and >90% of models agree on sign of change. Colors with white dots indicate areas with strong agreement, where >66% of models show change greater than the baseline variability and >66% of models agree on sign of change. Gray indicates areas with divergent changes, where >66% of models show change greater than the baseline variability, but <66% agree on sign of change. Colors with diagonal lines indicate areas with little or no change, less than the baseline variability in >66% of models. (There may be significant change at shorter timescales such as seasons, months, or days.). Analysis uses model data and methods building from WGI AR5 Figure SPM.8. See also Annex I of WGI AR5 [Boxes 21-3 and CC-RC].

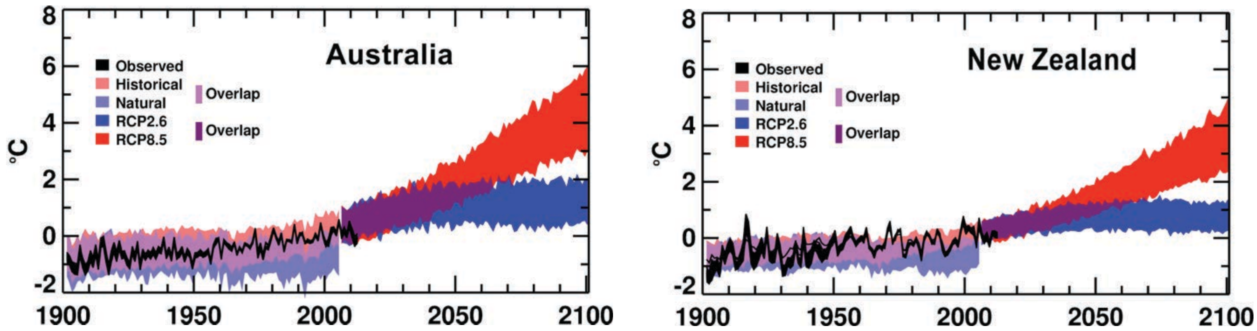

Figure 25-2: Observed and simulated variations in past and projected future annual average near-surface air temperature over land areas of Australia (left) and New Zealand (right). Black lines show various estimates from observational measurements. Shading denotes the 5-95 percentile range of climate model simulations driven with 'historical' changes in anthropogenic and natural drivers (63 simulations), historical changes in 'natural' drivers only (34), the 'RCP2.6' emissions scenario (63), and the 'RCP8.5' (63). Data are anomalies from the 1986-2005 average of the individual observational data (for the observational time series) or of the corresponding historical all-forcing simulations. Further details are given in Box 21-3.

[Illustration to be redrawn to conform to IPCC publication specifications.]

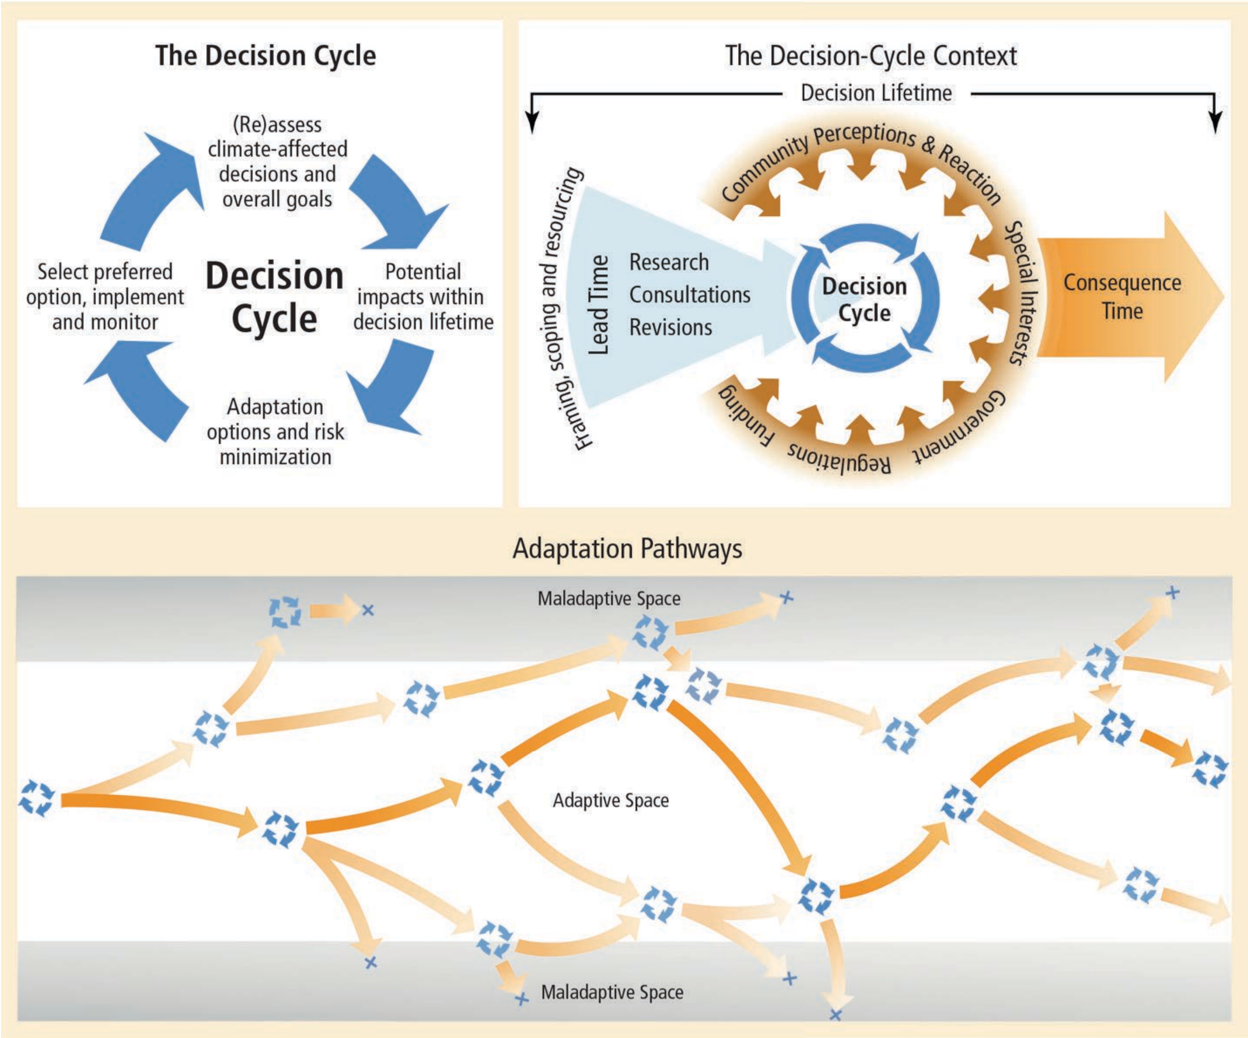

Figure 25-3: Adaptation as an iterative risk management process. Individual adaptation decisions comprise well known aspects of risk assessment and management (top left panel). Each decision occurs within and exerts its own sphere of influence, determined by the lead- and consequence time of the decision, and the broader regulatory and societal influences on the decision (top right panel). A sequence of adaptation decisions creates an adaptation pathway (bottom panel). There is no single ‘correct’ adaptation pathway, although some decisions, and sequences of decisions, are more likely to result in long-term maladaptive outcomes than others, but the judgment of outcomes depends strongly on societal values, expectations and goals.

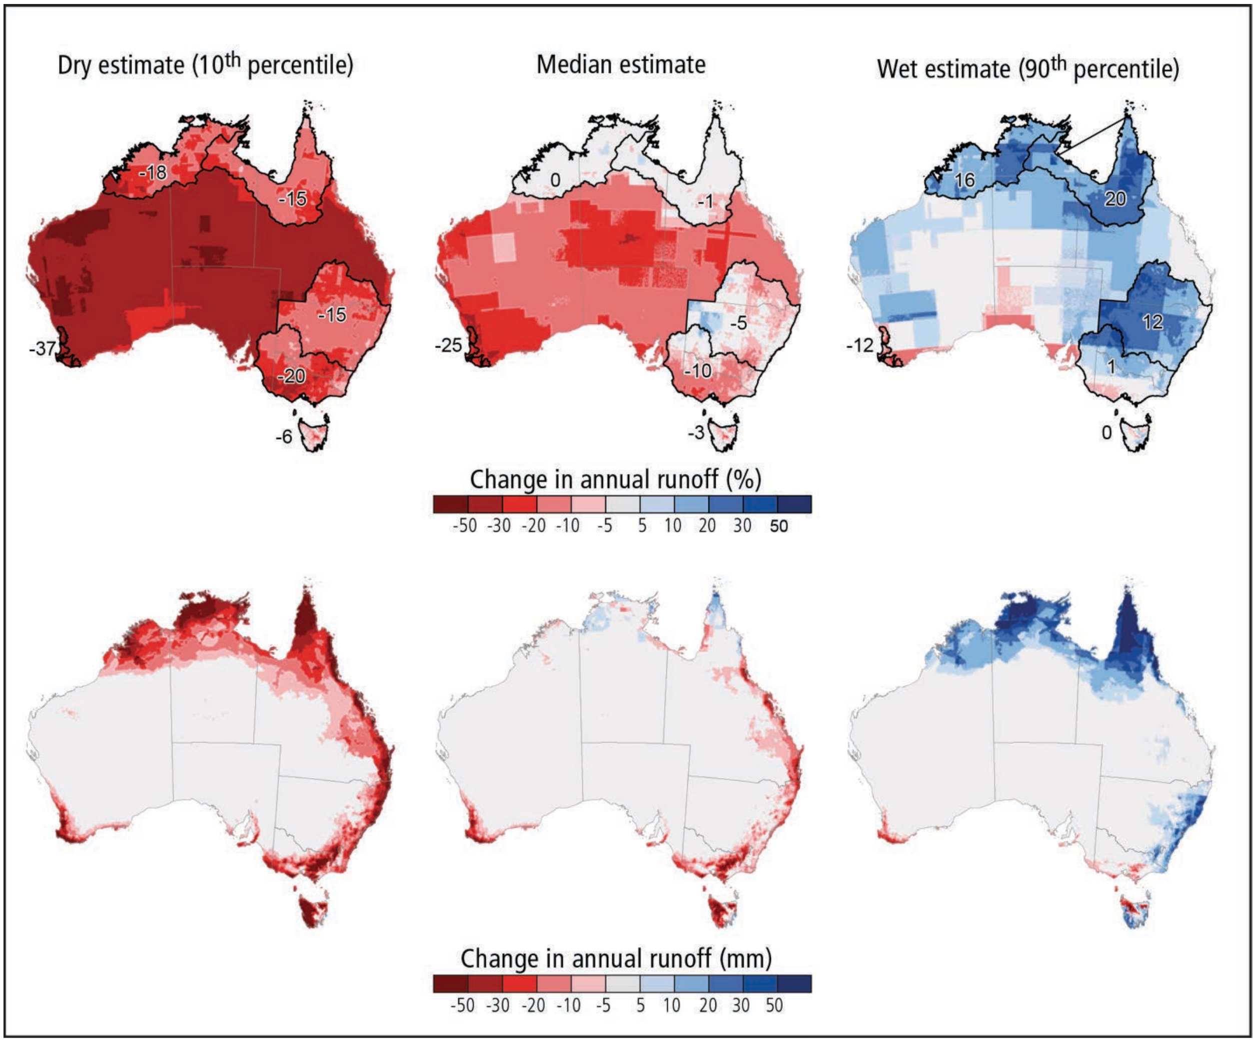

Figure 25-4: Estimated changes in mean annual runoff for 1°C global average warming above current levels. Maps show changes in annual runoff (percentage change; top row) and runoff depth (millimetres; bottom row), for dry, median and wet (10^{th} to 90^{th} percentile) range of estimates, based on hydrological modelling using 15 CMIP3 climate projections (Chiew *et al.*, 2009; CSIRO, 2009; Petheram *et al.*, 2012; Post *et al.*, 2012). Projections for 2°C global average warming are about twice that shown in the maps (Post *et al.*, 2011). (Figure adapted from Chiew and Prosser, 2011; Teng *et al.*, 2012).

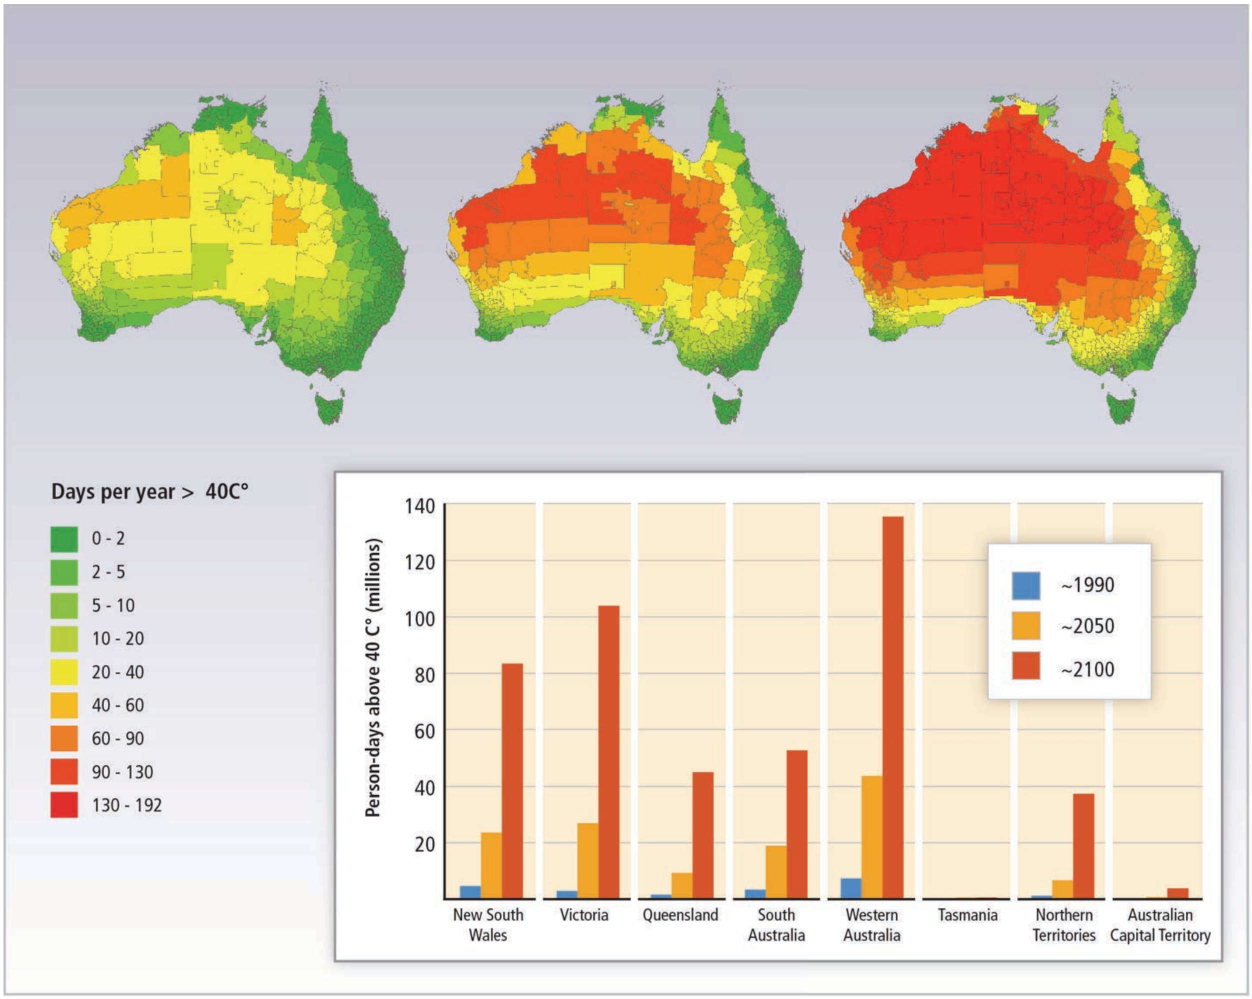

Figure 25-5: Projected changes in exposure to heat under a high emissions scenario (A1FI). Maps show the average number of days with peak temperatures >40°C, for ~1990 (based on available meteorological station data for the period 1975-2004), ~2050 and ~2100. Bar charts show the change in population heat exposure, expressed as person-days exposed to peak temperatures >40°C, aggregated by State/Territory and including projected population growth for a default scenario. Future temperatures are based on simulations by the GFDL-CM2 global climate model (Meehl *et al.*, 2007), re-scaled to the A1FI scenario; simulations based on other climate models could give higher or lower results. Data from Baynes *et al*. (2012).

Chapter 26. North America

Executive Summary

Overview

North America's climate has changed and some societally-relevant changes have been attributed to anthropogenic causes (*very high confidence*) [Figure 26-1]. Recent climate changes and individual extreme events demonstrate both impacts of climate-related stresses and vulnerabilities of exposed systems (*very high confidence*) [Figure 26-2]. Observed climate trends in North America include an increased occurrence of severe hot weather events over much of the US, decreases in frost days, and increases in heavy precipitation over much of North America (*high confidence*). [26.2.2.1] The attribution of observed changes to anthropogenic causes has been established for some climate and physical systems (e.g., earlier peak flow of snowmelt run-off and declines in the amount of water stored in spring snowpack in snow-dominated streams and areas of western United States and Canada (*very high confidence*) [Figure 26-1]. Evidence of anthropogenic climatic influence on ecosystems, agriculture, water resources, infrastructure, and urban and rural settlements is less clearly established, though, in many areas, these sectors exhibit substantial sensitivity to climate variability (*high confidence*) (26.3.1; 26.3.2; 26.4.2.1; 26.4.2.2; 26.4.3.1; Box 26-3; 26.5.1; 26.7.1.1; 26.7.2; 26.8.1; Figure 26-2).

Many climate stresses that carry risk – particularly related to severe heat, heavy precipitation and declining snowpack – will increase in frequency and/or severity in North America in the next decades (*very high confidence*). Global warming of approximately 2°C (above the pre-industrial baseline) is *very likely* to lead to more frequent extreme heat events and daily precipitation extremes over most areas of North America, more frequent low snow years, and shifts towards earlier snowmelt runoff over much of the western US and Canada [26.2.2.2]. Together with climate hazards such as higher sea levels and associated storm surges, more intense droughts, and increased precipitation variability, these changes are projected to lead to increased stresses to water, agriculture, economic activities and urban and rural settlements (high confidence) [26.3.2.1-26.3.2.4; 26.5.2; 26.7.1.2; 26.8.3]. Global warming of approximately 4°C is *very likely* to cause larger changes in extreme heat events, daily-scale precipitation extremes and snow accumulation and runoff, as well as emergence of a locally-novel temperature regime throughout North America [26.2.2.2]. This higher level of global temperature change is *likely* to cause decreases in annual precipitation over much of the southern half of the continent and increases in annual precipitation over much of the northern half of the continent [26.2.2.2]. The higher level of warming would present additional and substantial risks and adaptation challenges across a range of sectors (*high confidence*). [26.3.3, 26.5.2, 26.6.2, 26.7.2.2, 26.8.3]

We highlight below key findings on impacts, vulnerabilities, projections, and adaptation responses relevant to specific North American sectors: ecosystems, water, agriculture, human health, urban and rural settlements, infrastructure and the economy. We then highlight challenges and opportunities for adaptation, and future risks and adaptive capacity for three key climate-related risks.

Sector-Specific Climate Risks and Adaptation Opportunities

North American ecosystems are under increasing stress from rising temperatures, CO_2 concentrations, and sea-levels, and are particularly vulnerable to climate extremes (*very high confidence*). Climate stresses occur alongside other anthropogenic influences on ecosystems, including land-use changes, non-native species, and pollution, and in many cases will exacerbate these pressures (*very high confidence*). [26.4.1; 26.4.3]. Evidence since the Fourth Assessment Report highlights increased ecosystem vulnerability to multiple and interacting climate stresses in forest ecosystems, through wildfire activity, regional drought, high temperatures, and infestations (*medium confidence*) [26.4.2.1; Box 26-2]; and in coastal zones due to increasing temperatures, ocean acidification, coral reef bleaching, increased sediment load in run-off, sea level rise, storms, and storm surges (*high confidence*) [26.4.3.1]. In the near term, conservation and adaptation practices can buffer against climate stresses to some degree in these ecosystems, both through increasing system resilience, such as forest management to reduce vulnerability to infestation, and in reducing co-occurring non-climate stresses, such as careful oversight of fishing pressure (*medium confidence*) [26.4.4].

Water resources are already stressed in many parts of North America due to non-climate change anthropogenic forces, and are expected to become further stressed due to climate change (*high confidence*) [26.3, 26.3.1]. Decreases in snowpacks are already influencing seasonal streamflows (*high confidence*) [26.3.1]. While indicative of future conditions, recent floods, droughts, and changes in mean flow conditions cannot yet be attributed to climate change (*medium to high confidence)* [26.3.1, 26.3.2]. The 21st century is projected to witness decreases in water quality and increases in urban drainage flooding throughout most of North America under climate change as well as a decrease in instream uses such as hydropower in some regions (*high confidence)* [26.3.2.2, 26.3.2.3, 26.3.2.4]. Additionally, there will be decreases in water supplies for urban areas and irrigation in North America except in general for southern tropical Mexico, northwest coastal US, and west coastal Canada (*high to medium confidence*, 26.3.2.1). Many adaptation options currently available can address water supply deficits; adaptation responses to flooding and water quality concerns are more limited (*medium confidence*) [26.3.3].

Effects of temperature and climate variability on yields of major crops have been observed (*high confidence*) [25.5.1]. Projected increases in temperature, reductions in precipitation in some regions, and increased frequency of extreme events would result in net productivity declines in major North American crops by the end of the 21st Century without adaptation, although the rate of decline varies by model and scenario, and some regions, particularly in the north, may benefit (*very high confidence*) [26.5.2]. Given that North America is a significant source of global food supplies, projected productivity declines here may affect global food security (*medium confidence*)**.** At 2°C, adaptation has high potential to off-set projected declines in yields for many crops, and many strategies offer mitigation co-benefits; but effectiveness of adaptation would be reduced at 4°C *(high confidence)*. [26.5.3] Adaptation capacity varies widely among producers, and institutional support—currently lacking in some regions—greatly enhances adaptive potential (*medium confidence*) [26.5.4].

Human health impacts from extreme climate events have been observed, although climate change-related trends and attribution have not been confirmed to-date. Extreme heat events currently result in increases in mortality and morbidity in North America (*very high confidence*), with impacts that vary by age, location and socioeconomic factors (*high confidence*) [26.6.1.2]. Extreme coastal storm events can cause excess mortality and morbidity, particularly along the east coast of the United States, and the gulf coast of both Mexico and the United States (*high confidence*) [26.6.1.1]. A range of water-, food-, and vector-borne infectious diseases, air pollutants, and airborne pollens are influenced by climate variability and change (medium confidence) [26.6.1.3, 26.6.1.4, 26.6.1.5, 26.6.1.6]. Further climate warming in NA will impose stresses on the health sector through more severe extreme events such as heat waves and coastal storms, as well as more gradual changes in climate and CO_2 levels. [26.6.2] Human health impacts in NA from future climate extremes can be reduced by adaptation measures such as targeted and sustainable air conditioning, more effective warning and response systems, enhanced pollution controls, urban planning strategies, and resilient health infrastructure (*high confidence*) [26.6.3].

Observed impacts on livelihoods, economic activities, infrastructure and access to services in North American urban and rural settlements have been attributed to sea level rise, changes in temperature and precipitation, and occurrences of such extreme events as heat waves, droughts and storms (high confidence) [26.8.2.1]. Differences in the severity of climate impacts on human settlements are strongly influenced by context-specific social and environmental factors and processes that contribute to risk, vulnerability and adaptive capacity such as hazard magnitude, populations access to assets, built environment features and governance (high confidence) [26.8.2.1 and 26.8.2.2]. Some of these processes (e.g., the legacy of previous and current stresses) are common to urban and rural settlements, while others are more pertinent to some types of settlements than others. For example, human and capital risks are highly concentrated in some highly exposed urban locations, while in rural areas, geographic isolation and institutional deficits are key sources of vulnerability. Among the most vulnerable are indigenous peoples due to their complex relationship with their ancestral lands and higher reliance on subsistence economies, and those urban centers where high concentrations of populations and economic activities in risk-prone areas combine with several socio-economic and environmental sources of vulnerability (high confidence) [26.8.2.1 and 26.8.2.2]. Although larger urban centers would have higher adaptation capacities, future climate risks from heat waves, droughts, storms and sea level rise in cities would be enhanced by high population density, inadequate infrastructures, lack of institutional capacity and degraded natural environments (high agreement, medium evidence) [26.8.3].

Much of North American infrastructure is currently vulnerable to extreme weather events and, unless investments are made to strengthen them, would be more vulnerable to climate change (*medium confidence*). Water resources and transportation infrastructure are in many cases deteriorating, thus more vulnerable to extremes than strengthened ones (*high confidence*). Extreme events have caused significant damage to infrastructure in many parts of North America; risks to infrastructure are particularly acute in Mexico but are a big concern in all three countries (*high confidence*) [26.7].

Most sectors of the North American economy have been affected by and have responded to extreme weather, including hurricanes, flooding, and intense rainfall (*high confidence*) (Figure 26-2). Despite a growing experience with reactive adaptation, there are few examples of proactive adaptation anticipating future climate change impacts, and these are largely found in sectors with longer-term decision-making, including energy and public infrastructure. Knowledge about lessons learned and best adaptive practices by industry sector are not well-documented in the published literature [26.7]. There is an emerging concern that dislocation in one sector of the economy may have an adverse impact on other sectors due to supply chain interdependency (*medium confidence*) [26.7]. Slow onset perils – like sea level rise, drought, and permafrost thaw – are an emerging concern for some sectors, with large regional variation in awareness and adaptive capacity (*medium confidence*).

Adaptation Responses

Adaptation – including through technological innovation, institutional strengthening, economic diversification, and infrastructure design – can help to reduce risks in the current climate, and to manage future risks in the face of climate change (medium confidence) [26.8.4; 26.9.2]. There is increasing attention to adaptation among planners at all levels of government but particularly at the municipal level, with many jurisdictions engaging in assessment and planning processes. These efforts have revealed the significant challenges and sources of resistance facing planners at both the planning and implementation stages, particularly the adequacy of informational, institutional, financial and human resources, and lack of political will (*medium confidence*) [26.8.4.2; 26.9.3]. Specific strategies introduced into policy to date tend to be incremental rather than transformational. Fiscal constraints are higher for Mexican jurisdictions and sectors than for Canada or the US. The literature on sectoral-level adaptation is stronger in the areas of technological and engineering adaptation strategies than in social, behavioral and institutional strategies. Adaptation actions have the potential to result in synergies or tradeoffs with mitigation and other development actions and goals (*high confidence*) [26.8.4.2; 26.9.3].

26.1. Introduction

This chapter assesses literature on observed and projected impacts, vulnerabilities and risks as well as on adaptation practices and options in three North American countries: Canada, Mexico and United States (US). The North American Arctic region is assessed in Chapter 28: Polar Regions. North America ranges from the tropics to frozen tundra, and contains a diversity of topography, ecosystems, economies, governance structures and cultures. As a result, risk and vulnerability to climate variability and change differ considerably across the continent depending on geography, scale, hazard, socio-ecological systems, ecosystems, demographic sectors, cultural values and institutional settings. This chapter seeks to take account of this diversity and complexity as it affects and is projected to affect vulnerabilities, impacts, risks and adaptation across North America.

No single chapter would be adequate to cover the range and scope of the literature about climate change vulnerabilities, impacts and adaptations in our three focus countries. (Interested readers are encouraged to review the following reports: (Instituto Nacional de Ecología y Cambio Climático, 2012a; National Climate Assessment Development Advisory Committee, 2013). We therefore attempt to take a more integrative and innovative approach. In addition to describing current and future climatic and socioeconomic trends of relevance to understanding risk and vulnerability in North America (section 26.2), we contrast climate impacts, vulnerabilities and adaptations across and within the three countries in the following key sectors: water resources and management (section 26.3); ecosystems and biodiversity (section 26.4); agriculture and food security (section 26.5); human health (section 26.6); and key economic sectors and services (section 26.7). We use a comparative and place-based approach to explore the factors and processes associated with differences and commonalities in vulnerability, risk and adaptation between urban and rural settlements (section 26.8); and to illustrate and contrast the nuanced challenges and opportunities adaption entails at the city, the subnational and the national level (sections 26.8.4 and 26.9; Box 26-3). We highlight two case studies that cut across sectors, systems or national boundaries. The first, on wildfires (Box 26-2), explores some of the connections between climatic, physical and socioeconomic process (e.g., decadal climatic oscillation, droughts, wildfires land-use, and forest management) and across systems and sectors (e.g., fires direct and indirect impacts on local economies, livelihoods, built environments and human health). The second takes a look at one of the world's longest border between a high-income (US) and middle income country (Mexico) and briefly reflects on the challenges and opportunities of responding to climate change in a transboundary context (Box 26-1). We close with a section (26.10) summarizing key multi-sectoral risks and uncertainties and discussing some of the knowledge gaps that will need to be filled by future research.

Findings from the Fourth Assessment Report

This section summarizes *key findings on North America,* as identified in Chapter 13 of the Fourth IPCC assessment focused on Mexico (Magrin *et al.,* 2007), and Chapter 14 on Canada and the US (Field *et al.*, 2007). It focuses on observed and projected impacts, vulnerabilities and risks as well as on adaptation practices and options and highlights areas of agreement and difference between the AR4's two chapters and our consolidated North American chapter.

Observed impacts and processes associated with vulnerability. Both chapter 14 [14.2] and our chapter (Figure 26-2) find that over the past decades, economic damage from severe weather has increased dramatically. Our chapter confirms that although Canada and the US have considerably more adaptive capacity than Mexico, their vulnerability depends on the effectiveness and timing of adaptation and the distribution of capacity, which vary geographically and between sectors. [14.2.6; 14.4; 14.5] [26.2.2; 26.8.2]

Chapters 13 and 14 did not assess impacts, vulnerabilities and risks in urban and rural settlements, but rather assessed literature on *future risks* in the following sectors:

- *Ecosystems*: Both AR4 and our chapter find that ecosystems are under increased stress from increased temperatures, climate variability and other climate stresses (e.g., sea level rise and storm-surge flooding), and that these stresses interact with developmental and environmental stresses (e.g., as salt intrusion, pollution, population growth and the rising value of infrastructure in coastal areas) [13.4.4; 14.2.3; 14.4.3]. Differential capacities for range shifts and constraints from development, habitat fragmentation, invasive species, and broken ecological connections would alter ecosystem structure, function and services in terrestrial ecosystems [14.2; 14.4]. Both reports show that dry soils and warm temperatures are associated with increased wildfire activity and insect outbreaks in Canada and the US [14.2; 14.4; 26.4.2.1].
- *Water resources:* AR4 projects millions in Mexico to be at risk from the lack of adequate water supplies due to climate change[13.4.3]; our chapter, however, finds that water resources are already stressed by non-climatic factors, such as population pressure that will be compounded by climate change [26.3.1]. Both reports find that in the US and Canada rising temperatures would diminish snowpack and increase evaporation [26.2.2.1], thus affecting seasonal availability of water [14.2.1; 26.3.1]. The reports also agree that these effects will be amplified by water demand from economic development, agriculture and population growth, thus imposing further constraints to over-allocated water resources and increasing competition among agricultural, municipal, industrial and ecological uses [14.4.1; 14.4.6; 26.3.3]. Both agree water quality will be further stressed [14.4.1; 26.3.2.2; 13.4.3]. There is more information available now on water adaptation than in AR4 [14.5.1; 26.3.3; 13.5.1.3], and is possible to attribute changes in extreme precipitation, snowmelt and snowpack to climate change [26.3.1; 14.2.1; 13.2.4]
- *Agriculture*: The AR4 noted that while increases in grain yields in the US and Canada are projected by most scenarios [14.4.4], in Mexico the picture is mixed for wheat and maize, with different projected impacts depending on scenario used [13.4.2]. Research since the AR4 has offered more cautious projections of yield change in North America due to shifts in temperature and precipitation, particularly by 2100; and significant harvest losses due to recent extreme weather events have been observed [26.5.1]. Furthermore, our chapter reports on recent research that underscores the context specific nature of adaptation capacity and of institutional support and shows that these factors, which greatly enhance adaptive potential, are currently lacking in some regions [26.5.3].
- *Health*: AR4 focused primarily on a set of future health risks. These include changes in the geographical distribution and transmission of diseases such as dengue [13.4.5]; increases in respiratory illness, including exposure to pollen and ozone [14.4] and in mortality from hot temperatures and extreme weather in Canada and the US. AR4 also projects that climate change impacts on infrastructure and human health in cities of Canada and the US would be compounded by aging infrastructure, maladapted urban form and building stock, urban heat islands, air pollution, population growth and an aging population [14.4; 14.5]. Without increased investments in measures such as early warning and surveillance systems, air conditioning, and access to health care, hot temperatures and extreme weather in Canada and the US are predicted to result in increased adverse health impacts [14.4; 14.5]. Our chapter provides a more detailed assessment of these future risks [26.6], besides assessing a richer literature on observed health impacts [26.6.1].
- *Adaptation*: AR4 found that Mexico has early warning and risk management systems, yet it faces planning and management barriers. In Canada and the US, a decentralized response framework has resulted in adaptation that tends to be reactive, unevenly distributed, and focused on coping with rather than preventing problems [14.5]. Both chapters see ‘mainstreaming’ climate issues into decision making as key to successful adaptation [14.5; 13.5]. The current chapter provides a summary of the growing empirical literature on emerging opportunities and constraints associated with recent institutional adaptation planning activities since the AR4 [26.3.3; 26.4.3; 236.5.3; 26.6.3; 26.8.4;26.9].

In summary, scholarship on climate change impacts, adaptation and vulnerability has grown considerably since the AR4 in North America, particularly in Canada and the US. It is possible now not only to detect and attribute to anthropogenic climate change some impacts such as changes in extreme precipitation, snowmelt and snowpack, but also to examine trends showing increased insect outbreaks, wildfire events and coastal flooding. These latter trends have been shown to be sensitive to climate, but, like the local climate patterns that cause them, have not yet been positively attributed to anthropogenic climate change (see Figure 26-1).

[INSERT FIGURE 26-1 HERE
Figure 26-1 Detection and attribution of climate change impacts. Comparisons of the adequacy of currently available data to detect trends and the degree of understanding of causes of those changes in climatic extreme events in the United States (left; Peterson *et al.*, 2013) and degree of understanding of the climate influence in key impacts in North America (right). Note that “climate influence” means that the impact has been documented to be sensitive to climate, not that it has been attributed to climate change. Filled boxes indicate that formal detection and attribution to climate change has been performed for the given impact; shaded boxes indicate that a trend has been detected from background variability in the given impact, but formal attribution to climate change has not occurred and the trend could be due to other drivers; and open boxes indicate that a trend has not currently been detected. Key impacts are: 1) earlier peak flow of snowmelt run-off in snow-dominated streams and rivers in western North America [26.3.1], 2) declines in the amount of water stored in spring snowpack in snow-dominated areas of western North America [26.3.1], 3) northward and upward shifts in species’ distributions in multiple taxa of terrestrial species, although not all taxa and regions [26.4.1], 4) increases in coastal flooding [26.8.1], 5) increases in wildfire activity, including fire season length and area burned by wildfires in the western United States and boreal Canada [Box 26-2], 6) storm-related disaster losses in the United States (most of the increase in insurance claims paid has been attributed to increasing exposure of people and assets in areas of risk) [26.7.6.1, 26.8.1], 7) increases in bark beetle infestation levels in pine tree species in western North America [26.4.2.1], 8) yield increases due in part to increasing temperatures in Canada and higher precipitation in the US; yield variances attributed to climate variability in Ontario and Quebec; yield losses attributed to climate-related extremes across North America [26.5.1], 9) changes in storm-related mortality in the United States [26.6.1.2], 10) changes in heat-related mortality in the United States [26.6.1.2], 11) increases in tree mortality rates in old-growth forests in the western United States and western Canada from 1960-2007 [26.4.2.1], 12) changes in flooding in some urban areas due to extreme rainfall [26.3.1, 26.8.2.1], 13) increase in water supply shortages due to drought [26.8.1, 26.3], and 14) changes in cold-related heat mortality [26.6.1.2].]

26.2. Key Trends Influencing Risk, Vulnerability, and Capacities for Adaptation

26.2.1. Demographic and Socioeconomic Trends

26.2.1.1. Current Trends

Canada, Mexico and US share commonalities but also differ in key dimensions shaping risk, vulnerability and adaptation such as population dynamics, economic development, and institutional capacity. During the last years, the three countries, particularly the US, have suffered economic losses from extreme weather events (Figure 26-2). Hurricanes, droughts, floods and other climate-related hazards produce risk as they interact with increases in exposed populations, infrastructure and other assets and with the dynamics of such factors shaping vulnerability as wealth, population size and structure, and poverty (Figure 26-2 and Figure SPM.1). Population growth has been slower in Canada and US than in Mexico (Population Division, Department of Economic and Social Affairs, 2011). Yet population growth in Mexico also decreased from 3.4 percent between 1970-1980 to 1.5 percent yearly during 2000-2010. Populations in the three countries are aging at different rates (Figure 26-2). In 2010, 14.1% of the population in Canada was 60 years and older, compared to 12.7% in the US, and 6.1% in Mexico (Population Division, Department of Economic and Social Affairs, 2011). Urban populations have grown faster than rural populations, resulting in a North America that is highly urbanized (Canada 84.8%, Mexico 82.8% and US 85.8%). Urban populations are also expanding into peri-urban spaces, producing rapid changes in population and land use dynamics that can exacerbate risks from such hazards as floods and wildfires (Eakin *et al.*, 2010; Romero-Lankao *et al.*, 2012a). Mexico has a markedly higher poverty rate (34.8%) than Canada (9.1%) and the US (12.5%) (Figure 26-2), with weather events and climate affecting poor people’s livelihood assets, including crop yields, homes, food security, and sense of place (Chapter 13, section 26.8.2). Between 1970 and 2012, a 10 percent increase in single person households – who can be vulnerable because of isolation and low income and housing quality (Roorda *et al.*, 2010), has been detected in the US (Vespa *et al.*, 2013).

[INSERT FIGURE 26-2 HERE
Figure 26-2: Extreme events illustrating vulnerabilities for Mexico, the United States, and Canada. This figure offers a graphic illustration of location of extreme events and relevant vulnerability trends. The observed extreme events have not been attributed to anthropogenic climate change, yet they are climate-sensitive sources of impact illustrating vulnerability of exposed systems, particularly if projected future increases in the frequency and/or intensity of such events should materialize. The figure includes:

a) A map (bottom) with population density at 1km resolution highlighting exposure and represented using 2011 Landscan data (Bright *et al.*, 2012).
b) A map (top) with significant weather events taking place during 1993-2012. The map only includes disasters with overall losses of more than $1 billion US dollars in US, or more than $500 million US dollars in Mexico and Canada, adjusted to 2012 values (Source: (NatCatSERVICE, 2010). Hence, it does not include the occurrence of disasters of small and medium impact, and it does not capture the impacts of disasters on populations' livelihoods and wellbeing. Disasters represented by points that are located at the approximate geographic center of affected regions, frequently span more than one subnational jurisdiction (e.g., the 2012 drought affected 12 Mexican states, Annex Table).
c) Four panels (right) with trends in socio-demographic indicators used in the literature to measure vulnerability to hazards (Romero-Lankao *et al.*, 2012): poverty rates, percentage of elderly, GDP per capita and total population (Sources: Comisión Económica para América Latina y el Caribe; U.S. Census Bureau, 2011; Statistics Canada, 2012).]

While concentrations of growing populations, water, sanitation, transportation and energy infrastructure and industrial and service sectors in urban areas can be a source of risk, geographic isolation and high dispersion of rural populations also introduce risk because of long distances to essential services (section 26.8.2). Rural populations are more vulnerable to climate events due to smaller labor markets, lower income levels and reduced access to public services. Rural poverty could also be aggravated by changes in agricultural productivity, particularly in Mexico where 65% of the rural population is poor, agricultural income is seasonal, and most households lack insurance (Scott, 2007). Food price increases, which may also result from climate events, would contribute to food insecurity (World Bank, 2011; Lobell *et al.*, 2011).

Migration is a key trend affecting North America, recently with movements between urban centers and from rural Mexico into Mexico's cities, and in the US. Rates of migration from rural Mexico are positively associated with natural disaster occurrence and increased poverty trends (Saldaña-Zorilla and Sandberg, 2009), and with decreasing precipitation (Nawrotski *et al.*, 2013). Studies of migration induced by past climate variability and change indicate a preference for short-range domestic movement, a complex relationship to assets with indications that the poorest are less able to migrate, and the role of pre-existing immigrant networks in facilitating international migration (Oppenheimer, 2013).

North America has become more economically integrated following the 1994 North American Free Trade Agreement. Prior to a 2007-2008 reduction in trade, the three countries registered dynamic growth in industry, employment and global trade of agricultural and manufactured goods (World Bank, 2009). Notwithstanding North America's economic dynamism, increased socioeconomic disparities (Autor *et al.*, 2008) have affected such determinants of vulnerability as differentiated human development and institutional capacity within and across countries.

_____ START BOX 26-1 HERE _____

Box 26-1. Adapting in a Transboundary Context: the Mexico-U.S. Border Region

Extending over 3111 km (1933 miles; (U.S. Census Bureau, 2011), the border between the United States and Mexico, which can be defined in different ways (Varady and Ward, 2009), illustrates the challenges and opportunities of responding to climate change in a transboundary context. Changing regional climate conditions and socioeconomic processes combined shape differentiated vulnerabilities of exposed populations, infrastructure and economic activities.

Since at least 1999, the region has experienced high temperatures and aridity anomalies leading to drought conditions (Woodhouse *et al.*, 2010; Wilder *et al.*, 2013) affecting large areas on both sides of the border, and considered the most extreme in over a century of recorded precipitation patterns for the area (Seager and Vecchi, 2010; Cayan *et al.*, 2010; Nielsen-Gammon, 2011). Streamflow in already oversubscribed rivers such as the Colorado and Rio Grande (Nakaegawa *et al.*, 2013) has decreased. Climatological conditions for the area have been unprecedented, with sustained high temperatures that may have exceeded any experienced for 1,200 years. While these changes cannot conclusively be attributed to anthropogenic climate change, they are consistent with climate change projections (Woodhouse *et al.*, 2010).

The population of the Mexico-US Border is rapidly growing and urbanizing, doubling from just under 7 million in 1983 to over 15 million in 2012 (Peach and Williams, 2007). Since 1994, rapid growth in the area has been fueled by rapid economic development subsequent to passage of the North American Free Trade Agreement (NAFTA). Between 1990 and 2001 the number of *assembly factories* or *maquiladoras* in Mexico grew from 1700 to nearly 3,800, *with* 2,700 in the border area. By 2004, it was estimated that more than one million Mexicans were employed in more than 3,000 *maquiladoras* located along the border (U.S. Environmental Protection Agency and Secretaría de Medio Ambiente y Recursos Naturales, 2011; U.S. Environmental Protection Agency, 2012).

Notwithstanding this growth, challenges to adaptive capacity include high rates of poverty in a landscape of uneven economic development (Wilder *et al.*, 2013). Large sections of the urban population, particularly in Mexico, live in informal housing lacking the health and safety standards needed to respond to hazards, and with no insurance (Collins *et al.*, 2011). Any effort to increase regional capacity to respond to climate needs to take existing gaps into account. Additionally, there is a prevalence of incipient or actual conflict (Mumme, 1999), given by currently or historically contested allocation of land and water resources (e.g., an over-allocated Colorado river ending in Mexico above the Sea de Cortes (Getches, 2003). Climate change, therefore, would bring additional significant consequences for the region’s water resources, ecosystems, and rural and urban settlements.

The impacts of regional climatic and non-climatic stresses compound existing urban vulnerabilities that are different across countries. For instance, besides degrading highly diverse ecosystems (Wilder *et al.*, 2013), residential growth in flood-prone areas in Ciudad Juarez has not been complemented with the provision of determinants of adaptive capacity to residents, such as housing, health care and drainage infrastructure. As a result, while differences in mean hazard scores are not significantly different between Ciudad Juarez (Mexico) and El Paso (US), social vulnerability and average risk are three times and two times higher in Ciudad Juárez than in El Paso respectively (Collins, 2008).

Projected warming and drying would impose additional burdens on already stressed water resources and ecosystems and compound existing vulnerabilities for populations, infrastructure and economic activities (Wilder *et al.*, 2013). The recent drought in the region illustrated the multiple dimensions of climate-related events, including notable negative impacts on the agricultural sector, water supplies, food security, and risk of wildfire (discussed in Box 26.2) (Wehner *et al.*, 2011; Schwalm *et al.*, 2012; Hoerling *et al.*, 2012).

Adaptation opportunities and constraints are shared across international borders, creating the need for cooperation among local, national and international actors. Although there are examples of efforts to manage trans-border environmental issues, such as the US-Mexico International Boundary and Water Commission agreement (International Boundary and Water Commission, 2012), constraints to effective cooperation and collaboration include different governance structures (centralized in Mexico, decentralized in the US); institutional fragmentation; asymmetries in the use and dissemination of information, and language (Wilder *et al.*, 2010; Megdal and Scott, 2011; Wilder *et al.*, 2013).

_____ END BOX 26-1 HERE _____

26.2.1.2. Future Trends

The North American population is projected to continue growing, reaching between 531.8 (B2) and 660.1 (A2) million by 2050 (International Institute for Applied System Analysis, 2007). The percentage of elderly people (over

64 years) is also projected to continue to increase, by 23.4%-26.9% in Canada, 12.4%-18.4 % in Mexico, and 17.3%-20.9% in the US by 2050 (B2 and A2 respectively) (International Institute for Applied System Analysis, 2007). The elderly are highly vulnerable to extreme weather events (heat waves in particular, Figure 26-2) (Martiello and Giacchi, 2010; Diffenbaugh and Scherer, 2011; Romero-Lankao, 2012; White-Newsome *et al.*, 2012). Numbers of single-person households and female-headed households — both of which are vulnerable because of low income and housing quality – are anticipated to increase (Roorda *et al.*, 2010). Institutional capacity to address the demands posed by increasing numbers of vulnerable populations may also be limited, with resulting stress on health and the economy.

Three other shifts are projected to influence impacts, vulnerabilities and adaptation to climate change in North America: urbanization, migration, and socioeconomic disparity. With small differences between countries, both the concentration of growing populations in some urban areas and the dispersion of rural populations are projected to continue to define North America by 2050. Assuming no change in climate, between 2005 and 2030 the population of Mexico-City-Metro-Area will increase by 17.5%, while between 2007 and 2030 available water will diminish by 11.2% (Romero-Lankao, 2010). Conversely, education, a key determinant of adaptive capacity (Chapter 13), is expected to expand to low-income households, minorities, and women, which could increase the coping capacity of households and have a positive impact on economic growth (Goujon *et al.*, 2004). However, the continuation of current patterns of economic disparity and poverty would hinder future adaptive capacity. Inequality in Mexico is larger (Figure 26-2), having a Gini coefficient (according to which the higher the number the higher economic disparity) of 0.56, in contrast to 0.317 for Canada and 0.389 for the US (Organisation for Economic Co-operation and Development, 2010). Mexico is one of five countries in the world that is projected to experience the highest increases in poverty due to climate-induced extreme events (52% increase in rural households; 95.4% in urban wage-labor households) (CMIP3, A2) (Ahmed *et al.*, 2009).

Some studies project increased North American migration in response to climate change. Feng, Krueger and Oppenheimer (2010) estimated the emigration of an additional 1.4 to 6.7 million Mexicans by 2080 based on projected maize yield declines, range depending on model (B1, UKMO and GDFL). Oppenheimer speculates that the indirect impacts of migration "could be as substantial as the direct effects of climate change in the receiving area," because the arrival migrants can increase pressure on climate sensitive urban regions (Oppenheimer, 2013, 442).

26.2.2. Physical Climate Trends

Some processes important for climate change in North America are assessed in other Chapters of AR5, including WGI Chapter 2 (*Observations: Atmosphere and Surface*), WGI Chapter 4 (*Observations: Cryosphere*), WGI Chapter 12 (*Long-term Climate Change: Projections, Commitments and Irreversibility*), WGI Chapter 14 (*Climate Phenomena and their Relevance for Future Regional Climate Change*), WGI Annex I (*Atlas of Global and Regional Climate Projections*), and WGII Chapter 21 (*Regional Context*). In addition, comparisons of emissions, concentrations, and radiative forcing in the RCPs and SRES scenarios can be found in WGI Annex II (*Climate System Scenario Tables*).

26.2.2.1. Current Trends

It is *very likely* that mean annual temperature has increased over the past century over most of North America (WGI SPM.1) (Figure 26-3). Observations also show increases in the occurrence of severe hot events over the US over the late 20th century (Kunkel *et al.*, 2008), a result in agreement with observed late-20th-century increases in extremely hot seasons over a region encompassing northern Mexico, the US and parts of eastern Canada (Diffenbaugh and Scherer, 2011). These increases in hot extremes have been accompanied by observed decreases in frost days over much of North America (Alexander et al., 2006; Brown *et al.*, 2010) WGI 2.6.1, decreases in cold spells over the US (Kunkel *et al.*, 2008) WGI 2.6.1, and increasing ratio of record high to low daily temperatures over the US (Meehl *et al.*, 2009). However, warming has been less pronounced and less robust over areas of the central and southeastern US (e.g., (Alexander et al., 2006; Peterson *et al.*, 2008); WGI 2.6.1; WGI SPM.1) (Figure 26-3). It is possible that this pattern of muted temperature change has been influenced by changes in the hydrologic cycle (e.g., (Pan *et al.*, 2004; Portmann *et al.*, 2009), as well as by decadal-scale variability in the ocean (e.g., (Meehl *et al.*, 2012; Kumar *et al.*, 2013b).

[INSERT FIGURE 26-3 HERE
Figure 26-3: Observed and projected Changes in annual temperature and precipitation. (Top panel, left) observed temperature trends from 1901-2012 determined by linear regression [WGI AR5 Figures SPM.1 and 2.21]. (Bottom panel, left) Observed precipitation change from 1951-2010 determined by linear regression. [WGI AR5 Figure SPM.2] For observed temperature and precipitation, trends have been calculated where sufficient data permits a robust estimate (i.e., only for grid boxes with greater than 70% complete records and more than 20% data availability in the first and last 10% of the time period). Other areas are white. Solid colors indicate areas where change is significant at the 10% level. Diagonal lines indicate areas where change is not significant (Top and bottom panel, right) CMIP5 multi-model mean projections of annual average temperature changes and average percent change in annual mean precipitation for 2046-2065 and 2081-2100 under RCP2.6 and 8.5. Solid colors indicate areas with very strong agreement, where the multi-model mean change is greater than twice the baseline variability, and >90% of models agree on sign of change. Colors with white dots indicate areas with strong agreement, where >66% of models show change greater than the baseline variability and >66% of models agree on sign of change. Gray indicates areas with divergent changes, where >66% of models show change greater than the baseline variability, but <66% agree on sign of change. Colors with diagonal lines indicate areas with little or no change, less than the baseline variability in >66% of models. (There may be significant change at shorter timescales such as seasons, months, or days.). Analysis uses model data and methods building from WGI AR5 Figure SPM.8. See also Annex I of WGI AR5. [Boxes 21-3 and CC-RC]**]**

It is *very likely* that annual precipitation has increased over the past century over areas of the eastern US and Pacific Northwest (WGI Fig. 2.29) (Figure 26-3). Observations also show increases in heavy precipitation over Mexico, the US and Canada between the mid-20th century and the early 21st century (Peterson and Baringer, 2009; DeGaetano, 2009; Pryor *et al.*, 2009); WGI 2.6.2. Observational analyses of changes in drought are more equivocal over North America, with mixed sign of trend in dryness over Mexico, the US and Canada (WGI 2.6.2 and Fig 2.42) (Dai, 2011; Sheffield *et al.*, 2012). There is also evidence for earlier occurrence of peak flow in snow-dominated rivers globally (Rosenzweig, 2007); WGI 2.6.2). Observed snowpack and snow-dominated runoff have been extensively studied in the western US and western Canada, with observations showing primarily decreasing trends in the amount of water stored in spring snowpack from 1960-2002 (with the most prominent exception being the central and southern Sierra Nevada) (Mote, 2006) and primarily earlier trends in the timing of peak runoff over the 1948-2000 period (Stewart *et al.*, 2006) (WGI 4.5 and Fig. 4.21). Observations also show decreasing mass and length of glaciers in North America (WGI 4.3 and Fig. 4.9, 4.10, 4.11). Further, in assessing changes in the hydrology of the western US, it has been concluded that “up to 60% of the climate-related trends of river flow, winter air temperature, and snow pack between 1950 and 1999 are human-induced”(Barnett *et al.*, 2008).

Observational limitations prohibit conclusions about trends in severe thunderstorms (WGI 2.6.2) and tropical cyclones (WGI 2.6.3) over North America. The most robust trends in extratropical cyclones over North America are determined to be towards more frequent and intense storms over the northern Canadian Arctic and towards less frequent and weaker storms over the southeastern and southwestern coasts of Canada over the 1953-2002 period (WGI 2.7.4)(Wang *et al.*, 2006).

WGI concludes that “Global mean sea level (GMSL) has risen by 0.19 [0.17–0.21] m over the period 1901–2010” and that “it is *very likely* that the mean rate was 1.7 [1.5 to 1.9] mm yr^{-1} between 1901 and 2010 and increased to 3.2 [2.8 to 3.6] mm yr^{-1} between 1993 and 2010” (WGI 3 Executive Summary). In addition, observed changes in extreme sea level have been caused primarily by increases in mean sea level (WGI 3.7.5). Regional variations in the observed rate of sea level rise can result from processes related to atmosphere and ocean variability (such as lower rates along the west coast of the US) or vertical land motion (such as high rates along the US Gulf Coast), but the persistence of the observed regional patterns is unknown (WGI 3.7.3).

26.2.2.2. Climate Change Projections

Chapters 11 and 12 of the WGI contribution to the AR5 assess near-term and long-term future climate change, respectively. Chapter 14 of the WGI contribution assesses processes that are important for regional climate change, with section 14.8.3 focused on North America. Many of the WGI conclusions are drawn from Annex I of the WGI contribution to the AR5.

The CMIP5 ensemble projects *very likely* increases in mean annual temperature over North America, with *very likely* increases in temperature over all land areas in the mid- and late-21st-century periods in RCP2.6 and RCP8.5 (Figure 26-3). Ensemble-mean changes in mean annual temperature exceed 2˚C over most land areas of all three countries in the mid-21st-century period in RCP8.5 and the late-21st-century period in RCP8.5, and exceed 4˚C over most land areas of all three countries in the late-21st-century period in RCP8.5. However, ensemble-mean changes in mean annual temperature remain within 2˚C above the late 20th century baseline over most North American land areas in both the mid- and late-21st-century periods in RCP2.6. The largest changes in mean annual temperature occur over the high latitudes of the United States and Canada, as well as much of eastern Canada, including greater than 6˚C in the late-21st-century period in RCP8.5. The smallest changes in mean annual temperature occur over areas of southern Mexico, the Pacific Coast of the United States, and the southeastern United States.

The CMIP5 ensemble projects warming in all seasons over North America beginning as early as the 2016-2035 period in RCP2.6, with the greatest warming occurring in winter over the high latitudes (WGI Annex I and Figure 26-3)(Diffenbaugh and Giorgi, 2012). The CMIP5 and CMIP3 ensembles suggest that the response of warm-season temperatures to elevated radiative forcing is larger as a fraction of the baseline variability than the response of cold-season temperatures (Diffenbaugh and Scherer, 2011; Kumar *et al.*, 2013b), and the CMIP3 ensemble suggests that the response of temperature in low-latitude areas of North America is larger as a fraction of the baseline variability than the response of temperature in high-latitude areas (Diffenbaugh and Scherer, 2011). In addition, CMIP3 and a high-resolution climate model ensemble suggest that the signal-to-noise ratio of 21st century warming is far greater over the western US, northern Mexico and the northeastern US than over the central and southeastern US (Diffenbaugh *et al.*, 2011), a result that is similar to the observed pattern of temperature trend significance in the US (Figure 26-3).

Most land areas north of 45˚N exhibit *likely* or *very likely* increases in mean annual precipitation in the late-21st-century period in RCP8.5 (Figure 26-3). The high latitude areas of North America exhibit *very likely* changes in mean annual precipitation throughout the illustrative RCP periods, with *very likely* increases occurring in the mid-21st-century period in RCP2.6 and becoming generally more widespread at higher levels of forcing. In contrast, much of Mexico exhibits *likely* decreases in mean annual precipitation beginning in the mid-21st-century period in RCP8.5, with the area of *likely* decreases expanding to cover most of Mexico and parts of the southcentral and southwestern US in the late-21st-century period in RCP8.5. *Likely* changes in mean annual precipitation are much less common at lower levels of forcing. For example, *likely* changes in mean annual precipitation in the mid- and late-21st-century periods in RCP2.6 are primarily confined to increases over areas of Canada and Alaska, with no areas of Mexico and very few areas of the contiguous US exhibiting differences that exceed the baseline variability in more than 66% of the models.

CMIP5 projects increases in winter precipitation over Canada and Alaska, consistent with projections of a poleward shift in the dominant cold-season stormtracks (WGI 14.8.3) (Yin, 2005), extratropical cyclones (Trapp *et al.*, 2009) and areas of moisture convergence (WG1 14.8.3), as well as with projections of a shift towards positive North Atlantic Oscillation (NAO) trends (Hori *et al.*, 2007) WGI 14.8.3). CMIP5 also projects decreases in winter precipitation over the southwestern US and much of Mexico associated with the poleward shift in the dominant stormtracks and the expansion of subtropical arid regions (Seager and Vecchi, 2010); WGI 14.8.3). However, there are uncertainties in hydroclimatic change in western North America associated with the response of the tropical Pacific sea surface temperatures (SSTs) to elevated radiative forcing (particularly given the influence of tropical SSTs on the Pacific North American pattern (PNA) and north Pacific storm tracks) (Cayan *et al.*, 1999; Findell and Delworth, 2010; Seager and Vecchi, 2010); WGI 14.8.3), and not all CMIP5 models simulate the observed recent hydrologic trends in the region (Kumar *et al.*, 2013a)

For seasonal-scale extremes, CMIP5 projects substantial increases in the occurrence of extremely hot seasons over North America in early, middle and late 21st century periods in RCP8.5 (Diffenbaugh and Giorgi, 2012) (Figure 26-4). For example, during the 2046-2065 period in RCP8.5, more than 50% of summers exceed the respective late-20th-century maximum seasonal temperature value over most of the continent. CMIP3 projects similar increases in extremely hot seasons, including greater than 50% of summers exceeding a mid-20th-century baseline throughout much of North America by the mid-21st-century in the A2 scenario (Duffy and Tebaldi, 2012), and greater than 70% of summers exceeding the highest summer temperature observed on record over much of the western US, southeastern US and southern Mexico by the mid-21st-century in the A2 scenario (Battisti and Naylor, 2009). CMIP5 also projects substantial decreases in snow accumulation over the US and Canada (Diffenbaugh *et al.*, 2012) (Figure 26-4), suggesting that the increases in cold-season precipitation over these regions reflect a shift towards increasing fraction of precipitation falling as rain rather than snow (Diffenbaugh *et al.*, 2012). Over much of the western US and western Canada, greater than 80% of years exhibit March snow amount that that is less than the late-20th-century median value beginning in the mid-21st-century period in RCP8.5, with the ensemble-mean change exceeding 2 standard deviations of the ensemble spread. Likewise, greater than 60% of years exhibit March snow amount that is less than the late-20th-century minimum value in the late-21st-century period in RCP8.5, with the ensemble-mean change exceeding 2 standard deviations of the ensemble spread (Diffenbaugh and Giorgi, 2012) (Figure 26-4). CMIP5 also projects increases in the occurrence of extremely dry summer seasons over much of Mexico, the US and southern Canada (Figure 26-4). The largest increases occur over southern Mexico, where greater than 30% of summers in the late-21st-century period in RCP8.5 exhibit seasonal precipitation that is less than the late 20th century minimum summer precipitation.

[INSERT FIGURE 26-4 HERE
Figure 26-4: Projected changes in extremes in North America. (a) The percentage of years in the 2046–2065 period of RCP8.5 in which the summer temperature is greater than the respective maximum summer temperature of the 1986–2005 baseline period (Diffenbaugh and Giorgi, 2012). (b) The percentage of years in the 2080-2099 period of RCP8.5 in which the summer precipitation is less than the respective minimum summer precipitation of the 1986-2005 baseline period (Diffenbaugh and Giorgi, 2012) (c) The percentage difference in the 20-year return value of annual precipitation extremes between the 2046-2065 period of RCP4.5 and the 1986-2005 baseline period (from (Kharin *et al.*, 2013). The hatching indicates areas where the differences are not significant at the 5% level. (d) The percentage of years in the 2070-2099 period of RCP8.5 in which the March snow water equivalent is less than the respective minimum March snow water equivalent of the 1976–2005 period (Diffenbaugh *et al.*, 2012). The black (white) stippling indicate areas where the multimodel mean exceeds 1.0 (2.0) standard deviations of the multi-model spread. (a-d) The RCPs and time periods are those used in the peer-reviewed studies in which the panels appear. The 2046-2065 period of RCP8.5 and the 2046-2065 period of RCP4.5 exhibit global warming in the range of 2-3˚C above the pre-industrial baseline (WGI Fig. 12.40). The 2080-2099 and 2070-2099 periods of RCP8.5 exhibit global warming in the range of 4-5˚C above the pre-industrial baseline (WGI Fig. 12.40).]

For daily-scale extremes, almost all areas of North America exhibit *very likely* increases of at least 5˚C in the warmest daily maximum temperature by the late-21st-century period in RCP8.5. Likewise, most areas of Canada exhibit *very likely* increases of at least 10˚C in the coldest daily minimum temperature by the late-21st-century period in RCP8.5, while most areas of the US exhibit *very likely* increases of at least 5˚C and most areas of Mexico exhibit *very likely* increases of at least 3˚C (Sillmann *et al.*, 2013) (WGI Fig. 12.13). In addition, almost all areas of North America exhibit *very likely* increases of 5% to 20% in the 20-year return value of extreme precipitation by the mid-21st-century period in RCP4.5 (Figure 26-4), while most areas of the US and Canada exhibit *very likely* increases of at least 5% in the maximum 5-day precipitation by the late-21st-century period in RCP8.5 (Sillmann *et al.*, 2013)(WGI Fig. 12.13). Further, almost all areas of Mexico exhibit *very likely* increases in the annual maximum number of consecutive dry days by the late-21st-century period in RCP8.5 (Sillmann *et al.*, 2013) (WGI Fig. 12.13).

26.3. Water Resources and Management

Water withdrawals are exceeding stressful levels in many regions of North America such as the southwest US, northern and central Mexico (particularly Mexico City), southern Ontario and the southern Canadian Prairies (Romero-Lankao, 2010; National Water Commission of Mexico, 2010; Sosa-Rodriguez, 2010; Averyt *et al.*, 2011;

Environment Canada, 2013a). Water quality is also a concern with 10% to 30% of the surface monitoring sites in Mexico having polluted water (National Water Commission of Mexico, 2010), and about 44% of assessed stream miles, and 64% of assessed lake areas in the US not clean enough to support their uses (U.S. Environmental Protection Agency, 2004). Stations in Canada's 16 most populated drainage basins reported at least fair quality, with many reporting good or excellent quality (Environment Canada, 2013b). In basins outside of the populated areas there are some cases of declining water quality where impacts are related to resource extraction, agriculture, and forestry (Hebben, 2009).

Water management infrastructure in most areas of North America is in need of repair, replacement or expansion (Section 26.7). Climate change, land use changes and population growth, and demand increases will add to these stresses(U.S. Global Change Research Program, 2009).

26.3.1. Observed Impacts of Climate Change on Water Resources

Droughts and Floods: As reported in WG1, Chapter 10 and 26.2.2.1, it is not possible to attribute changes in drought frequency in North America to anthropogenic climate change (Prieto-González *et al.*, 2011; Axelson *et al.*, 2012; Orlowsky and Senevirantne, 2013) (Figure 26-1). Few discernible trends in flooding have been observed in the US (Chapter 3). Changes in the magnitude or frequency of flood events have not been attributed to climate change. Floods are generated by multiple mechanisms (e.g., land use, seasonal changes and urbanization); trend detection is confounded by flow regulation, teleconnections and long-term persistence (section 26.2.2.1; (Kumar *et al.*, 2009; Collins, 2009; Smith *et al.*, 2010; Villarini and Smith, 2010; Villarini *et al.*, 2011; Hirsch and Ryberg, 2012; Prokoph *et al.*, 2012; Instituto Nacional de Ecología y Cambio Climático, 2012a; Peterson *et al.*, 2013).

Mean Annual Streamflow: While annual precipitation and runoff increases have been found in the Midwestern and Northwestern United States, decreases have been observed in southern states (Georgakakos *et al.*, 2013) . Chapter 3, WG2 notes the correlation between changes in streamflow and observed regional changes in temperature and precipitation. Kumar et al. (2009) suggest that human activities that have influenced observed trends in streamflow making attribution of changes to climate difficult in many watersheds. Nonetheless, earlier peak flow of snowmelt run-off in snow-dominated streams and rivers in western North America has been formally detected and attributed to anthropogenic climate change (Barnett *et al.*, 2008; Das *et al.*, 2011) (Figure 26-1).

Snow Melt: Warm winters produced earlier runoff and discharge but less snow water equivalent and shortened snowmelt seasons in many snow-dominated areas of North America (Barnett *et al.*, 2005; Rood *et al.*, 2008; Reba *et al.*, 2011) (Section 26.2.2., Chapter 3).

26.3.2. Projected Climate Change Impacts and Risks

26.3.2.1. Water Supply

Most of this assessment focuses on surface water as there are few groundwater studies (Tremblay *et al.*, 2011; Georgakakos *et al.*, 2013). Impacts and risks vary by region and model used.

In arid and semi-arid western US and Canada and in most of Mexico, except the southern tropical area, water supplies are projected to be further stressed by climate change, resulting in less water availability and increased drought conditions (Seager *et al.*, 2007; Instituto Mexicano de Tecnología del Agua, 2010; Cayan *et al.*, 2010; Montero Martinez *et al.*, 2010; MacDonald, 2010; Comisión Nacional del Agua, 2011; Prieto-González *et al.*, 2011; Bonsal *et al.*, 2012; Sosa-Rodriguez, 2013; Orlowsky and Senevirantne, 2013; Diffenbaugh and Field, 2013). Compounding factors include salt water intrusion, and increased groundwater and surface water pollution (Leal Asencio *et al.*, 2008).

In the US southwest and southeast, ecosystems and irrigation are projected to be particularly stressed by decreases in water availability due to the combination of climate change, growing water demand, and water transfers to urban and industrial users (Seager *et al.*, 2009; Georgakakos *et al.*, 2013). In the Colorado River Basin crop irrigation requirements for pasture grass are projected to increase by 20% by 2040 and by 31% by 2070 (Dwyer *et al.*, 2012). In the Rio Grande basin, New Mexico, runoff is projected decrease by 8%-30% by 2080 due to climate change. Water transfers may entail significant transaction costs associated with adjudication and potential litigation; and might have economic, environmental, social, and cultural impacts that vary by water user (Hurd and Coonrod, 2012). In Mexico, water shortages combined with increased water demands are projected to increase surface and groundwater over exploitation (Comisión Nacional del Agua, 2011).

Other parts of North American are projected to have different climate risks. The vulnerability of water resources over the tropical southern region of Mexico is projected to be low for 2050: precipitation decreases from 10%-5% in the summer and no precipitation changes in the winter. After 2050, greater winter precipitation is projected, increasing the possibility of damaging hydropower and water storage damns by floods, while precipitation is projected to decrease by 40%-35% in the summer (Instituto Mexicano de Tecnología del Agua, 2010).

Throughout the 21st century, cities in NW Washington are projected to have drawdown of average seasonal reservoir storage in the absence of demand reduction because of less snow pack even though annual stream flows increase. Without accounting for demanding increases, projected reliability of all systems remains above 98% through mid and late century (Vano *et al.*, 2010a; Comisión Nacional del Agua, 2011). Throughout the eastern US, water supply systems will be negatively impacted by lost snowpack storage; rising sea levels contributing to increased storm intensities and salt water intrusion; possibly lower stream-flows; land use and population changes; and other stresses (Sun *et al.*, 2008; Obeysekera *et al.*, 2011).

In Canada’s Pacific Northwest Region, cool season flows are expected to increase, while warm seasons flows would decrease (Hamlet, 2011). Southern Alberta, where approximately two-thirds of Canadian irrigated land is located, is projected to experience declines in mean annual stream flow, especially during the summer (Shepherd *et al.*, 2010; Poirier and de Loë, 2012; Tanzeeba and Gan, 2012). In the Athabasca River Basin in northern Alberta, modeling results consistently indicate large projected declines in mean annual flows (Kerkhoven and Gan, 2011). In contrast, modeling results for basins in Manitoba indicate an increase in mean annual runoff (Choi *et al.*, 2009). Some model results for the Fraser River Basin in British Columbia indicate increases in mean annual runoff by the end of the 21st Century, while others indicate decreases (Kerkhoven and Gan, 2011). In central Quebec, (Chen *et al.*, 2011b) project a general increase in discharge during November-April, and a general decrease in summer discharge under most climate change conditions.

26.3.2.2. Water Quality

Many recent studies project water quality declines due to the combined impacts of climate change and development (Daley *et al.*, 2009; Tu, 2009; Praskievicz and Chang, 2011; Wilson and Weng, 2011; Tong *et al.*, 2012). Increased wildfires linked to a warming climate are expected to affect water quality downstream of forested headwater regions (Emelko *et al.*, 2011). Model simulation of lakes under a range of plausible higher air temperatures (Tahoe, Great Lakes, Lake Onondaga and shallow polymictic lakes), depending on the system, predict a range of impacts such as increased phytoplankton, fish and cyanobacteria biomass, lengthened stratification periods with risks of significant hypolimnetic oxygen deficits in late summer with solubilization of accumulated phosphorous and heavy metals with accelerated reaction rates, and decreased lake clarity (Dupuis and Hann, 2009; Trumpickas *et al.*, 2009; Sahoo *et al.*, 2011; Taner *et al.*, 2011). Model simulations have found seasonal climate change impacts on nonpoint source pollution loads, while others have found no impact (Marshall and Randhir, 2008; Tu, 2009; Taner *et al.*, 2011; Praskievicz and Chang, 2011).

Changes in physical-chemical-biological parameters and micropollutants are predicted to negatively affect drinking water treatment and distribution systems (Delpla *et al.*, 2009; Carriere *et al.*, 2010; Emelko *et al.*, 2011). Wastewater treatment plants would be more vulnerable as increases in rainfall and wet weather lead to higher rates of inflow and infiltration (New York City Department of Environmental Protection, 2008; King County Department of Natural Resources and Parks, 2008; Flood and Cahoon, 2011). They would also face reduced hydraulic capacities due to higher sea levels and increased river and coastal flooding (Flood and Cahoon, 2011), with higher sea levels also threatening sewage collection systems (Rosenzweig *et al.*, 2007; King County Department of Natural Resources and Parks, 2008)

26.3.2.3. Flooding

Projected increases in flooding (Georgakakos *et al.*, 2013) may affect sectors ranging from agriculture and livestock in southern tropical Mexico (National Water Commission of Mexico, 2010) to urban and water infrastructure in areas such as Dayton, Ohio, metro Boston and the Californian Bay-Delta region (Committee on Flood Control Alternatives in the American River Basin *et al.*, 1995; Kirshen *et al.*, 2006; California Department of Water Resources, 2009; Wu, 2010). Floods could begin earlier, have earlier peaks and longer durations (e.g., southern Quebec basin). Urbanization can compound the impacts of increased flooding due to climate change, particularly in the absence of flood management infrastructure that takes climate change into account (Hejazi and Markus, 2009; Mailhot and Duchesne, 2010; Sosa-Rodriguez, 2010). (Ntelekos *et al.*, 2010) estimate that annual riverine flood losses in the USA could increase from approximately $2 billion now to $7-$19 billion annually by 2100 depending upon emission scenario and economic growth rate.

26.3.2.4 Instream Uses

Projections of climate impacts on instream uses vary by region and time-frame. Hydropower generation, affected by reduced lake levels, is projected to decrease in arid and semi-arid areas of Mexico (Comisión Intersecretarial de Cambio Climatico, 2009; Sosa-Rodriguez, 2013) and in the Great Lakes (Buttle *et al.*, 2004; Mortsch *et al.*, 2006; Georgakakos *et al.*, 2013). In the US Pacific Northwest under several emission scenarios. it is projected to increase in 2040 by approximately 5% in the winter and decrease by approximately 13% in the summer, with annual reductions of approximately 2.5%. Larger increases and decreases are projected by 2080 (Hamlet *et al.*, 2010). On the Peribonka River system in Quebec, annual mean hydropower production will similarly decrease in the short-term increase by as much as 18 % in late 21st century (Minville *et al.*, 2009). Navigation on the Great Lakes, Mississippi River and other inland waterways may benefit from less ice cover but will be hindered by increased floods and low river levels during droughts (Georgakakos *et al.*, 2013).

26.3.3. Adaptation

There are a range of structural and non-structural adaptation measures being implemented with many being no-regret policies. For instance, in preparation for more intense storms, New York City is using green infrastructure to capture rainwater before it can flood the combined sewer system and is elevating boilers and other equipment above ground (Bloomberg, 2012). The Mexican cities of Monterrey, Guadalajara, Mexico City and Tlaxcala are reducing leaks from water systems (Comisión Intersecretarial de Cambio Climatico, 2009; National Water Commission of Mexico, 2010; Sosa-Rodriguez, 2010; Romero-Lankao, 2010). Regina, SK has increased urban water conservation efforts (Natural Resources Canada, 2008).

The 540-foot high, 1300-foot long concrete Ross Dam in the state of Washington, US was built on a special foundation so it could later be raised in height (Simmons, 1974). Dock owners in the Trent-Severn Waterway in the Great Lakes have moved their docks into deeper water to better manage impacts on shorelines (Coleman *et al.*, 2013). The South Florida Water Management District is assessing the vulnerability to sea level rise of its aging coastal flood control system and exploring adaptation strategies, including a strategy known as forward pumping (Obeysekera *et al.*, 2011). In Cambridge, Ontario, extra capacity culverts are being installed in anticipation of larger runoff (Scheckenberger *et al.*, 2009).

Water meters have been installed to reduce consumption by different users such as Mexican and Canadian farmers and in households of several Canadian cities (Instituto Nacional de Ecología y Cambio Climático, 2006; Natural Resources Canada, 2008). Agreements and regulations are underway such as the 2009 SECURE Water Act which establishes a federal climate change adaptation program with required studies to assess future water supply risks in the western U.S (42 USC § 10363). One such large, multi-year study was recently completed in the US for the Colorado River (Bureau of Reclamation, 2013) and others are planned. Agreements and regulations are underway, such as the 2007 Shortage Sharing Agreement for the management of the Colorado River, driven by concerns about water conservation, planning, better reservoir coordination, and preserving flexibility to respond to climate change(Bureau of Reclamation, 2007). Quebec Province is requiring dam safety inspections every 10 years to account for new knowledge on climate change impacts (Centre d'expertise hydrique du Québec, 2003). Expanded beyond flood and hydropower management to now include climate change, the Columbia River Treaty is a good example of an international treaty to manage a range of water resources challenges(U.S. Army Corps of Engineers and Bonneville Power Administration, 2013).

26.4. Ecosystems and Biodiversity

26.4.1. Overview

Recent research has documented gradual changes in physiology, phenology and distributions in North American ecosystems consistent with warming trends (Dumais and Prévost, 2007). Changes in phenology and species' distributions, particularly in the United States and Canada, have been attributed to rising temperatures, which have in turn been attributed to anthropogenic climate change via joint attribution (Root *et al.*, 2005; Vose *et al.*, 2012). Concomitant with 20th century temperature increases, northward and upward shifts in plant, mammal, bird, lizard, and insect species' distributions have been documented extensively in the western United States and eastern Mexico (Parmesan, 2006; Kelly and Goulden, 2008; Moritz *et al.*, 2009; Tingley *et al.*, 2009; Sinervo *et al.*, 2010). These distribution shifts consistent with climate-change interact with other environmental changes such as land-use change, hindering the ability of species to respond (Ponce-Reyes *et al.*, 2013).

A range of techniques have been applied to assess the vulnerability of North American ecosystems and species to changes in climate (Loarie *et al.*, 2009; Anderson *et al.*, 2009; Glick and Stein, 2011). A global risk analysis based on dynamic global vegetation models identified boreal forest in Canada as notably vulnerable to ecosystem shift (Scholze *et al.*, 2006). Since the AR4, the role of extreme events, including droughts, flood, hurricanes, storm surges, and heat waves, is a more prominent theme in studies of climate change impacts on North American ecosystems (Chambers *et al.*, 2007; IPCC, 2012).

A number of ecosystems in North America are vulnerable to climate change. For example, species in alpine ecosystems are at high risk due to limited geographic space into which to expand (Villers-Ruiz and Castañeda-Aguado, In press). Many forest ecosystems are susceptible to wildfire and large-scale mortality and infestations events (section 26.4.1). Across the continent, potentially rapid rates of climate change may require location shifts at velocities well outside the range in historical reconstructions (Sandel *et al.*, 2011; Schloss *et al.*, 2012). Changes in temperature, precipitation amount, and carbon dioxide concentrations can have different effects across species and ecological communities (Parmesan, 2006; Matthews *et al.*, 2011), leading to ecosystem disruption and reorganization (Smith *et al.*, 2011; Dukes *et al.*, 2011), as well as movement or loss.

The following section focuses in more depth on climate vulnerabilities in forests and coastal ecosystems. These ecosystems span all three North American countries, are illustrative cases of where understanding the opportunities for conservation and adaptation practices is important, and recent research advances and new evidence of increased vulnerabilities since AR4 motivate further exploration. Further treatment of grasslands and shrublands can be found in AR5 WGII 4.3.3.2.2, wetlands and peatlands 4.3.3.3, and tundra, alpine, and permafrost systems in 4.3.3.4. Additional synthesis of climate change impacts on terrestrial, coastal and ocean ecosystems can be found in Chapter 8 of the US National Climate Assessment (Groffman *et al.*, 2013).

26.4.2. Tree Mortality and Forest Infestation

26.4.2.1. Observed Impacts

Droughts of unusual severity, extent, and duration have affected large parts of western and southwestern North America and resulted in regional-scale forest dieback in Canada, US and Mexico. Extensive tree mortality has been related to drought exacerbated by high summertime temperatures in trembling aspen (*Populus tremuloides*), pinyon pine (*Pinus edulis*) and lodgepole pine (*Pinus contorta*) since the early 2000s (Breshears *et al.*, 2005; Hogg *et al.*, 2008; Raffa *et al.*, 2008; Michaelian *et al.*, 2011; Anderegg *et al.*, 2012). In 2011 and 2012 forest dieback in Northern and central Mexico was associated with extreme temperatures and severe droughts (Comisión Nacional Forestal, 2012a).Widespread forest-mortality events triggered by extreme climate events can alter ecosystem structure and function (Phillips *et al.*, 2009; Allen *et al.*, 2010; Anderegg *et al.*, 2013). Similarly, multi-decadal changes in demographic rates, particularly mortality, indicate climate-mediated changes in forest communities over longer periods (Hogg and Bernier, 2005; Williamson *et al.*, 2009). Average annual mortality rates increased from less than 0.5% of trees per year in the 1960s in forests of western Canada and the US to, respectively, 1.5-2.5% (Peng *et al.*, 2011), and 1.0-1.5% in the 2000s in the US (van Mantgem *et al.*, 2009).

The influences of climate change on ecosystem disturbance, such as insect outbreaks have become increasingly salient and suggest that these disturbances could have a major influence on North American ecosystems and economy in a changing climate. In terms of carbon stores these outbreaks have the potential to turn forests into carbon sources (Kurz *et al.*, 2008a; Kurz *et al.*, 2008b; Hicke *et al.*, 2012). Warm winters in western Canada and US have increased winter survival of the larvae of bark beetles, helping drive large-scale forest infestations and forest die-off in western North America since the early 2000s (Bentz *et al.*, 2010). Beginning in 1994, mountain pine beetle outbreaks have severely affected over 18 million hectares of pine forests in British Columbia, and outbreaks are expanding northwards (Energy, Mines and Resources: Forest Management Branch, 2012).

26.4.2.2. Projected Impacts and Risks

Projected increases in drought severity in southwestern forests and woodlands in United States and northwestern Mexico suggest that these ecosystems may be increasingly vulnerable, with impacts including vegetation mortality (Seager and Vecchi, 2010; Williams *et al.*, 2010; Overpeck and Udall, 2010) and an increase of biological agents such as beetles, borers, pathogenic fungi, budworms and other pests (Drake *et al.*, 2005). An index of forest drought stress calibrated from tree rings indicates that projected drought stress by the 2050s in the SRES A2 scenario from the CMIP3 model ensemble, due primarily to warming-induced rises in vapor pressure deficit, exceeds the most severe droughts of the past 1,000 years (Park *et al.*, 2013).

Under a scenario with large changes in global temperature (SRES A2) increases in growing-season temperature in forest soils in southern Quebec are as high as 5.0 C towards the end of the century and decreases of soil water content reach 20-40% due to elevated evapotranspiration rates (Houle *et al.*, 2012). More frequent droughts in tropical forests may change forest structure and regional distribution, favoring a higher prevalence of deciduous species in the forests of Mexico (Drake *et al.*, 2005; Trejo *et al.*, 2011).

Shifts in climate are expected to lead to changes in forest infestation, including shifts of insect and pathogen distributions into higher latitudes and elevations (Bentz *et al.*, 2010). Predicted climate warming is expected to have effects on bark beetle population dynamics in the western United States, western Canada, and northern Mexico that may include increases in developmental rates, generations per year, and changes in habitat suitability (Waring *et al.*, 2009). As a result, the impacts of bark beetles on forest resources are expected to increase (Waring *et al.*, 2009).

Wildfire, a potentially powerful influence on North American forests in the 21st century, is discussed in Box 26-2.

26.4.3. Coastal Ecosystems

Highly productive estuaries, coastal marshes and mangrove ecosystems are present along the Gulf coast and the East and West coasts of North America. These ecosystems are subject to a wide range of non-climate stressors, including urban and tourist developments and the indirect effects of overfishing (Mortsch *et al.*, 2006; Bhatti *et al.*, 2006; Lund *et al.*, 2007; Comisión Nacional para el Conocimiento y Uso de la Biodiversidad *et al.*, 2007). Climate change adds risks from sea-level rise, warming, ocean acidification, extratropical cyclones, altered upwelling, and hurricanes and other storms.

26.4.3.1. Observed Climate Impacts and Vulnerabilities

Sea level rise, which has not been uniform across the coasts of North America (Crawford *et al.*, 2007; Kemp *et al.*, 2008; Leonard *et al.*, 2009; Zavala-Hidalgo *et al.*, 2010; Sallenger *et al.*, 2012), is directly related to flooding and loss of coastal dunes and wetlands, oyster beds, seagrass and mangroves (Feagin *et al.*, 2005; Cooper *et al.*, 2008; Najjar *et al.*, 2010; Ruggiero *et al.*, 2010; McKee, 2011; Martinez Arroyo *et al.*, 2011).

Increases in sea surface temperature in estuaries alter metabolism, threatening species, especially cold water fish (Crawford *et al.*, 2007). Historical warm periods have coincided with low salmon abundance and restriction of fisheries in Alaska (Crozier *et al.*, 2008; U.S. Global Change Research Program, 2009). North Atlantic cetaceans, and tropical coral reefs in the Gulf of California and the Caribbean have been affected by increases in the incidence of diseases associated with warm waters and low water quality (Mumby *et al.*, 2011; International Council for the Exploration of the Sea, 2011).

Increased concentrations of CO_2 in the atmosphere due to human emissions are causing ocean acidification (Executive summary chapters 5 and 6; FAQ 5.1). Along the temperate coasts of North America acidification directly affects calcareous organisms, including colonial mussel beds, with indirect influences on food webs of benthic species (Wootton *et al.*, 2008). Increased acidity in conjunction with high temperatures has been identified as a serious threat to coral reefs and other marine ecosystems in the Bahamas and the Gulf of California(Doney *et al.*, 2009; Hernández *et al.*, 2010; Mumby *et al.*, 2011).

Tropical storms and hurricanes can have a wide range of effects on coastal ecosystems, potentially altering hydrology, geomorphology (erosion), biotic structure in reefs and nutrient cycling. Hurricane impacts on the coastline change dramatically the marine habitat of sea turtles, reducing feeding habitats, such as coral reefs and areas of seaweed, and nesting places. (Márquez, R. and Jiménez, Ma. del C., 2010; Liceaga-Correa *et al.*, 2011)

26.4.3.2. Projected Impacts and Risks

Projected increases in sea levels, particularly along the coastlines of Florida, Louisiana, North Carolina, and Texas (Kemp *et al.*, 2008; Leonard *et al.*, 2009; Weiss *et al.*, 2011), will threaten many plants in coastal ecosystems through increased inundation, erosion, and salinity levels. In settings where landward shifts are not possible, a 1 m rise in sea level will result in loss of wetlands and mangroves along the Gulf of Mexico of 20% (in Tamaulipas) to 94% (in Veracruz) (Flores Verdugo *et al.*, 2010).

Projected impacts of increased water temperatures include contraction of coldwater fish habitat and expansion of warm-water fish habitat (Mantua *et al.*, 2010), which can increase the presence of invasive species that threaten resident populations (Janetos *et al.*, 2008). Depending on scenario, Chinook salmon in the Pacific Northwest may decline by 20 to 50% by 2040-50 (Battin *et al.*, 2007; Crozier *et al.*, 2008), integrating across restrictions in productivity and abundance at the southern end of their range and expansions at the northern end (Azumaya *et al.*, 2007), although habitat restoration and protection particularly at lower elevations may help mitigate declines in abundance.

Continuing ocean acidification will decrease coral growth and interactions with temperature increases will lead to increased risk of coral bleaching, leading to declines in coral ecosystem biodiversity (Veron *et al.*, 2009) (5.4.2.4, Box CC-OA). Oyster larvae in Chesapeake Bay grew more slowly when reared with CO_2 levels between 560 and 480ppm compared to current environmental conditions (Gazeau *et al.*, 2007; Miller *et al.*, 2009; Najjar *et al.*, 2010).

While future trends in thunderstorms and tropical cyclones are uncertain (26.2.2), any changes, particularly an increase in the frequency of category 4 and 5 storms (Bender *et al.*, 2010; Knutson *et al.*, 2010) could have profound impacts on mangrove ecosystems, which require 25 years for recovery from storm damage (Kovacs *et al.*, 2004; Flores Verdugo *et al.*, 2010).

26.4.4. Ecosystems Adaptation, and Mitigation

In North America, a number of adaptation strategies, are being applied in novel and flexible ways to address the impacts of climate change (Mawdsley *et al.*, 2009; National Oceanic and Atmospheric Administration, 2010; Gleeson *et al.*, 2011; Poiani *et al.*, 2011). The best of these are based on detailed knowledge of the vulnerabilities and sensitivities of species and ecosystems, and with a focus on opportunities for building resilience through effective ecosystem management. Government agencies and nonprofit organizations have established initiatives that emphasize the value of collaborative dialogue between scientists and practitioners, indigenous communities, and grass-roots organizations to develop no-regrets and co-benefits adaptation strategies (Ogden and Innes, 2009; Gleeson *et al.*, 2011; Halofsky *et al.*, 2011; Cross *et al.*, 2012; Instituto Nacional de Ecología y Cambio Climático, 2012b; Cross *et al.*, 2013).

Examples of adaptation measures implemented to respond to climate change impacts on ecosystems are diverse. They include programs to reduce the incidence of Canadian forest pest infestations (Johnston *et al.*, 2010); breeding programs for resistance to diseases and insect pests (Yanchuk and Allard, 2009); use of forest programs to reduce the incidence of forest fires and encourage agroforestry in areas of Mexico (Sosa-Rodriguez, 2013); and selection by forest or fisheries managers of activities that are more adapted to new climatic conditions (Vasseur and Catto, 2008). Example programs have addressed commercial fishing, mass tourism (Pratchett *et al.*, 2008), and enforcement mechanisms for using water regulation technologies to maintain quantity and quality in wetlands around the Great Lakes and San Francisco, California (Mortsch *et al.*, 2006; Okey *et al.*, 2012). Assisted migration is increasingly discussed as a potential management option to maintain health and productivity of forests; yet the technique has logistical and feasibility challenges (Keel, 2007; Hoegh-Guldberg *et al.*, 2008; Winder *et al.*, 2011).

Several lines of evidence indicate that effective adaptation requires changes in approach and becomes much more difficult if warming exceeds 2°C above preindustrial levels (Comisión Nacional para el Conocimiento y Uso de la Biodiversidad *et al.*, 2007; Mansourian *et al.*, 2009; U.S. Forest Service, 2010; Glick and Stein, 2011; Barragan *et al.*, 2011; Instituto Nacional de Ecología y Cambio Climático, 2012b). Even though options for effective adaptation are increasingly constrained at warming over 2°C, some opportunities will remain. In particular, efforts to maintain or increase forest carbon stocks can lead to numerous benefits, including not only benefits for atmospheric CO_2 (Anderson and Bell, 2009; Anderson *et al.*, 2011). Even where there are opportunities, managers face challenges in designing management practices that favor carbon stocks, while at the same time maintaining biodiversity, recognizing the rights of indigenous people, and contributing to local economic development (Food and Agriculture Organization, 2012).

_____ START BOX 26-2 HERE _____

Box 26-2. Wildfires

Wildfire is a natural process, critical to nutrient cycling, controlling populations of pests and pathogens, biodiversity and fire-adapted species (Bond and Van Wilgen, 1996). However, since the mid-1980s large wildfire activity in North America has been marked by increased frequency and duration, and longer wildfire seasons (Westerling *et al.*, 2006; Williamson *et al.*, 2009). Recent wildfires in western Canada, the US and Mexico relate to long and warm spring and summer droughts, particularly when they are accompanied by winds (Holden *et al.*, 2007; Comisión

Nacional Forestal, 2012b). Interacting processes such as land-use changes associated with the expansion of settlements and activities in peri-urban areas or forested areas, combined with the legacies of historic forest management that prescribed fire suppression, also substantially increase wildfire risk (Radeloff *et al.*, 2005; Peter *et al.*, 2006; Theobald and Romme, 2007; Fischlin *et al.*, 2007; Gude *et al.*, 2008; Collins and Bolin, 2009; Hammer *et al.*, 2009; Brenkert-Smith, 2010).

Drought conditions are strongly associated with wildfire occurrence, as dead fuels such as needles and dried stems promote the incidence of firebrands and spot fires (Keeley and Zedler, 2009; Liu *et al.*, 2012). Drought trends vary across regions (Groisman *et al.*, 2007; Girardin *et al.*, 2012): the western US has experienced drier conditions since the 1970s (Peterson *et al.*, 2013); drought periods in Alberta and Idaho have coincided with large burned areas (Pierce and Meyer, 2008; Kulshreshtha, 2011); heterogeneous patterns of drought severity and a reduction of wildfire risk have been detected for the circumboreal region (Girardin *et al.*, 2009). Decadal climatic oscillations also contribute to differences in drought, and thus in wildfire occurrences. The areas burned in the continent boreal forest and in northwest and central Mexico correlate to the dynamics of seasonal land/ocean temperature variability (Macias Fauria and Johnson, 2006; Skinner *et al.*, 2006; Villers-Ruíz and Hernández-Lozano, 2007; Macias Fauria and Johnson, 2008; Girardin and Sauchyn, 2008); which is shifting toward hotter temperatures and longer droughts. Such human practices as slash-and-burn agriculture can have negative impacts on Mexican forests (Bond and Keeley, 2005; Comisión Nacional de Áreas Naturales Protegidas and The Nature Conservancy, Programa México, 2009).

Drought index projections and climate change regional models show increases in wildfire risk during the summer and fall on the southeast Pacific coast, Northern Plains and the Rocky Mountains (Liu *et al.*, 2012). In places like Sierra Nevada, mixed conifer forests, which have a natural cycle of small, non-crown fires, are projected to have massive crown-fires (Bond and Keeley, 2005) (Table 26-1).

While healthy forests (Davis, 2004) and many fire-maintained systems that burn at lower intensities can provide carbon sequestration and thus mitigation co-benefits (e.g., Longleaf pine savanna, Sierra mixed-conifer)(Fried *et al.*, 2008; North *et al.*, 2012), forests affected by pests and fires are less effective carbon sinks, and wildfires themselves are a source of emissions.

Wildfires pose a direct threat to human lives, property and health. Over the last 30 years, 155 people were killed in wildfires across North America, including 103 in the United States, 50 in Mexico and 2 in Canada (Centre for Research on the Epidemeology of Disasters, 2012). Direct effects include injury and respiratory effects from smoke inhalation, with firefighters at increased risk (Naeher *et al.*, 2007; Reisen and Brown, 2009; Reisen *et al.*, 2011). Wildfire activity causes impacts on human health (section 26.6).

Minimizing adverse effects of wildfires involves short-term and long-term strategies such as planned manipulation of vegetation composition and stand structure (Girardin *et al.*, 2012; Terrier *et al.*, 2013), suppression of fires where required, fuel treatments, use of fire-safe materials in construction, community planning, and reduction of arson. Not all negative consequences of fire can be avoided, though a mixture of techniques can be used to minimize adverse effects (Girardin *et al.*, 2012). Prescribed fire may be an important tool for managing fire risk in Canada and the US (Hurteau and North, 2010; Wiedinmyer and Hurteau, 2010; Hurteau *et al.*, 2011). Managers in the US have encouraged reduction of flammable vegetation around structures with different levels of success (Stewart *et al.*, 2006). However, such efforts depend largely on land-use planning, the socio-economic capacity of communities at risk, the extent of resource dependence, community composition, and the risk perceptions, attitudes and beliefs of decision-makers, private property owners, and affected populations (McFarlane, 2006; Repetto, 2008; Collins and Bolin, 2009; Martin *et al.*, 2009; Trainor *et al.*, 2009; Brenkert-Smith, 2010). Indigenous peoples are at higher risk from wildfire and may have unique requirements for adaptation strategies (Carroll *et al.*, 2010; Christianson *et al.*, 2012a; Christianson *et al.*, 2012b).

Effective forest management requires stakeholder involvement and investment. The provision of adequate information on smoke, prescribed fire, pest management, and forest thinning is crucial, as is building trust between stakeholders and land managers (Dombeck *et al.*, 2004; Flint *et al.*, 2008; Chang *et al.*, 2009). Institutional shifts from reliance on historical records toward incorporation of climate forecasting in forest management is also crucial to effective adaptation (McKenzie *et al.*, 2004; Millar *et al.*, 2007; Kolden and Brown, 2010).

_____ END BOX 26-2 HERE _____

26.5. Agriculture and Food Security

Projected declines in global agricultural productivity (Chapter 7) have implications for food security among North Americans. Because North America is a major exporter (Food and Agriculture Organization, 2009; Schlenker and Roberts, 2009), shifts in agricultural productivity here may have implications for global food security. Canada and the US are relatively food secure, although households living in poverty are vulnerable. 17.6% of Mexicans are food insecure (Monterroso *et al.*, 2012). Indigenous peoples are highly vulnerable due to high reliance on subsistence (Chapter 12). While this section focuses on agricultural production, food security is related to multiple factors (See Chapter 7).

26.5.1. Observed Climate Change Impacts

Historic yield increases are attributed in part to increasing temperatures in Canada and higher precipitation in the US (Pearson *et al.*, 2008; Sakurai *et al.*, 2011; Nadler and Bullock, 2011); (high agreement, medium evidence), although multiple non-climatic factors affect historic production rates. In many North American regions optimum temperatures have been reached for dominant crops, thus continued regional warming would diminish rather than enhance yields (Jones *et al.*, 2005) (high confidence). Regional yield variances over time have been attributed to climate variability –e.g., Ontario (Cabas *et al.*, 2010) and Quebec (Almaraz *et al.*, 2008). Since 1999 a marked increase in crop losses attributed to climate-related events such as drought, extreme heat and storms has been observed across North America (Hatfield *et al.*, 2013), with significant negative economic effects (Swanson *et al.*, 2007; Chen and McCarl, 2009; Costello *et al.*, 2009) (high confidence). In Mexico, agriculture accounted for 80% of weather-related financial losses since 1990 (Saldaña-Zorrilla, 2008) (Figure 26-2).

26.5.2. Projected Climate Change Risks

Studies project productivity gains in northern regions and where water is not projected to be a limiting factor, across models, time frames and scenarios (Hatfield *et al.*, 2008; Pearson *et al.*, 2008; Wheaton *et al.*, 2010; Stöckle *et al.*, 2010); (high confidence). Overall yields of major crops in North America are projected to decline modestly by mid-century and more steeply by 2100 among studies that do not consider adaptation (very high confidence). Certain regions and crops may experience gains in the absence of extreme events, and projected yields vary by climate model (Paudel and Hatch, 2012; Liu *et al.*, 2013).

Among studies projecting yield declines, two factors stand out: exceedance of temperature thresholds, and water availability. Yields of several important North American agriculture sectors—including grains, forage, livestock and dairy—decline significantly above temperature thresholds (Wolfe *et al.*, 2008; Schlenker and Roberts, 2009; Craine *et al.*, 2010) Temperature increases affect product quality as well –e.g., coffee (Lin, 2007), wine grapes (Hayhoe *et al.*, 2004; Jones *et al.*, 2005), wheat (Porter and Semenov, 2005), fruits and nuts (Lobell *et al.*, 2006), and cattle forage (Craine *et al.*, 2010).

Projected temperature increases would reduce corn, soy and cotton yields by 2020, with declines ranging from 30-82% by 2099 depending on crop and scenario (steepest decline for corn, A1) (Schlenker and Roberts, 2009). Studies also project increasing inter-annual yield variability over time (Sakurai *et al.*, 2011; Urban *et al.*, 2012). Several studies focus on California, one of North America's most productive agricultural regions. Modest and variable yield changes among several California crops are projected to 2026, with yield declines from 9-29% by 2097 (A2, DAYCENT model). (Lobell and Field, 2011; Lee *et al.*, 2011) found little negative effect for California perennials by 2050 due to projected climate change, assuming irrigation access (GCM ensemble, A2 and B1). (Hannah *et al.*, 2013), however, project large declines in land suitability for California viticulture by 2050 (with increases further north) with RCPs 4.5 and 8.5 (GCM ensemble); declines greater under RCP 8.5. Heat-induced livestock stress, combined with reduced forage quality, would reduce milk production and weight gain in cattle (Wolfe *et al.*, 2008; Hernandez *et al.*, 2011).

Precipitation increases off-set but do not entirely compensate for temperature-related declines in productivity (Kucharik and Serbin, 2008). In regions projected to experience increasing temperatures combined with declining precipitation, declines in yield and quality are more acute (Craine *et al.*, 2010; Monterroso Rivas *et al.*, 2011).

Projected change in climate will reduce soil moisture and water availability in the US Western/Southwest, the Western Prairies in Canada, and central and northern Mexico (Pearson *et al.*, 2008; U.S. Global Change Research Program, 2009; Cai *et al.*, 2009; Esqueda *et al.*, 2010; Vano *et al.*, 2010b; Kulshreshtha, 2011) (very high confidence). CMIP5 models indicate soil moisture decreases across the continent in Spring and Summer under RCP8.5, with high agreement (Dirmeyer *et al.*, 2013). Based on a combined exposure/consumptive water use model, the US Great Plains is identified as one of four global future vulnerability hotspots for water availability from the 2030s and beyond, where anticipated water withdrawals would exceed 40% of freshwater resources (Liu *et al.*, 2013). In western US and Canada, projected earlier Spring snowmelt and reduced snowpack would affect productivity negatively regardless of precipitation, as water availability in Summer and Fall are reduced (Schlenker *et al.*, 2007; Forbes *et al.*, 2011; Kienzle *et al.*, 2012).

Projected increases in extreme heat, drought and storms affect productivity negatively (Chen and McCarl, 2009; Kulshreshtha, 2011). The northeastern and southeastern US have been identified as "vulnerability hotspots" for corn and wheat production respectively by 2045 with vulnerability worsening thereafter, using a combined drought exposure and adaptive capacity assessment, with only slight differences between A1B and B2 scenarios (Fraser *et al.*, 2013). Central North America is identified as among the globe's regions of highest risk of heat stress by 2070 (NIES GCM; A1B) (Teixeira *et al.*, 2013).

26.5.3. A Closer Look at Mexico

Much of Mexico's landbase is already marginal for two of the country's major crops: corn and beef (Buechler, 2009). Severe desertification in Mexico due to non-climate drivers further compromises productivity (Huber-Sannwald *et al.*, 2006). Land classified suitable for rain-fed corn is projected to decrease from 6.2% currently to between 3% and 4.3% by 2050 (UKHadley B2, ECHAM5/MPI A2) (Monterroso Rivas *et al.*, 2011). The distribution of most races of corn is expected to be reduced and some eliminated by 2030 (A2, three climate models) (Ureta *et al.*, 2012). Precipitation declines of 0-30% are projected over Mexico by 2040; with the most acute declines in Northwestern Mexico, the primary region of irrigated grain farming (declines steeper in A2 than A1B (18 model ensemble).

Although projected increases in precipitation may contribute to increase in rangeland productivity in some regions (Monterroso Rivas *et al.*, 2011), a study in Veracruz indicates that the effects of projected maximum summer temperatures on livestock heat stress are expected to reach the "Danger level" (at which losses can occur) by 2020 and continue to rise (A2, B2, three GCMs) (Hernandez *et al.*, 2011). Coffee, an economically important crop supporting 500,000 primarily indigenous households (González Martínez, 2006), is projected to decline 34% by 2020 in Veracruz if historic temperature and precipitation trends continue (Gay *et al.*, 2006); see also (Schroth *et al.*, 2009), on declines in Chiapas).

Many of Mexico's agricultural communities are also considered highly vulnerable, due to high sensitivity and/or low adaptive capacity (Monterroso *et al.*, 2012). The agriculture sector here consists primarily of small farmers (Claridades Agropecuarias 2006), who face high livelihood risks due to limited access to credit and insurance (Eakin and Tucker, 2006; Wehbe *et al.*, 2008; Saldaña-Zorilla and Sandberg, 2009; Walthall *et al.*, 2012).

26.5.4. Adaptation

The North American agricultural industry has the adaptive capacity to off-set projected yield declines and capitalize on opportunities under 2° warming. (Butler and Huybers, 2012) project a reduction in US corn yield loss from 14% to 6% with 2° warming, with spatial shifts in varietal selection (not accounting for variability in temperature and precipitation). Incremental strategies, such as planting varieties better suited to future climate conditions and changing planting dates, have been observed across the continent (Bootsma *et al.*, 2005; Conde *et al.*, 2006; Eakin and Appendini, 2008; Coles and Scott, 2009; Nadler and Bullock, 2011; Paudel and Hatch, 2012; Campos *et al.*, 2013). In some sectors we are seeing multi-organizational investments in adaptation. International coffee retailers and non-governmental organizations, for example, are engaged in enhancing coffee farmers' adaptive capacity (Schroth *et al.*, 2009; Soto-Pinto and Anzueto, 2010). Other strategies specifically recommended for Mexico include soil remediation; improved use of climate information; rainwater capture and drip irrigation (Sosa-Rodriguez, 2013). New crop varieties better suited to future climates, including GMOs, are under development in the US (e.g. (Chen *et al.*, 2012), although potential risks have been noted (Quist and Chapela, 2001). Current trends in agricultural practices in commercial regions such as the Midwestern US, however, amplify productivity risks posed by climate change (Hatfield *et al.*, 2013). Incremental strategies will have reduced effectiveness under a 2099/4°C warming scenario, which would require more systemic adaptation, including production and livelihood diversification (Howden *et al.*, 2007; Mehta *et al.*, 2013; Smith and Gregory, 2013; Asseng *et al.*, 2013).

Some adaptive strategies impose financial costs and risks onto producers (Craine *et al.*, 2010;Wolfe *et al.*, 2008), which may be beyond the means of smallholders (Mercer *et al.*, 2012) or economically precluded for low-value crops. Technological improvements improve yields under normal conditions but do not protect harvests from extremes (U.S. Global Change Research Program, 2009;Wittrock *et al.*, 2011). Others may have maladaptive effects (e.g. increased groundwater and energy consumption). Crop-specific weather index insurance, for example (widely implemented in Mexico to support small farmers), may impose disincentives to invest in diversification and irrigation (Fuchs and Wolff, 2010).

Many strategies have co-benefits, however, in fact investments in agricultural adaptation represent a cost-effective mitigation strategy (Lobell *et al.*, 2013). Low- and no-till practices reduce soil erosion and runoff, protect crops from extreme precipitation (Zhang and Nearing, 2005), retain soil moisture, reduce biogenic and geogenic greenhouse gas emissions (Nelson *et al.*, 2009; Suddick *et al.*, 2010), and build soil organic carbon (Aguilera *et al.*, 2013). Planting legumes and weed management on pastures enhance both forage productivity and soil carbon sequestration (Follett and Reed, 2010). Shade perennials increase soil moisture retention (Lin, 2010) and contribute to local cooling (Georgescu *et al.*, 2011). Crop diversification mediates the impacts of climate and market shocks (Eakin and Appendini, 2008) and enhances management flexibility (Chhetri *et al.*, 2010).

Barriers and Enablers

Market forces and technical feasibility alone are insufficient to foster sectoral-level adaptation (Kulshreshtha, 2011). Institutional support is key, found to be inadequate in many contexts (Bryant *et al.*, 2008; Klerkx and Leeuwis, 2009; Jacques *et al.*, 2010; Tarnoczi and Berkes, 2010; Brooks and Loevinsohn, 2011; Alam *et al.*, 2012; Anderson and McLachlan, 2012)(high confidence). Even many suggested adaptation strategies with anticipated economic benefits are often not adopted by farmers, suggesting the need for more attention to culture and behavior (Moran *et al.*, 2013). Attitudinal studies among US farmers indicate limited acknowledgement of anthropogenic climate change, associated with lower levels of support for adaptation (Arbuckle Jr *et al.*, 2013; Gramig *et al.*, 2013) (high agreement, medium evidence).

Other key enablers are access to and quality of information (Tarnoczi and Berkes, 2010; Tarnoczi, 2011; Baumgart-Getz *et al.*, 2012; Tambo and Abdoulaye, 2012), particularly regarding optimum crop management, production inputs and optimum crop-specific geographic information. Social networks are important for information dissemination and farmer support (Chiffoleau, 2009; Wittrock *et al.*, 2011; Baumgart-Getz *et al.*, 2012). Networks among producers may be especially important to the level of awareness and concern farmers hold about climate change(Frank *et al.*, 2010; Sánchez-Cortés and Chavero, 2011), while also enabling extensive farmer-to-farmer exchange of adaptation strategies (Eakin *et al.*, 2009).

26.6. Human Health

Large national assessments of climate and health have been carried out in the US and Canada (Belanger *et al.*, 2008a) (see references in 26.1). These have highlighted the potential for changes in impacts of extreme storm and heat events, air pollution, pollen, and infectious diseases, drawing from a growing NA research base analyzing observed and projected relationships among weather, vulnerability and health. The causal pathways leading from climate to health are complex, and can be modified by factors including economic status, pre-existing illness, age, other health risk factors, access to health care, built and natural environments, adaptation actions and others. Human health is an important dimension of adaptation planning at the local level, much of which has so-far focused on warning and response systems to extreme heat events (New York State Climate Action Council, 2012).

26.6.1. Observed Impacts, Vulnerabilities and Trends

26.6.1.1. Storm-Related Impacts

The magnitude of health impacts of extreme storms depends on interactions between exposure and characteristics of the affected communities (Keim, 2008). Coastal and low-lying infrastructure and populations can be vulnerable due to flood-related interruptions in communications, healthcare access, and mobility. Health impacts can arise through direct pathways of traumatic death and injury (e.g., drowning, impacts of blowing and falling objects; contact with power wires) as well as more indirect, longer-term pathways related to damage to health and transportation infrastructure, contamination of water and soil, vector-borne diseases, respiratory diseases and mental health (Gamble *et al.*, 2008). Infectious disease impacts from flooding include creation of breeding sites for vectors (Ivers and Ryan, 2006) and bacterial transmission through contaminated water and food sources causing gastrointestinal disease. Chemical toxins can be mobilized from industrial or contaminated sites (Euripidou and Murray, 2004). Elevated indoor mold levels associated with flooding of buildings and standing water are identified as risk factors for cough, wheeze and childhood asthma (Bornehag *et al.*, 2001; Jaakkola *et al.*, 2005). Mental health impacts can arise due to the stress of evacuation, property damage, economic loss, and household disruption (Weisler *et al.*, 2006; Gamble *et al.*, 2008; Berry *et al.*, 2010; Bethel *et al.*, 2011). Since 1970, there has been no clear trend in US hurricane deaths, once the singular Katrina event is set aside (Blake *et al.*, 2007).

26.6.1.2. Temperature Extremes

Studies throughout North America have shown that high temperatures can increase the mortality and/or morbidity (e.g., Medina-Ramon and Schwartz, 2007; Kovats and Hajat, 2008; O'Neill and Ebi, 2009; Anderson and Bell, 2009; Knowlton *et al.*, 2009; Deschenes *et al.*, 2009; Kenny *et al.*, 2010; Hajat and Kosatsky, 2010; Cueva-Luna *et al.*, 2011; Hurtado-Díaz *et al.*, 2011; Romero-Lankao *et al.*, 2012b). Extremely cold temperatures have also been associated with increased mortality (Medina-Ramon and Schwartz, 2007), an effect separate from the seasonal phenomenon of excess winter mortality, which does not appear to be directly related to cold temperatures (Kinney, 2012). To date, trends over time in cold-related deaths have not been investigated. Most available NA evidence derives from the US and Canada, though one study reported significant heat- and cold-related mortality impacts in Mexico City (McMichael *et al.*, 2008). US EPA has tracked the death rate in the US from 1979 to 2009 for which death certificates list the underlying cause of death as heat related (U.S. Environmental Protection Agency, Office of Atmospheric Programs, 2012). No clear trend upwards or downwards is yet apparent in this indicator. Note that this case definition is thought to significantly underestimate the total impacts of heat on mortality.

26.6.1.3. Air Quality

Ozone and particulate matter (e.g., PM2.5 and PM10) have been associated with adverse health effects in many locations in North America (Romero-Lankao *et al.*, 2013b). Emissions, transport, dilution, chemical transformation, and eventual deposition of air pollutants all can be influenced by meteorological variables such as temperature, humidity, wind speed and direction, and mixing height (Kinney, 2008). Although air pollution emission trends will play a dominant role in future pollution levels, climate change may make it harder to achieve some air quality goals (Jacob and Winner, 2009). Forest fire is a source of particle emissions in NA, and can lead to increased cardiac and respiratory-disease incidence, as well as direct mortality (Rittmaster *et al.*, 2006; Ebi *et al.*, 2008). The indoor environment also can affect health in many ways, e.g., via penetration of outdoor pollution, emissions or pollutants indoors, moisture-related problems, and transmission of respiratory infections. Indoor moisture leads to mold growth, a problem that is exacerbated in colder regions such as northern NA in the winter (Potera, 2011). Climate variability and change will affect indoor air quality, but with direction and magnitude that remains largely unknown (Institute of Medicine, 2011).

26.6.1.4. Pollen

Exposure to pollen has been associated with a range of allergic outcomes, including exacerbations of allergic rhinitis (Cakmak *et al.*, 2002; Villeneuve *et al.*, 2006) and asthma (Delfino, 2002). Temperature and precipitation in the months prior to the pollen season affect production of many types of tree and grass pollen (Reiss and Kostic, 1976; Minero *et al.*, 1998; Lo and Levetin, 2007; U.S. Environmental Protection Agency, 2008). Ragweed pollen production is responsive to temperatures and to CO_2 concentrations (Ziska and Caulfield, 2000; Wayne *et al.*, 2002; Ziska *et al.*, 2003; Singer *et al.*, 2005). Because pollen production and release can be affected by temperature, precipitation, and CO_2 concentrations, pollen exposure and allergic disease morbidity could change in response to climate change. However, to date, the timing of the pollen season is the only evidence for observed climate-related impacts. Many studies have indicated that pollen seasons are beginning earlier (Emberlin *et al.*, 2002; Rasmussen, 2002; Clot, 2003; Teranishi *et al.*, 2006; Frei and Gassner, 2008; Levetin and Van, 2008; Ariano *et al.*, 2010). Ragweed season length has increased at some monitoring stations in the United States (Ziska *et al.*, 2011). Research on trends in NA has been hampered by the lack of long-term, consistently collected pollen records (U.S. Environmental Protection Agency, 2008).

26.6.1.5. Waterborne Diseases

Waterborne infections are an important source of morbidity and mortality in North America. Commonly reported infectious agents in US and Canadian outbreaks include legionella bacterium, the cryptosporidium parasite, campylobacter, and giardia (Belanger *et al.*, 2008b; Center for Disease Control and Prevention, 2011). Cholera remains an important agent in Mexico (Greer *et al.*, 2008). Risk of waterborne illness is greater among the poor, infants, elderly, pregnant women, and immune-compromised individuals (Rose *et al.*, 2001; Gamble *et al.*, 2008) . In Mexico City, declining water quality has led to ineffective disinfection of drinking water supplies (Mazari-Hiriart *et al.*, 2005; Sosa-Rodriguez, 2010).

Changes in temperature and hydrological cycles can influence the risk of waterborne diseases (Curriero *et al.*, 2001; Greer *et al.*, 2008; Harper *et al.*, 2011). Severe storms have been shown to play a role in water-borne disease risks in Canada (Thomas *et al.*, 2006). Floods enhance the potential for runoff to carry sediment and pollutants to water supplies (Karl *et al.*, 2008). Disparities in access to treated water were identified as a key determinant of under age-5 morbidity due to water borne illnesses in the central State of Mexico (Jimenez-Moleon and Gomez-Albores, 2011).

26.6.1.6. Vectorborne Diseases

The extent to which climate change has altered, and will alter, the geographic distribution of vectors of infectious disease remains uncertain because of the inherent complexity of the ecological system. Spatial and temporal distribution of disease vectors depend not only on climate factors, but also on land use/change, socio-economic and socio-cultural factors, prioritization of vector control, access to health care and human behavioral responses to perception of disease risk, among other factors (Lafferty, 2009; Wilson, 2009). Although temperature drives important biological processes in these organisms, climate variability on a daily, seasonal or interannual scale may result in organism adaptation and shifts, though not necessarily expansion, in geographic range (Lafferty, 2009; Tabachnick, 2010; McGregor, 2011). Range shifts may alter the incidence of disease depending on host receptiveness and immunity, as well as the ability of the pathogen to evolve so that strains are more effectively and efficiently acquired (Reiter, 2008; Beebe *et al.*, 2009; Rosenthal, 2009; Russell, 2009; Epstein, 2010).

North Americans are currently at risk from a number of vector-borne diseases, including Lyme disease (Ogden *et al.*, 2008; Diuk-Wasser *et al.*, 2010), dengue fever (Jury, 2008; Ramos *et al.*, 2008; Johansson *et al.*, 2009; Kolivras, 2010; Degallier *et al.*, 2010; Lambrechts *et al.*, 2011; Riojas-Rodriguez *et al.*, 2011; Lozano-Fuentes *et al.*, 2012), West Nile virus (Morin and Comrie, 2010; Gong *et al.*, 2011) and Rocky Mountain spotted fever, to name a few. Risk is increasing from invasive vector-borne pathogens, such as chikungunya (Ruiz-Moreno *et al.*, 2012) and Rift Valley fever viruses (Greer *et al.*, 2008). There is also potential risk from invasive vector-borne pathogens, such as chikungunya (Ruiz-Moreno *et al.*, 2012) and Rift Valley fever viruses (Greer *et al.*, 2008). Mexico is listed as high risk for dengue fever by the WHO. There has been an increasing number of cases of Lyme disease in Canada and Lyme disease vectors are spreading along climate-determined trajectories (Leighton *et al.*, 2012; Koffi *et al.*, 2012).

26.6.2. Projected Climate Change Impacts

Projecting future consequences of climate warming for heat-related mortality and morbidity is challenging, due in large part to uncertainties in the nature and pace of adaptations that populations and societal infrastructure will undergo in response to long-term climate change (Kinney *et al.*, 2008). Additional uncertainties arise from changes over time in population demographics, economic well-being, and underlying disease risk, as well as in the model-based predictions of future climate and our understanding of the exposure-response relationship for heat-related mortality. However, climate warming will lead to continuing health stresses related to extreme high temperatures, particularly for the northern parts of North America. The health implications of warming winters remain uncertain (Kinney, 2012).

Several recent studies have projected future health impacts due to air pollution in a changing climate (Knowlton *et al.*, 2004; Bell *et al.*, 2007; Tagaris *et al.*, 2009; Tagaris *et al.*, 2010; Chang *et al.*, 2010). There is a large literature examining future climate influences on outdoor air quality in North America, particularly for ozone (Murazaki and Hess, 2006; Steiner *et al.*, 2006; Tao *et al.*, 2007; Kunkel *et al.*, 2007; Holloway *et al.*, 2008; Lin *et al.*, 2008; Nolte *et al.*, 2008; Wu *et al.*, 2008; Avise *et al.*, 2009; Chen *et al.*, 2009; Liao *et al.*, 2009; Racherla and Adams, 2009; Lin *et al.*, 2010; Tai *et al.*, 2010). This work suggests with *medium confidence* that ozone concentrations could increase under future climate change scenarios if emissions of precursors were held constant (Jacob and Winner, 2009). However, analyses show that future increases can be offset through measures taken to limit emission of pollutants (Kelly *et al.*, 2012). The literature for PM2.5 is more limited than that for ozone, and shows a more complex pattern of climate sensitivities, with no clear net influence of warming temperatures (Liao *et al.*, 2007; Tagaris *et al.*, 2008; Avise *et al.*, 2009; Pye *et al.*, 2009; Mahmud *et al.*, 2010). On the other hand, $PM_{2.5}$ plays a crucial role. Regarding outdoor pollen, warming will lead to further changes in the seasonal timing of pollen release (high confidence). Another driver of future pollen could be changing spatial patterns of vegetation as a result of climate change.

Regarding clean water supplies, extreme precipitation can overwhelm combined sewer systems and lead to overflow events that can threaten human health (Patz *et al.*, 2008). Conditional on a future increase in such events, we can anticipate increasing risks related to water-borne diseases.

Whether future warmer winters in the United States and Canada will promote transmission of diseases like dengue and malaria is uncertain, in part, because of access to amenities such as screening and air-conditioning that provide barriers to human-vector contact. Socio-economic factors also play important roles in determining risks. Better longitudinal datasets and empirical models are needed to address research gaps on climate-sensitive infectious diseases, as well as to provide a better mechanism for weighting the roles of external drivers such as climate change on a macro/micro scale, human-environmental changes on a regional to local scale, and extrinsic factors in the transmission of vector-borne infectious diseases (Wilson, 2009; McGregor, 2011).

26.6.3. Adaptation Responses

Early warning and response systems can be developed to build resilience to events like heat waves, storms and floods (Ebi, 2011) and protect susceptible populations, which include infants, children, the elderly, individuals with pre-existing diseases, and those living in socially and/or economically disadvantaged conditions (Pinkerton *et al.*, 2012). Adaptation planning at all scales to build resilience for health systems in the face of a changing climate is a growing priority (Kinney *et al.*, 2011).

Adaptation to heat events can occur via physiologic mechanisms, indoor climate control, urban-scale cooling initiatives, and with implementation of warning and response systems (Romero-Lankao *et al.*, 2012b). Additional research is needed on the extent to which warning systems prevent deaths (Harlan and Ruddell, 2011). Efforts to reduce GHG emissions could provide health co-benefits, including reductions in heat-related and respiratory illnesses (Health Chapter, US National Climate Assessment).

26.7. Key Economic Sectors and Services

There is mounting evidence that many economic sectors across North America have experienced climate impacts and are adapting to the risk of loss and damage from weather perils. This section covers the literature for the energy, transportation, mining, manufacturing, construction and housing, and insurance sectors in North America. Recent studies find a range of adaptive practices and adaptation responses to experience with extreme events, and only an emerging consideration of proactive adaptation in anticipation of future global warming.

26.7.1. Energy

26.7.1.1. Observed Impacts

Energy demand for cooling has increased as building stock and air conditioning penetration have increased (Wilbanks *et al.*, 2012). Extreme weather currently poses risk to the energy system (Wilbanks *et al.*, 2012). For example, Hurriacne Sandy results in a loss of power to 8.5 million customers in the Northeast US (National Oceanic and Atmospheric Administration, 2013). Energy consumption is a major user of water resources in North America, with 49% of the water withdrawals in the US for thermoelectric power (Kenny *et al.*, 2009).

26.7.1.2. Projected Impacts

Demand for summer cooling is projected to increase and demand for winter heating is projected to decrease. Total energy demand in North America is projected to increase in coming decades because of non-climate factors (Galindo, 2009; National Energy Board, 2011; Energy Information Administration, 2013). Climate change is projected to have varying geographic impacts. In Canada, a net decrease in residential annual energy demand is projected by 2050 and by 2100 (Isaac and Van Vuuren, 2009; Schaeffer *et al.*, 2012). It is difficult to project changes in net energy demand in the US because of uncertainties in such factors as climate change, and change in technology, population, and energy prices. Peak demand for electricity is projected to increase more than the average demand for electricity, with capacity expansion needed in many areas (Wilbanks *et al.*, 2012). Given the projected increases in energy demand in the southern United States from climate change (Auffhammer and Aroonruengsawat, 2011; Auffhammer and Aroonruengsawat, 2012) it is reasonable to conclude that Mexico will have a net increase in demand.

Major water resource related concerns include effects of increased cooling and other demands for water and water-scarcity in the west; effects of extreme weather events, sea-level rise, hurricanes, and seasonal droughts in the southeast; and effects of increased cooling demands in the northern regions (Wilbanks *et al.*, 2008; Wilbanks *et al.*, 2012; McDonald, 2012; U.S. Department of Energy, 2013) .

The magnitude of projected impacts on hydropower potential will vary significantly between regions and within drainage basins(Desrochers *et al.*, 2009; Shrestha *et al.*, 2012; Kienzle *et al.*, 2012). Annual mean hydropower production in the Peribonka River in Quebec is estimated to increase by approximately 10% by mid-century and 20% late in the century under the A2 scenario (Minville *et al.*, 2009).

Higher temperatures and increased climate variability can have adverse impacts on renewable energy production such as wind and solar (U.S. Department of Energy, 2013). Changing cloud cover affects solar energy resources, changes in winds affect wind power potentials, and temperature change and water availability can affect biomass production (Wilbanks *et al.*, 2008; U.S. Department of Energy, 2013) .

26.7.1.3. Adaptation

Many adaptations are underway to reduce vulnerability of the energy sector to extreme climate events such as heat, drought, and flooding (U.S. Department of Energy, 2013). Adaptation includes many approaches such as increased supply and demand efficiency (e.g., through more use of insulation), more use of urban vegetation and reflective surfaces, improved electric grid, reduced reliance on above ground distribution systems, and distributed power (Wilbanks *et al.*, 2012). Important barriers to adaptation include uncertainty about future climate change, inadequate information on costs of adaptation, lack of climate resilient energy technologies, and limited price signals (U.S. Department of Energy, 2013). Strategies resulting in energy demand reduction would reduce greenhouse gas emissions and reduce the vulnerability of the sector to climate change.

26.7.2. Transportation

26.7.2.1. Observed Impacts

Much of the transportation infrastructure across North America is aging, or inadequate (Mexico) which may make it more vulnerable to damage from extreme events and climate change. Approximately 11% of all US bridges are structurally deficient, 20% of airport runways are in fair or poor condition, and more than half of all locks are more than 50 years old (US Department of Transportation 2013). More than US$2 trillion is needed to bring infrastructure in the US up to “good condition” (American Society of Civil Engineers, 2009) p. 6. Canadian infrastructure had an investment deficit of C$125 billion in the 1980s and 1990s (Mirza and Haider, 2003).

Some transportation systems have been harmed (Figure 26-2). For example, in 2008, Hurricane Ike caused $2.4 billion in damages to ports and waterways in Texas. (McDonald, 2012). The “superflood” in Tennessee and Kentucky in 2010 caused $2.3 billion in damage (National Oceanic and Atmospheric Administration, 2013).

Hurricane Sandy resulted in flooding of portions of New York City’s subway system, overtopping of runways at La Guardia airport, and caused $400 million in damage to the New Jersey transit system (National Oceanic and Atmospheric Administration, 2013).

26.7.2.2. Projected Impacts

Scholarship on projected climate impacts on transportation infrastructure focuses mostly on US and Canada. Increases in high temperatures, intense precipitation, drought, sea level, and storm surge could affect transportation across the United States. The greatest risks would be to coastal transportation infrastructure, but there could be benefits to marine and lake transportation in high latitudes from less ice cover (Transportation Research Board, 2008). A 1-meter sea level rise combined with a 7-meter storm surge could inundate over half of the highways, arterials, and rail lines in the US Gulf coast (Savonis *et al.*, 2008). Declining water levels in the Great Lakes would increase shipping costs by restricting vessel drafts and reducing vessel cargo volume (Millerd, 2011). In southern Canada by the 2050s, cracking of roads from freeze and thaw would decrease under the B2 and A2 scenarios, structures would freeze later and thaw earlier, while higher extreme temperatures could increase rutting (Mills *et al.*, 2009) and related maintenance and rehabilitation costs (Canadian Council of Professional Engineers, 2008).

A 1 to 1.5°C increase in global mean temperature would increase the costs of keeping paved and unpaved roads in the United States in service by, respectively, US$2 to US$3 billion per year by 2050 (Chinowsky *et al.*, 2013). Tens of thousands to more than 100,000 bridges in the US could be vulnerable to increasing peak river flows in the mid- and late-21st Century under the A1B and A2 scenarios. Strengthening vulnerable bridges to be less vulnerable to climate change is estimated to cost approximately US$100 to $250 billion (Wright *et al.*, 2012).

26.7.2.3. Adaptation

Adaptation steps are being taken in North America, particularly to protect transportation infrastructure from sea level rise and storm surge in coastal regions. Almost all of the major river and bay bridges destroyed by Hurricane Katrina surge waters were rebuilt at higher elevations, and the design of the connections between the bridge decks and piers were strengthened (Grenzeback and Luckmann, 2006).

Adaptation actions include protecting coastal transportation from sea level rise and more intense coastal storms or possibly relocating infrastructure. Many Midwestern states are examining channel protection and drainage designs, while transportation agencies in Canada and the United States have been preparing to manage the aftermath of extreme weather events (Meyer *et al.*, 2013). In addition, new materials may be needed so pavement and rail lines can better withstand more extreme temperatures.

26.7.3. Mining

26.7.3.1. Observed Impacts

Climatic sensitivities of mining activities, including exploration, extraction, processing, operations, transportation and site remediation, have been noted in the limited literature (Chiotti and Lavender, 2008; Furgal and Prowse, 2008; Meza-Figueroa *et al.*, 2009; Ford *et al.*, 2010a; Locke *et al.*, 2011; Gómez-álvarez *et al.*, 2011; Kirchner *et al.*, 2011; Pearce *et al.*, 2011; Stratos Inc, 2011). Drought-like conditions have affected the mining sector by limiting water supply for operations (Pearce *et al.*, 2011), enhancing dust emissions from quarries (Pearce *et al.*, 2011) and increasing concentrations of heavy metals in sediments (Gómez-álvarez *et al.*, 2011). Heavy precipitation events have caused untreated mining wastewater to be flushed into river systems (Pearce *et al.*, 2011). High loads of contamination (from metals, sulfate and acid) at three mine sites in the United States were measured during rainstorm events following dry periods (Nordstrom, 2009).

26.7.3.2. Projected Impacts

Climate change is perceived by Canadian mine practitioners as an emerging risk, and in some cases, a potential opportunity (Ford *et al.*, 2010a; Ford *et al.*, 2011; Pearce *et al.*, 2011; National Round Table on the Environment and the Economy, 2012), with potential impacts on transportation (Ford *et al.*, 2011) and limited water availability (Acclimatise, 2009) from projected drier conditions (Sun *et al.*, 2008; Seager and Vecchi, 2010) being identified as key issues.

An increase in heavy precipitation events projected for much of North America (Warren and Egginton, 2008; Nordstrom, 2009) would adversely affect the mining sector. A study on acid rock damage drainage in Canada concluded that an increase in heavy precipitation events presented a risk of both environmental impacts and economic costs (Stratos Inc, 2011) Damage to mining infrastructure from extreme events, for active and post-operation mines, is also a concern (Pearce *et al.*, 2011). Climate change impacts that affect the bottom-line of mining companies (through direct impacts or associated costs of adaptation), would have consequences for employment, for both the mining sectors and local support industries (Backus *et al.*, 2013).

26.7.3.3. Adaptation

Despite increasing awareness, there are presently few documented examples of proactive adaptation planning within the mining sector (Acclimatise, 2009; Ford *et al.*, 2010a; Ford *et al.*, 2011). However, adjustments to management practices to deal with short-term water shortages, including reducing water intake, increasing recycling and establishing infrastructure to move water from tailing ponds, pits and quarries, have worked successfully in the past (Chiotti and Lavender, 2008). Integrating climate change considerations at the mine planning and design phase increases the opportunity for effective and cost-efficient adaptation (Stratos Inc, 2011).

26.7.4. Manufacturing

26.7.4.1. Observed Impacts

There is little literature focused on climate change and manufacturing, although one study suggested that manufacturing is among the most sensitive sectors to weather in the US (Lazo *et al.*, 2011). Weather affects the supply of raw material, production process, transportation of goods, and demand for certain products. In 2011, automobile manufacturers in North America experienced production losses associated with shortages of components due to flooding in Thailand (Newswire, 2011). In 2013, reduced cattle-supply and higher feed prices associated with drought in Texas led to a decision to close a beef processing plant (Beef Today Editors, 2013). Drought also caused delays for barge shipping on the Mississippi River in 2012 (Reuters, 2012). Major storms, like Hurricanes Sandy, Katrina and Andrew, significantly disrupted manufacturing activities, including plant shutdowns due to direct damages and/or loss of electricity and supply disruptions due to unavailability of parts, and difficulties delivering products due to compromised transportation networks (Baade *et al.*, 2007; Dolfman *et al.*, 2007).

26.7.4.2. Projected Impacts

The drier conditions (Sun *et al.*, 2008; Seager and Vecchi, 2010; Wehner *et al.*, 2011) would present challenges, especially for manufacturers located in regions already experiencing water stress. This could lead to increased conflicts over water between sectors and regions, and affect the ability of regions to attract new facilities or retain existing operations. A study of the effect of changes in precipitation (A1B scenario) on 70 industries in the US between 2010 and 2050 found potentially significant losses in production and employment due to declines in water availability and the interconnectedness of different industries (Backus *et al.*, 2013).

Another potential concern for manufacturing relates to impacts of heat on worker safety and productivity. Several studies suggest that higher temperatures and humidity would lead to decreased productivity and increased occupational health risks (e.g., Kjellstrom *et al.*, 2009; Hanna *et al.*, 2011; Kjellstrom and Crowe, 2011).

26.7.4.3. Adaptation

Some companies are beginning to recognize the risks climate change presents to their manufacturing operations, and consider strategies to build resilience (National Round Table on the Environment and the Economy, 2012). Coca Cola has a water stewardship strategy focusing on improving water use efficiency at its manufacturing plants, while Rio Tinto Alcan is assessing climate change risks for their operations and infrastructure, which include vulnerability of transport systems, increased maintenance costs, and disruptions due to extreme events (National Round Table on the Environment and the Economy, 2012). Air conditioning is a viable and effective adaptation option to address some of the impacts of warming, though it does incur greater demands for electricity and additional costs (Scott *et al.*, 2008a). Sourcing raw materials from different regions and relocating manufacturing plants are other adaptation strategies that can be used to increase resiliency and reduce vulnerability.

26.7.5. Construction and Housing

26.7.5.1. Observed Impacts

The risk of damage from climate change is important for construction industries, though little research has systematically explored the topic (Morton *et al.*, 2011). Private data from insurance companies report a significant increase in severe weather damage to buildings and other insured infrastructure over several decades (Munich Re, 2012).

26.7.5.2. Projected Impacts

Most studies project a significant further increase in damage to homes, buildings and infrastructure (Bjarndadottir *et al.*, 2011; IPCC, 2012). Affordable adaptation in design and construction practices could reduce much of the risk of climate damage for new buildings and infrastructure, involving reform in Building Codes and other standards (Feltmate and Thistlethwaite, 2012). However, adaptation best practices in design and construction are often prohibitively expensive to apply to existing buildings and infrastructure, so much of the projected increase in climate damage risk involves existing buildings and infrastructure.

26.7.5.3. Adaptation

Engineering and construction knowledge exists to design and construct new buildings to accommodate the risk of damage from historic extremes and anticipated changes in severe weather (Kelly, 2010; Ministry of Municipal Affairs and Housing, 2011; Insurance Institute for Business and Home Safety, 2012). Older buildings may be retrofit to increase resilience, but these changes are often more expensive to introduce into an existing structure than if they were included during initial construction.

The housing and construction industries have made advances toward climate change mitigation by incorporating energy efficiency in building design (Heap, 2007). Less progress has been made in addressing the risk of damage from extreme weather events (Kenter, 2010). In some markets, like the Gulf Coast of the United States, change is under way in the design and construction of new homes in reaction to recent hurricanes (Levina *et al.*, 2007; Kunreuther and Michel-Kerjan, 2009; Insurance Institute for Business and Home Safety, 2011), but in most markets across North America there has been little change in building practices. The cost of adaptation measures combined with limited long-term liability for future buildings has influenced some builders to take a wait-and-see attitude (Morton *et al.*, 2011). Exploratory work is under way to consider implementation of building codes that would focus on historic weather experience and also introduce expected future weather risks (Auld *et al.*, 2010; Ontario Ministry of Environment, 2011).

26.7.6. Insurance

26.7.6.1. Observed Impacts

Property insurance and reinsurance companies across North America experienced a significant increase in severe weather damage claims paid over the past three or four decades(Cutter and Emrich, 2005; Munich Re, 2011; Bresch and Spiegel, 2011). Most of the increase in insurance claims paid has been attributed to increasing exposure of people and assets in areas of risk (Pielke Jr *et al.*, 2008; Barthel and Neumayer, 2012). A role for climate change has not been excluded, but the increase to date in damage claims is largely due to growth in wealth and population (IPCC, 2012).

Severe weather and climate risks have emerged over the past decade as the leading cost for property insurers across North America, resulting in significant change in industry practices. The price of insurance increased in regions where the risk of loss and damage has increased. Discounts have been introduced where investments in adaptation have reduced the risk of future weather losses (Mills, 2012). Further detailed discussion on the insurance sector and climate change can be found in section 10.7.

26.7.6.2. Projected Impacts

Without adaptation, there is an expectation that severe weather insurance damage claims would increase significantly over the next several decades across North America (World Bank, 2010). The risk of damage is expected to rise due to continuing growth in wealth, the population living at risk, and climate change. There is also an expectation that some weather perils in North America will increase in severity, including Atlantic hurricanes and the area burned by wildfire (Karl *et al.*, 2008; Balshi *et al.*, 2009), and other perils in frequency, including intense rainfall events (IPCC, 2012).

26.7.6.3. Adaptation

The insurance industry is one of the most studied sectors in North America in terms of climate impacts and adaptation. Most adaptation in the insurance industry has been in response to an increase in severe weather damage, with little evidence of proactive adaptation in anticipation of future climate change (Mills and Lecomte, 2006; Mills, 2007; Mills, 2009; Kunreuther and Michel-Kerjan, 2009; Leurig, 2011; Autorite des Marches Financiers, 2011; Gallagher, 2012). In addition to pricing decisions based on an actuarial analysis of historic loss experience, many insurance companies in the United States and Canada now use climate model information to help determine the prices they charge and discounts they offer. Most insurance companies have established specialized claims handling procedures for responding to catastrophic events (Kovacs, 2005; Mills, 2009).

A recent study of more than 2,000 major catastrophes since 1960 found that insurance is a critical adaptive tool available to help society minimize the adverse economic consequences of natural disasters (von Peter *et al.*, 2012). Government insurance programs for coverage of flood in the United States have been affected by recent hurricanes and previously subsidized premiums have been changed to more accurately reflect risk (Federal Emergency Management Agency, 2013). In the United States and Canada, homeowners make extensive use of insurance to manage a broad range of risks, and those with insurance recover quickly following most extreme weather events. However the majority of public infrastructure is not insured and it frequently takes more than a decade before government services fully recover. In contrast, Mexico has a well-developed program for financing the rebuilding of public infrastructure following a disaster (FONDEN) but insurance markets are only beginning to emerge for homeowners and businesses. In 2012, per capita spending on property and casualty insurance was US$2,239.20 in the United States, US$2,040.40 in Canada, and US$113.00 in Mexico (Seiler *et al.*, 2013).

Insurance companies are also working to influence the behavior of their policyholders to reduce the risk of damage from climate extremes (Kovacs, 2005; Anderson *et al.*, 2006; Mills, 2009). For example, the industry supports the work of the Insurance Institute for Business and Home Safety in the United States, and the Institute for Catastrophic Loss Reduction in Canada, in working to champion change in the building code and communicate to property owners, governments and other stakeholders best practices for reducing the risk of damage from hurricanes, tornadoes, winter storms, wildfire, flood and other extremes.

26.8. Urban and Rural Settlements

Recently a growing body of literature and national assessments have focused on climate-related impacts, vulnerabilities and risks in North American settlements (e.g., US-NCA chapters 11 and 14 and AR5 chapters 8 and 9).

26.8.1. Observed Weather and Climate Impacts

Observed impacts on lives, livelihoods, economic activities, infrastructure and access to services in North American human settlements have been attributed to sea level rise (26.2.2.1), changes in temperature and precipitation, and occurrences of extreme events like heat waves, droughts and storms (Figure 26-2).

Only a handful of these impacts have been attributed to anthropogenic climate change, such as shifts in Pacific Northwest marine ecosystems, which have restricted fisheries and thus affected fishing communities (U.S. Global Change Research Program, 2009). As well, (MacKendrick and Parkins, 2005; Parkins and MacKendrick, 2007; Parkins, 2008; Holmes, 2010) identified 30 communities and 25,000 families in British Columbia negatively affected by the mountain pine beetle outbreak (See 26.4.1.1).

While *droughts* are among the more notable extreme events affecting North American urban and rural settlements recently, with severe occurrences in the Canadian Prairies causing economic and employment losses (2001-2), changes in drought frequency in North America have not been attributed to anthropogenic climate change (Figure 26-1). The 2010-2012 drought across much of the US and Northern Mexico was considered the most severe in a century (MacDonald, 2010). It affected 80% of agricultural land in the US, with 2,000 counties designated disaster zones by September (U.S. Department of Agriculture, Economic Research Service, 2012). Impacts include the loss of 3.2 million tons of maize in Mexico, placing 2.5 million at risk of food insecurity (Direccion General de Comunicacion Social, 2012). Among the most severely affected were indigenous peoples, such as the Rarámuri of Chihuahua (ibid.). Closely associated with droughts, the impacts of recent wildfires have been significant (See Box 26.2), and have intensified inequalities in vulnerability between amenity migrants and low-income residents in peri-urban areas of California and Colorado (Collins and Bolin, 2009).

Other extreme-events include *heat-waves*, resulting in excess urban mortality (O'Neill and Ebi, 2009; Romero-Lankao *et al.*, 2012b); and affecting infrastructure and built environments –e.g., road pavement in Chicago buckled under temperatures over 100^{o}F (CBS Chicago, 2012); in Colorado two wildfires burned over 600 homes (National Climate Data Center, 2013).

Extreme storms and extreme precipitation have also impacted several North American regions (Figures 26-1 and 26-2). Flood frequency has increased in some cities, a trend sometimes associated with more intense precipitation (e.g., Mexico City and Charlotte NC, US) (Villarini *et al.*, 2009; Magana, 2010), while in others this trend is associated with a transition from flood events dominated by snowmelt to those caused by warm-season thunderstorms (e.g., Québec, Canada and Milwaukee, US) (Ouellet *et al.*, 2012; Yang *et al.*, 2013). As illustrated by Sandy (Neria and Shultz, 2012; Powell *et al.*, 2012), storms impact human health and healthcare access (section 26.6.1.1), and impacts on infrastructure and the built environment have been costly. Heavy precipitation, storm surges, flash-floods and wind, including flooding on the US East Coast, and Midwest (2011), hurricanes and floods in the city of Villa Hermosa (Comisión Económica para América Latina y el Caribe,) and other urban areas in southern Mexico (2004-5), have compromised homes and businesses (Comfort, 2006; Kirshen *et al.*, 2008; Jonkman *et al.*, 2009; Romero-Lankao, 2010). Hurricane Wilma alone caused $1.8 billion in damage, among the biggest insurance losses in Latin American history (Galindo *et al.*, 2009).

The impacts of interacting hazards compound vulnerabilities (26.8.2). Coastal settlements are at risk from the combined occurrence of coastal erosion, health effects, infrastructure and economic damage from storm surges. Earlier thaw (Friesinger and Bernatchez, 2010), SLR, and coastal flooding have been detected along the mid-Atlantic, Gulf of Mexico, and St. Lawrence (Kirshen *et al.*, 2008; Zavala-Hidalgo *et al.*, 2010; Friesinger and Bernatchez, 2010; Rosenzweig *et al.*, 2011; Tebaldi *et al.*, 2012).

Climate impacts on the ecosystem-function and -services (e.g., water supplies, biodiversity or flood protection) provided to human settlements are another concern. While acknowledged in some places (e.g., Mexico City Climate Action Plan), they have received relatively less scholarship attention (Hunt and Watkiss, 2011).

26.8.2. Observed Factors and Processes Associated with Vulnerability

Differences in the severity of climate impacts on human settlements are strongly influenced by context-specific vulnerability factors and processes (Table 26.1, Cutter *et al.*, 2013), some of which are common to many settlements, while others are more pertinent to some types of settlements than others. Human settlements simultaneously face a multilevel array of non-climate-related hazards (e.g., economic, industrial, technological) that contribute to climate change vulnerability (McGranahan *et al.*, 2007; Satterthwaite *et al.*, 2007; Romero-Lankao and Dodman, 2011). In the following we highlight key sources of vulnerability for urban and rural systems.

26.8.2.1. Urban Settlements

Hazard risks in urban settlements are enhanced by the *concentration* of populations, economic activities, cultural amenities and built environments particularly when they are in highly-exposed locations such as coastal and arid areas. Cities of concern include those in the Canadian prairies and US-Mexico border region; and major urban areas including Boston, New York, Chicago, Washington DC, Los Angeles, Villa Hermosa, Mexico City and Hermosillo (Comisión Económica para América Latina y el Caribe; Bin *et al.*, 2007; Collins, 2008; Kirshen *et al.*, 2008; Collins and Bolin, 2009; Gallivan *et al.*, 2009; Rosenzweig *et al.*, 2010; Hayhoe *et al.*, 2010; Romero-Lankao, 2010; Wittrock *et al.*, 2011).

Risks may also be heightened by *multiple interacting hazards*. Slow-onset events such as urban heat-islands, for instance, interact with poor air-quality in large North American cities to exacerbate climate impacts on human health (Romero-Lankao *et al.*, 2013a). As illustrated by recent weather events (Figure 26.2), however, hazard interactions can also follow individual, high-magnitude extreme events of short duration, with cascading effects across interconnected energy, transportation, water and health infrastructures and services to contribute to and compound urban vulnerability (Gasper *et al.*, 2011). Wildfire vulnerability in the southwest has been compounded by peri-urban growth (Collins and Bolin, 2009; Brenkert-Smith, 2010). Under current financial constraints in many cities, climate-related economic losses can reduce resources available to address social issues, thus threatening institutional capacity and urban livelihoods (Kundzewicz *et al.*, 2008).

The *urbanization process* and *urban built-environments* of North America can amplify climate impacts as they change land-use and land-surface physical characteristics (e.g., surface albedo, Chen *et al.*, 2011a). A 34% increase in US urban land development (Alig *et al.*, 2004) between 1982 and 1997 had implications for water supplies and extreme event impacts. Effects on water are of special concern (section 26.3), as urbanization can enhance or reduce precipitation, depending on climate regime, geographical location and regional patterns of land, energy and water use (Cuo *et al.*, 2009). Urbanization also has significant impacts on flood climatology through atmospheric processes tied to the Urban Heat Island (UHI), the Urban Canopy Layer (UCL), and the aerosol composition of airsheds (Ntelekos *et al.*, 2010). The UHI can also increase health risks differentially, due to socio-spatial inequalities across and within North American cities (Harlan *et al.*, 2008; Miao *et al.*, 2011).

Urbanization imposes path dependencies that can amplify or attenuate vulnerability (Romero-Lankao and Qin, 2011). For example, the overexploitation of Mexico City's aquifer by 19.1 - 22.2 m^3/s has reduced groundwater levels and caused subsidence, undermining building foundations and infrastructure and increasing residents' vulnerability to earthquakes and heavy rains (Romero-Lankao, 2010).

Elements of the *built-environment* such as housing stock, urban form, the condition of water and power infrastructures, and changes in urban and ecological services also affect vulnerability. Large, impermeable surfaces and buildings disrupt drainage channels and accelerate run-off (Walsh *et al.*, 2005). Damage from floods can be much more catastrophic if drainage or waste collection systems are inadequate to accommodate peak flows

(Richardson, 2010; Sosa-Rodriguez, 2010). While many Canadian and US cities are in need of infrastructure adaptation upgrades (Doyle *et al.*, 2008; Conrad, 2010), Mexican cites are faced with existing infrastructure deficits (Niven *et al.*, 2010; Hardoy and Romero Lankao, 2011), and high levels of socio-spatial segregation (Smolka and Larangeira, 2008) (section 26.7).

Recent weather hazards (Figure 26-2) illustrate that economic activities and highly-valued physical capital of cities (real estate, interconnected infrastructure systems) are very sensitive to climate-related disruptions that can result in high impacts; activities in some urban areas are particularly exposed to key resource constraints (e.g., water in the US-Mexico Border; oil industry in Canada, US and Mexico; Levy et al., 2010; Conrad, 2010); others are dependent upon climate-sensitive sectors (e.g., tourism) (Lal *et al.*, 2011). Disruptions to production, services and livelihoods, and changes in the costs of raw materials also impact the economic performance of cities (Hunt and Watkiss, 2011).

Cities are relatively better endowed than rural populations with individual and neighborhood assets such as income, education, quality of housing and access to infrastructure and services that offer protection from climate hazards. However, intra-urban socio-spatial differences in access to these assets shape response capacities (Harlan and Ruddell, 2011; Romero-Lankao *et al.*, 2013a). All this means that class and socio-spatial segregation are key determinants not only of vulnerability but also of inequalities in risk generation and distribution within cities. Economic elites are better positioned to access the best land and enjoy the rewards of environmental amenities such as clean air, safe drinking water, open space, and tree shade (Morello-Frosch *et al.*, 2002; Harlan *et al.*, 2006; Harlan *et al.*, 2008; Ruddell *et al.*, 2011). Although wealthy sectors are moving into risk prone coastal and forested areas (Collins, 2008), and certain hazards (air pollution) affect both rich and poor alike (Romero-Lankao *et al.*, 2013a), climate risks tend to be disproportionally borne by the poor or otherwise marginalized populations (Cutter *et al.*, 2008; Collins and Bolin, 2009; Romero-Lankao, 2010; Wittrock *et al.*, 2011). In some cities, marginalized populations are moving to peri-urban areas with inadequate services, a portfolio of precarious livelihood mechanisms, and inappropriate risk-management institutions (Collins and Bolin, 2009; Eakin *et al.*, 2010; Monkkonen, 2011; Romero-Lankao *et al.*, 2012a).

Although cities have comparatively higher access than rural municipalities to determinants of institutional capacity such as human resources and revenue pools, their governance arrangements are often hampered by jurisdictional conflicts, asymmetries in information and communication access, fiscal constraints on public services including emergency personnel, and top-down decision making. These governance issues exacerbate urban vulnerabilities and constrain urban adaptation planning (Carmin *et al.*, 2012; Romero-Lankao *et al.*, 2013a).

26.8.2.2. Rural Settlements

The legacy of previous and current stresses contributing to rapid population growth or loss in North American rural communities, reduced employment, or degradation of local knowledge systems, can increase vulnerability (Brklacich *et al.*, 2008; Coles and Scott, 2009; McLeman, 2010). North American rural communities have a higher proportion of lower income and unemployed populations and higher poverty than cities (Whitener and Parker, 2007; Lal *et al.*, 2011; Skoufias *et al.*, 2011). 55% of Mexico's rural residents live in poverty, and the livelihood of 72% of these is in farming (Saldaña-Zorrilla, 2008). US and Canadian rural communities have older populations (McLeman, 2010) and lower education levels (Lal *et al.*, 2011). Indigenous communities have lower education levels, and high levels of poverty, but are younger than average populations (Downing and Cuerrier, 2011). The legacy of their colonial history, furthermore, has stripped Indigenous communities of land and many sources of social and human capital (Brklacich *et al.*, 2008; Hardess *et al.*, 2011). Conversely, rural and indigenous community members possess valuable local and experiential knowledge regarding regional ecosystem services (Nakashima *et al.*, 2011).

Rural economies have limited economic diversity and relatively high dependence on climate-sensitive sectors (Johnston *et al.*, 2008; Natural Resources Canada, 2008; Molnar, 2010); they are sensitive to climate-induced reductions in resource supply and productivity, in addition to direct exposure to climate hazards (Daw *et al.*, 2009). Single-sector economic dependence contributes significantly to vulnerability (Cutter *et al.*, 2003). Engagement in export markets presents opportunity but also exposure to economic volatility (Eakin, 2006; Saldaña-Zorilla and Sandberg, 2009), and economic downturns take attention away from climate change adaptation. Farming and fishing provide both economic and food security, the impacts of climate thus posing a double threat to livelihood (Badjek *et al.*, 2010), particularly among women (Bee *et al.*, 2013). Inter-related factors affecting vulnerability in forestry and fishing communities include over-harvesting, and the cumulative environmental effects of multiple land use activities (Brklacich *et al.*, 2008). Many tourism-based communities are dominated by seasonal economies and low-wage, service-based employment (Tufts, 2010), and small businesses that lack resources for emergency planning (Hystad and Keller, 2006; Hystad and Keller, 2008). Non-renewable resource industries are sensitive to power, water, and transportation disruptions associated with hazards.

Geographic isolation can be a key source of vulnerability for rural communities in North America, imposing long commutes to essential services like hospitals, and non-redundant transportation corridors that can be compromised during extreme events (Chouinard *et al.*, 2008). Many Indigenous communities are isolated, raising the costs and limiting the diversity of imported food, fuel and other supplies, rendering the ability to engage in subsistence harvesting especially critical for both cultural and livelihood wellbeing (Andrachuk and Pearce, 2010; Hardess *et al.*, 2011). Many indigenous peoples also maintain strong cultural attachment to ancestral lands, and thus are especially sensitive to declines in the ability of that land to sustain their livelihoods and cultural wellbeing (Downing and Cuerrier, 2011).

Rural physical infrastructure is often inadequate to meet service needs or is in poor condition (McLeman and Gilbert, 2008; Krishnamurthy *et al.*, 2011), especially for Indigenous communities (section 26.9, Brklacich *et al.*, 2008; Hardess *et al.*, 2011; Lal *et al.*, 2011). A lack of redundant power and communication services can compromise hazard response capacity.

26.8.3. Projected Climate Risks on Urban and Rural Settlements

Urbanization, migration, economic disparity, and institutional capacity will influence future impacts and adaptation to climate change in North American human settlements (section 26.2.1). Water related concerns are assessed in 26.3.2.1 and 26.3.2.3). We describe below a variety of future climate risks identified in the literature, many of which focus on cities (Chapters 8 and 9) and, with the exception of larger centers such as New York and Boston, are qualitative in nature (Hunt and Watkiss, 2011). This is due in part to the difficulty in downscaling the prediction of trends in key trends in climate parameters to an appropriate scale

Model-based *sea-level-rise* (SLR) projections of future risks to cities are characterized by large uncertainties due to global factors (e.g., the dynamics of polar ice-sheets WGI) and regional factors (e.g., regional shifts in ocean circulation, high of the adjacent ocean and local land high) (Blake *et al.*, 2011) (WGI chapter 3). The latter will determine differential SLR impacts on regional land development of coastal settlements (U.S. Government Accountability Office, 2007; Yin *et al.*, 2009; Sobel *et al.*, 2010; Conrad, 2010; Millerd, 2011), making some areas particularly vulnerable to inundation (Cooper and Sehlke, 2012). SLR can also exacerbate vulnerability to extreme events such as hurricanes (Frazier *et al.*, 2010).

Temperature increases would lead to additional health hazards. Baseline warmer temperatures in cities are expected to be further elevated by extreme heat events whose intensity and frequency is projected to increase during the 21st century (section 26.2.2), particularly in northern mid-latitude cities (Jacob and Winner, 2009). Participation in some outdoor activities would also increase as a result of projected increases in warm days (Scott and McBoyle, 2007). Projected snowfall declines in Canada and the Northeast US would reduce length of winter sport seasons and thus affect the economic wellbeing of some communities (McBoyle *et al.*, 2007; Scott *et al.*, 2008b).

Any increase in frequency of *extreme events*, such as intense precipitation, flooding and prolonged dry periods would affect particularly the populations, economic activities, infrastructures and services on coasts, flood-prone deltas and arid regions (Nicholls *et al.*, 2008; Kirshen *et al.*, 2008; Richardson, 2010; Weiss *et al.*, 2011). For example, by the end of this century, New York City is projected to experience nearly twice as many extreme precipitation days compared to today (A2, mean ensemble of 17 models). (Ntelekos *et al.*, 2010; Cayan *et al.*, 2010) project an increase in the number and duration of droughts in the southwest US, with most droughts expected to last over five years by 2050 (GDFL CM2.1 and CNRM CM3, A2 and B1). Assuming no adaptation, total loses from river flooding in metropolitan Boston are estimated to exceed $57 billion by 2100, of which $26 billion is attributed to climate change (Nicholls *et al.*, 2008; Kirshen *et al.*, 2008; Richardson, 2010; Weiss *et al.*, 2011).

Future climate risks on *lives and livelihoods* have been relatively less studied. A handful of studies focused on forestry are notable, indicating potentially substantial shifts in livelihood options without adaptation. Sohngen and Sedjo (Sohngen and Sedjo, 2005) estimate losses from climate change in the Canadian/US timber sector of $1.4 – $2.1 billion per year over the next century. Anticipated future supply reductions in British Columbia as a consequence of the pine beetle outbreak vary from 10 to 62% (Patriquin *et al.*, 2007). Substantial declines in suitable habitat for valued tree species in Mexico have been projected (Gómez-Mendoza and Arriaga, 2007; Gomez-Diaz *et al.*, 2011).

Scholars are starting to project future risks from interacting hazards. For instance, by 2070 with a 0.5m rise in sea-level and under scenarios of socioeconomic growth, storm surges and subsidence, populations at risk in New York, Miami and New Orleans might increase three-fold, while asset exposure will increase more than 10-fold (Hanson *et al.*, 2011).

Essential *infrastructure and services* are key concerns (sections 26.3 and 26.7). Increased occurrence of drought affecting water availability is projected for southwestern US/Northern Mexico, the southern Canadian Prairies and central Mexico, combined with projected increases in water demand due to rapid population growth and agriculture (Schindler and Donahue, 2006; MacDonald, 2010; Lal *et al.*, 2011). Using A1B and A2 scenarios, (Escolero-Fuentes *et al.*, 2009) projected that by 2050, Mexico City and its watersheds will experience a more intense hydrological cycle and a reduction of between 10 to 17% in per capita available water. Sea-level rise is predicted to threaten water and electricity infrastructure with inundation and increasing salinity (Sharp, 2010).

26.8.4. Adaptation

26.8.4.1. Evidence of Adaptation

26.8.4.1.1. What are populations doing? Autonomous Adaptation

As illustrated by recent extreme events (Figure 26-2), individuals and households in North America have not only be affected by extremes, but have also been responding to climate impacts mostly through incremental actions, for example by purchasing additional insurance, or reinforcing homes to withstand extreme weather (Simmons and Sutter, 2007; Romero-Lankao *et al.*, 2012a). Some individuals respond by diversifying livelihoods (Newland *et al.*, 2008; Rose and Shaw, 2008) or migrating (See 26.1.1) (Black *et al.*, 2011).

The propensity to respond to climate and weather hazards is strongly influenced not only by access to household assets, but also by community and governmental support. The emergency response to Sandy illustrates this. Although New York and New Jersey witnessed vivid scenes of 'medical humanitarianism,' because of inadequate communication and coordination among agencies, public health support did not always reach those most in need (Abramson and Redlener, 2013).

The perceived risks of climate change among individuals are equally important. Strong attachment to place and occupation may motivate willingness to support incremental adaptation, enhance coping capacity and foster adaptive learning (Collins and Bolin, 2009; Romero-Lankao, 2010; Aguilar and Santos, 2011; Wittrock *et al.*, 2011). They have also been found to serve as barriers to transformational adaptation (Marshall *et al.*, 2012). Residents of the US stand out in international research as holding lower levels of perceived risk of climate change (AXA Ipsos, 2012), which may limit involvement in household-level adaptation, or support for public investments in adaptation.

26.8.4.1.2. What are governments doing? Planned Adaptation

Leadership in adaptation is far more evident locally than at other tiers of government in North America (Richardson, 2010; Vasseur, 2011; Vrolijks *et al.*, 2011; Henstra, 2012; Carmin *et al.*, 2012). Few municipalities have moved into the implementation stage, however; most programs are in the process of problem diagnosis and planning (Perkins *et al.*, 2007; Moser and Satterthwaite, 2008; Romero-Lankao and Dodman, 2011). Systematic assessments of vulnerability are rare, particularly in relation to population groups (Vrolijks *et al.*, 2011). Surveys of municipal leaders showed adaptation is rarely incorporated into planning, due to lack of resources, information and expertise (Horton and Richardson, 2011), and the prevalence of other issues considered higher priority, suggesting the need for subnational and federal-level facilitation in the form of resources and enabling regulations .

Climate change policies have been motivated by concerns for local economic or energy security and the desire to play leadership roles (Rosenzweig *et al.*, 2010; Anguelovski and Carmin, 2011; Romero-Lankao *et al.*, 2013a). Some policies constitute "integrated" strategies (New York) (Perkins *et al.*, 2007; Rosenzweig *et al.*, 2010), and coordinated participation of multiple municipalities (Vancouver) (Richardson, 2010). Sector-specific climate risk management plans have also emerged (e.g., water conservation in Phoenix, US and Regina, Canada; wildfire protection in Kamloops, Canada and Boulder, US). Municipalities affected by the mountain pine beetle have taken many steps toward adaptation (Parkins, 2008), and coastal communities in eastern Canada are investing in saltwater marsh restoration to adapt to rising sea levels (Marlin *et al.*, 2007). Green roofs, forest thinning and urban agriculture have all been expanding (Chicago, New York, Kamloops, Mexico City), as have flood protection (New Orleans, Chicago), private and governmental insurance policies (section 26.10, Browne and Hoyt, 2000; Ntelekos *et al.*, 2010), safe saving schemes (common in Mexico), air pollution controls (Mexico City), and hazard warning systems (Collins and Bolin, 2009; Coffee *et al.*, 2010; Romero-Lankao, 2010; Aguilar and Santos, 2011).

26.8.4.2. Opportunities and Constraints

Adaptation in human settlements is influenced by local access to resources, political will and the capacity for institutional-level attention and multilevel/multisectoral coordination (Burch, 2010; Romero-Lankao *et al.*, 2013a) (discussed further in the next section).

26.8.4.2.1. Adaptation is path-dependent

Adaptation options are constrained by past settlement patterns and decisions. The evolution of cities as economic hubs, for example, affects vulnerability and resilience (Leichenko, 2011). Urban expansion into mountain, agricultural, protected and otherwise risk-prone areas (Boruff *et al.*, 2005; McGranahan *et al.*, 2007; Collins and Bolin, 2009; Conrad, 2010) invariably alters regional environments. Development histories foreclose some resilience pathways. Previous water development, for example, can result in irreversible overexploitation and degradation of water resources.

26.8.4.2.2. Institutional capacity

At all levels of governance, adaptation in North America is affected by numerous determinants of institutional capacity. Three have emerged in the literature as particularly significant challenges for urban and rural settlements:

- *Economic Resources:* Rural communities face limited revenues combined with higher costs of supplying services (Williamson *et al.*, 2008; Posey, 2009). Small municipal revenue pools translate into fiscal constraints necessary to support public services, including emergency personnel and health care (Lal *et al.*, 2011). Although large cities tend to have greater fiscal capacity, most do not receive financial support for adaptation (Carmin *et al.*, 2012), yet face the risk of higher economic losses.
- *Information and social capital:* Differences in access and use of information, and capacity for learning and innovation, affect adaptive capacity (Romero-Lankao *et al.*, 2013a). Levels of knowledge and prioritization can be low among municipal planners. Information access can be limited, even among environmental

planners (Picketts *et al.*, 2012). The relationship between trust and participation in support networks (social capital) and adaptive capacity is generally positive, however strong social bonds may support narratives that under-estimate climate risk (Wolf *et al.*, 2010; Romero-Lankao *et al.*, 2012b).

- *Participation:* Considering the overlap among impacts and sources of vulnerability in North American human settlements, long-term effectiveness of local adaptation hinges upon inclusion of all stakeholders. Stakeholder involvement lengthens planning time frames, may elicit conflicts, and power relationships can constrain access (Few *et al.*, 2007; Colten *et al.*, 2008). However, effective stakeholder engagement has tremendously enhanced adaptation planning, eliciting key sources of information regarding social values, securing legitimacy (Aguilar and Santos, 2011), and fostering adaptive capacity of involved stakeholders.

_____ START BOX 26-3 HERE _____

Box 26-3. Climate Responses in Three North American Cities

With populations of 20.5, 14 and 2.3 million people, respectively, the metropolitan areas of Mexico City, New York, and Vancouver are facing multiple risks that climate change is projected to aggravate. These risks range from sea level rise, coastal flooding and storm surges in New York and Vancouver to heat waves, heavy rains and associated flooding, air pollution, and heat-island effects in all the three cities (Rosenzweig and Solecki, 2010; Leon and Neri, 2010; City of Vancouver, 2012). Many of these risks result not only from long-term global and regional processes of environmental change, but also from local changes in land and water uses and in atmospheric emissions induced by urbanization (Romero-Lankao, 2010; Leon and Neri, 2010; Kinney *et al.*, 2011; Solecki, 2012).

The three cities have been frontrunners in the climate arena. In Mexico City, the Program of Climate Action 2008–2012 (PAC) and the 2011 Law for Mitigation and Adaptation to Climate Change are parts of a larger 15-year "Green Agenda," with most of designated funds committed to reducing 7 million tonnes of CO_2 equivalent by 2012 (Romero-Lankao *et al.*, 2013). New York City's and Vancouver's Plans are similarly mitigation-centred. As of 2007 New-York's long-term sustainability plan included adaptation (Solecki, 2012; Ray *et al.*, 2013), while Vancouver launched its municipal adaptation plan in July 2012. The shifts in focus from mitigation to adaptation have followed as it has become increasingly clear that even if mitigation efforts are wholly successful, some adverse impacts due to climate change are unavoidable.

Urban leaders in all three cities have emerged as global leaders in sustainability. Mayor Bloomberg of New York; Mayor Ebrard of Mexico City, and David Cadman of Vancouver have, respectively, led the C40, World Mayors Council on Climate Change and International Council for Local Environmental Initiatives (ICLEI). Scientists, private sector actors and nongovernmental organizations have been of no lesser importance. To take advantage of a broad-based interaction between various climate change actors, Mexico City has set up a Virtual Climate Change Centre to serve as a repository of knowledge, models and data on climate change impacts, vulnerability and risks (Romero-Lankao *et al.*, 2013). Information sharing by climate change actors has also taken place in New York, where scientists, and insurance and risk management experts have served on the Panel on Climate Change to advise the city on the science of climate change impacts and "protection levels specific to the city's critical infrastructure" (Solecki, 2012): 564).

The climate plans of the three cities are far reaching, including mitigation and adaptation strategies related to their sustainability goals. The three cities emphasize different priorities in their climate action plans. Mexico City seeks to reduce water and transportation emissions through such actions as improvements in infrastructure and changes in the share of public transport. Vancouver has prioritized the separation of sanitary and stormwater systems, yet this adaptation is not expected to be complete until 2050 (City of Vancouver, 2012). It will also take New York much time, money and energy to expand adaptation strategies beyond the protection of water systems to include all essential city infrastructure (Ray *et al.*, 2013). Overall, few proposed actions will result in immediate effects, and instead call for additional planning, highlighting the significant effort necessary for comprehensive responses.

Overall, adaptation planning in the three cities faces many challenges. In all three regions, multi-jurisdictional governance structures with differing approaches to climate change challenge the ability for coordinated responses (Solecki, 2012; Romero-Lankao *et al.*, 2013). Conflicts in priorities and objectives between various actors and sectors are also prevalent (Burch, 2010). For instance, authorities in Mexico City concerned with avoiding growth into risk-prone and conservation areas (Aguilar and Santos, 2011) compete for regulatory space within a policy agenda that is already coping with a wide range of economic and developmental imperatives (Romero-Lankao *et al.*, 2013).

Climate responses require new types of localized scientific information, such as vulnerability analyses and flood risk assessments, which are not always available (Romero-Lankao *et al.*, 2012a; Ray *et al.*, 2013). Little is known, for instance, about how to predict and respond to common and differential levels of risk experienced by different human settlements. Comprehensive planning is still limited as well. For example, although scholarship exists on disparities in household- and population-level vulnerability and adaptive capacity (Villeneuve and Burnett, 2003; Cutter *et al.*, 2003; Douglas *et al.*, 2012; Romero-Lankao *et al.*, 2013b), equity concerns have received relatively less attention by either of the three cities. Even when local needs are identified, such as the need to protect higher risk homeless and low-income populations (Vancouver), they are often not addressed in action plans.

_____ END BOX 26-3 HERE _____

26.9. Federal and Subnational Level Adaptation

Along with many local governments (section 26.8.4), federal, and subnational tiers of government across North America are developing climate change adaptation plans. These initiatives, which began at the subnational levels (e.g., (Nunavut Department of Sustainable Development, 2003), appear to be preliminary and relatively little has been done to implement specific measures.

26.9.1. Federal Level Adaptation

All three national governments are addressing adaptation to some extent, with a national strategy and a policy framework (Mexico), a federal policy framework (Canada), and the United States having delegated all federal agencies to develop adaptation plans.

In 2005, the Mexican government created the *Inter-Secretarial Commission to Climate Change* (CICC – Comisión Inter-Secretarial de Cambio Climático) to coordinate national public policy on climate change (Comisión Inter-Secretarial de Cambio Climático, 2005; Sosa-Rodriguez, 2013).The government's initiatives are being delivered through the *National Strategy for Climate Change 2007-2012* (Intersecretarial Commission on Climate Change, 2007) and, the *Special Programme on Climate Change 2009-2012*, which identify priorities in research, cross-sectoral action such as developing early warning systems, and capacity development to support mitigation and adaptation actions (Comisión Inter-Secretarial de Cambio Climático, 2009). The *Policy Framework for Medium Term Adaptation* (Consejo Intersecretarial de Cambio Climático, 2010) aims at framing a single national public policy approach on adaptation with a time-horizon up to 2030. The General Law of Climate Change requires state governments to implement mitigation and adaptation actions (Diario Oficial de la Federación, 2012).

Canada is creating a Federal Adaptation Policy Framework intended to mainstream climate risks and impacts into programs and activities to help frame government priorities (Environment Canada, 2011a). In 2007, the federal Government made a four-year adaptation commitment to develop six Regional Adaptation Collaboratives (RAC) in provinces across Canada, ranging in size and scope, from flood protection and drought planning, to extreme weather risk management; and assessing the vulnerability of Nunavut's mining sector to climate change (Natural Resources Canada, 2011). In 2011, the federal government renewed financial support for several adaptation programs and provided new funding to create a Climate Adaptation and Resilience Program for Aboriginals and Northerners, and Enhancing Competitiveness in a Changing Climate program (Environment Canada, 2011b). Canada recently launched an Adaptation Platform to advance adaptation priorities across the country (Natural Resources Canada, 2013).

The US government embarked in 2009 on a government-wide effort to have all federal agencies address adaptation; to apply understanding of climate change to agency missions and operations; to develop, prioritize, and implement actions; and to evaluate adaptations and learn from experience. (The White House, 2009; Bierbaum *et al.*, 2012). A 2013 plan issued by the President enhanced the US government effort supporting adaptation (Executive Office of the President, 2013). The US Government provides technical and information support for adaptation by non-federal actors, but does not provide direct financial support for adaptation (Parris *et al.*, 2010).

Some federal agencies took steps to address climate change adaptation prior to this broader interagency effort. In 2010, the US Department of Interior created Climate Science Centers to integrate climate change information and management strategies in eight regions and 21 Landscape Conservation Cooperatives (Secretary of the Interior, 2010), while the US Environmental Protection Agency's Office of Water developed a climate change strategy (U.S. Environmental Protection Agency, National Water Program, 2011).

26.9.2. Subnational Level Adaptation

A number of states and provinces in all three countries have developed adaptation plans. For example, in Canada, Quebec's 2013-2020 adaptation strategy outlines 17 objections covering a number of managed sectors and ecosystems (Government of Quebec, 2012). British Columbia is modernizing its *Water Act* to alter water allocation during drought to reduce agricultural crop and livestock loss and community conflict, while protecting aquatic ecosystems (British Columbia Ministry of the Environment, 2010).

In the US California was the first state to publish an adaptation plan calling for a 20% reduction in per capita water use by 2020 (California Natural Resources Agency, 2009). Maryland first developed a plan on coastal resources and then broadened it to cover human health, agriculture, ecosystems, water resources, and infrastructure (Maryland Commission on Climate Change Adaptation and Response Working Group, 2008; Maryland Department of the Environment on behalf of the Maryland Commission on Climate Change, 2010). The State of Washington is addressing environment, infrastructure, and communities; human health and security; ecosystems, species, and habitat; and natural resources (Washington State Built Environment: Infrastructure & Communities Topic Advisory Group, 2011; Washington State Human Health and Security Topic Advisory Group, 2011; Washington State Species, Habitats and Ecosystems Topic Advisory Group, 2011; Washington State Natural Resources Working Lands and Waters Topic Advisory Group, 2011).

Of the three national governments, only Mexico requires that states develop adaptation plans. In Mexico, seven of 31 states, Veracruz, Mexico City, Nuevo León, Guanajuato, Puebla, Tabasco, and Chiapas, have all developed their *State Programmes for Climate Change Action* (Programas Estatales de Acción ante el Cambio Climático - PEACC), while Baja California Sur, Hidalgo, and Campeche are in the final stage and 17 states are still in the planning and developing stage (Instituto de Ecología del Estado de Guanajuato, 2011). The proposed adaptation actions focus mainly on: 1) reducing physical and social vulnerability of key sectors and populations; 2) conservation and sustainable management of ecosystems, biodiversity, and ecosystem services; 3) developing risk management strategies; 4) strengthening water management; 5) protecting human health, and; 6) improving current urban development strategies, focusing on settlements and services, transport and land use planning.

26.9.3. Barriers to Adaptation

Chapter 16 provides a more in-depth discussion on adaptation barriers and limits. Adaptation plans tend to exist as distinct documents and are often not integrated into other planning activities (Preston *et al.*, 2011). Most adaptation activities have only involved planning for climate change rather than specific actions, and few measures have been implemented (Preston *et al.*, 2011; Bierbaum *et al.*, 2012).

Even though Canada and the US are relatively well-endowed in their capacity to adapt, there are significant constraints on adaptation, with financing being a significant constraint in all three countries (Carmin *et al.*, 2012). Barriers include legal constraints (e.g., (Jantarasami *et al.*, 2010) lack of coordination across different jurisdictions

(Smith *et al*., 2009; National Research Council, 2010; Instituto Nacional de Ecología y Cambio Climático, 2012b), leadership (Smith *et al.*, 2009; Moser and Ekstrom, 2010), and divergent perceptions about climate change (Bierbaum *et al.*, 2012; Moser, 2013). Although obtaining accurate scientific data was ranked less important by municipalities(Carmin *et al.*, 2012), an important constraint is lack of access to scientific information and capacity to manage and use it (Moser and Ekstrom, 2010; Instituto Nacional de Ecología y Cambio Climático, 2012b). Adaptation activities in developed countries such as the US tend to address hazards and propose adaptations that tend to protect current activities rather than facilitate long term change. In addition, the adaptation plans generally do not attempt to increase adaptive capacity (Eakin and Patt, 2011). However, making changes to institutions needed to enable or promote adaptations can be costly (Marshall, 2013).

Although multilevel and multisectoral coordination is a key component of effective adaptation, it is constrained by factors such as mismatch between climate and development goals, political rivalry, and lack of national support to regional and local efforts (Brklacich *et al.*, 2008; Sander-Regier *et al.*, 2009; Brown, 2009; Sydneysmith *et al.*, 2010), (Craft and Howlett, 2013; Romero-Lankao *et al.*, 2013a). Traditionally, environmental or engineering agencies are responsible for climate issues (e.g., Mexico City, Edmonton and London, Canada), but have neither the decision making power nor the resources to address all dimensions involved. Adaptation planning requires long-term investments by government, business, grassroots organizations and individuals (e.g., Romero-Lankao, 2007; Croci *et al.*, 2010; Sarah, 2010; Richardson, 2010).

26.9.4. Maladaptation, Trade-Offs, and Co-Benefits

Adaptation strategies may introduce trade-offs or maladaptive effects for policy goals in mitigation, industrial development, energy security, and health (Hamin and Gurran, 2009; Laukkonen *et al.*, 2009). Snow-making equipment, for example, mediates snowpack reductions, but has high water and energy requirements (Scott *et al.*, 2007). Irrigation and air conditioning have immediate adaptive benefits for North American settlements, but are energy-consumptive. Sea walls protect coastal properties, yet negatively affect coastal processes and ecosystems (Richardson, 2010).

Conventional sectoral approaches to risk management and adaptation planning undertaken at different temporal and spatial scales have exacerbated vulnerability in some cases e.g., peri-urban areas in Mexico (Eakin *et al.*, 2010; Romero-Lankao, 2012). Approaches that delegate response planning to residents in the absence of effective knowledge exchange have resulted in maladaptive effects (Friesinger and Bernatchez, 2010).

Other strategies offer synergies and co-benefits. Policies addressing air pollution (Harlan and Ruddell, 2011) or housing for the poor, particularly in Mexico (Colten *et al.*, 2008), can often be adapted at low or no cost to fulfill adaptation and sustainability goals (Badjek *et al.*, 2010). Efforts to temper declines in production or competitiveness in rural communities could involve mitigation innovations, including carbon sequestration forest plantations (Holmes, 2010). Painting roofs white reduces the effects of heat and lowers energy demand for cooling (Akbari *et al.*, 2009).

Adaptation planning can be greatly enhanced by incorporating regionally or locally-specific vulnerability information (Clark *et al.*, 1998; Barsugli *et al.*, 2012; Romsdahl *et al.*, 2013). Methods for mapping vulnerability have been improved and effectively utilized (Romero-Lankao *et al.*, 2013b). Similarly, strategies supporting cultural preservation and subsistence livelihood needs among Indigenous peoples would enhance adaptation (Ford *et al.*, 2010b), as would integrating traditional culture with other forms of knowledge, technologies, education and economic development (Hardess *et al.*, 2011).

26.10. Key Risks, Uncertainties, Knowledge Gaps, and Research Needs

26.10.1. Key Multi-Sectoral Risks

We close this chapter with our assessment of key current and future regional risks from climate change with an evaluation of the potential for risk reduction through adaptation (Table 26-1). Two of the three examples, wildfires and urban floods, illustrate that multiple climate drivers can result in multiple impacts (e.g., loss of ecosystems integrity, property damage and health impacts due to wildfires and urban floods). The three risks evaluated in Table 26-1 also show that *relative risks* depend on the context specific articulation and dynamics of such factors as

- The magnitude and rate of change of relevant climatic and non-climatic drivers and hazards. For instance, the risk of urban floods depends not only on global climatic conditions (current versus future global mean temperatures of 2˚C and 4˚C), but also on urbanization, a regional source of hazard risk that can enhance or reduce precipitation, as it affects the hydrologic cycle and, hence, has impacts on flood climatology (section 26.8.2.1);
- The internal properties and dynamics of the system being stressed. For example, some ecosystems are more fire-adapted than others. Some populations are more vulnerable to heat-stress because of age, pre-existing medical conditions, working conditions and lifestyles (e.g., outdoor workers, athletes);
- Adaptation potentials and limits. For example, while residential air conditioning (A/C) can effectively reduce health risk, availability and usage of A/C is often limited among the most vulnerable individuals. Furthermore, A/C is sensitive to power failures and its use has mitigation implications.

[INSERT TABLE 26-1 HERE
Table 26-1: Key risks from climate change and the potential for risk reduction through adaptation. Key risks are identified based on assessment of the literature and expert judgments made by authors of this chapter, with supporting evaluation of evidence and agreement in the referenced chapter sections. Each key risk is characterized as very low, low, medium, high, or very high. Risk levels are presented for the near-term era of committed climate change (here, for 2030-2040), in which projected levels of global mean temperature increase do not diverge substantially across emissions scenarios. Risk levels are also presented for the longer-term era of climate options (here, for 2080-2100), for global mean temperature increase of 2°C and 4°C above preindustrial levels. For each timeframe, risk levels are estimated for the current state of adaptation and for a hypothetical highly adapted state. As the assessment considers potential impacts on different physical, biological, and human systems, risk levels should not necessarily be used to evaluate relative risk across key risks. Relevant climate variables are indicated by symbols.]

The judgments about risk conveyed by the Table 26-1 are based on assessment of the literature and expert judgment by chapter authors living under current socio-economic conditions. Therefore, risk levels are estimated for each timeframe, assuming a continuation of current adaptation potentials and constraints. Yet over the course of the 21st century, socioeconomic and physical conditions can change considerably for many sectors, systems and places. The dynamics of wealth generation and distribution, technological innovations, institutions, even culture, can substantially affect North American levels of risk tolerance within the social and ecological systems considered in the Table (see also Box TS.8).

26.10.2. Uncertainties, Knowledge Gaps, and Research Needs

The literature on climate impacts, adaptation and vulnerability in North America has grown considerably, as has the diversity of sectors and topics covered (e.g., urban and rural settlements, food security, and adaptation at local, state and national levels). However, limitations in the topical and geographical scope of this literature are still a challenge (e.g., more studies have focused on insurance than on economic sectors such as industries, construction and transportation). It is also challenging to summarize results across many studies and identify trends in the literature when there are differences in methodology, theoretical frameworks and causation narratives (e.g., between outcome and contextual approaches) making it hard to compare “apples to oranges” (Romero-Lankao *et al.*, 2012b) While the US and Canada have produced large volumes of literature, Mexico lags well behind. It was, therefore, difficult to devote equal space to observed and projected impacts, vulnerabilities and adaptations in Mexico in comparison with its Northern neighbors. With its large land area, population and important, albeit understudied, climate change risks and vulnerabilities, more climate change research focusing on Mexico is direly needed.

The literature on North America tends to be dominated by sector level analyses. Yet, climate change interacts with other physical and social processes to create differential risks and impact levels. These differences are mediated by context-specific physical and social factors shaping the vulnerability of exposed systems and sectors. Furthermore, while studies often focus on isolated sectorial effects, impacts happen in communities, socio-ecologic systems and regions, and shocks and dislocations in one sector or region often affect other sectors and regions due to social and physical interdependencies. This point is illustrated by our border region and wildfire boxes and the human settlements section, which discuss place-based impacts, vulnerabilities and adaptations. Unfortunately, literature using placed-based or integrated approaches to these complexities is limited. Indeed although in early drafts the authors of this chapter attempted to put more emphasis on place-based analysis and comparisons, the literature was inadequate to support such an effort. The IPCC includes chapters on continents and large regions to make it possible to assess how multiple climate change impacts can affect these large areas. However, this macro view gives insufficient detail on context specific local impacts and risks, missing the on-the-ground reality that the effects of climate change are and will be experienced at much smaller scales, and those smaller scales are often where meaningful mitigation and adaptation actions can be generated. In order to give local actors relevant information on which to base these local actions, more research is needed to better understand the local and regional effects of climate change across sectors.

Frequently Asked Questions

FAQ 26.1: What impact is climate having on North America? *[to remain at the end of the chapter]*
Recent climate changes and extreme events demonstrate clear impacts of climate-related stresses in North America (*high confidence*). There has been increased occurrence of severe hot weather events over much of the US and increases in heavy precipitation over much of North America (*high confidence*). Such events as droughts in northern Mexico and south-central US, floods in Canada, and hurricanes such as Sandy, demonstrate exposure and vulnerability to extreme climate (*high confidence).* Many urban and rural settlements, agricultural production, water supplies, and human health have been observed to be vulnerable to these and other extreme weather events (Figure 26-2). Forest ecosystems have been stressed through wildfire activity, regional drought, high temperatures, and infestations, while aquatic ecosystems are being affected by higher temperatures and sea level rise.

Many decision makers, particularly in the United States and Canada, have the financial, human and institutional capacity to invest in resilience, yet a trend of rising losses from extremes has been evident across the continent (Figure 26-2), largely due to socio-economic factors, including a growing population, equity issues and increased property value in areas of high exposure. In addition, climate change is *very likely* to lead to more frequent extreme heat events and daily precipitation extremes over most areas of North America, more frequent low snow years, and shifts towards earlier snowmelt runoff over much of the western US and Canada (*high confidence*). These changes combined with higher sea levels and associated storm surges, more intense droughts, and increased precipitation variability are projected to lead to increased stresses to water, agriculture, economic activities and urban and rural settlements (*high confidence*).

FAQ 26.2: Can adaptation reduce the adverse impacts of climate in North America?
[to remain at the end of the chapter]
Adaptation – including land use planning, investments in infrastructure, emergency management, health programs, and water conservation – has significant capacity to reduce risks from current climate and climate change (Figure 26-3). There is increasing attention to adaptation among planners at all levels of government but particularly at the municipal level, with many jurisdictions engaging in assessment and planning processes. Yet, there are few documented examples of implementation of proactive adaptation and these are largely found in sectors with longer-term decision-making, including energy and public infrastructure *(high confidence*). Adaptation efforts have revealed the significant challenges and sources of resistance facing planners at both the planning and implementation stages, particularly the adequacy of informational, institutional, financial and human resources, and lack of political will (*medium confidence*).

While there is high capacity to adapt to climate change across much of North America, there are regional and sectoral disparities in economic resources, governance capacity, and access to and ability to utilize information on climate change which limit adaptive capacity in many regions and among many populations such as the poor and indigenous communities. For example, there is limited capacity for many species to adapt to climate change, even with human intervention. At lower levels of temperature rise, adaptation has high potential to off-set projected declines in yields for many crops, but this effectiveness is expected to be much lower at higher temperatures. The risk that climate stresses will cause profound impacts on ecosystems and society – including the possibility of species extinction or severe adverse socio-economic shocks – highlights limits to adaptation.

Table 26-1: Key risks from climate change and the potential for risk reduction through adaptation. Key risks are identified based on assessment of the literature and expert judgments made by authors of this chapter, with supporting evaluation of evidence and agreement in the referenced chapter sections. Each key risk is characterized as very low, low, medium, high, or very high. Risk levels are presented for the near-term era of committed climate change (here, for 2030-2040), in which projected levels of global mean temperature increase do not diverge substantially across emissions scenarios. Risk levels are also presented for the longer-term era of climate options (here, for 2080-2100), for global mean temperature increase of 2°C and 4°C above preindustrial levels. For each timeframe, risk levels are estimated for the current state of adaptation and for a hypothetical highly adapted state. As the assessment considers potential impacts on different physical, biological, and human systems, risk levels should not necessarily be used to evaluate relative risk across key risks. Relevant climate variables are indicated by symbols.

Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
Loss of ecosystem integrity, property loss, human morbidity and mortality due to **wildfires** (*high confidence*)	Some ecosystems are more fire-adapted than others. Forest managers and municipal planners are increasingly incorporating fire protection measures (e.g., prescribed burning, introduction of resilient vegetation). Institutional capacity to support ecosystem adaptation is limited. Adaptation of human settlements is constrained by rapid private property development in high-risk areas and by limited household-level adaptive capacity.		26.4, 26.8.1.2, Box 26-2	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Heat-related human mortality (*high confidence*)	Residential air conditioning (A/C) can effectively reduce risk. However, availability and usage of A/C is often limited among the most vulnerable individuals, and is subject to complete loss during power failures. In addition, there are vulnerable populations including athletes and outdoor workers for whom air conditioning is not available. Community- and household-scale adaptations have the potential to reduce exposure to heat extremes via: family support; heat warnings; cooling centers; greening; high albedo surfaces, etc.		26.6.1.2, 26.8.1.2	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Property and infrastructure damage; supply chain, ecosystem and social system disruption; public health; and water quality impairement from river and coastal **urban floods** (*high confidence*)	Implementing management of urban drainage is expensive and very disruptive to urban areas. There are many no-regret strategies with co-benefits (e.g., less impervious surfaces leading to more groundwater recharge, green infrastructure, and roof-top gardens). Sea level rise increases water elevations in coastal outfalls, which impedes drainage. In many cases, older rainfall design standards are being used which need to be updated to reflect current climate conditions. Significant challenges are also being faced by urban managers due to increased flooding from coastal storms and river-flooding.		26.2.2.2, 26.3.3.2, 26.3.3.3, 26.3.4, 26.4.2, 26.4.2.2, 26.6.1.1, 26.6.1.5, 26.6.2, 26.7, 26.7.1.1, 26.7.5.2.2, 26.8.1.1,26.8.1.2, 26.8.2.1, 26.8.3, 26.8.4.1.2	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	
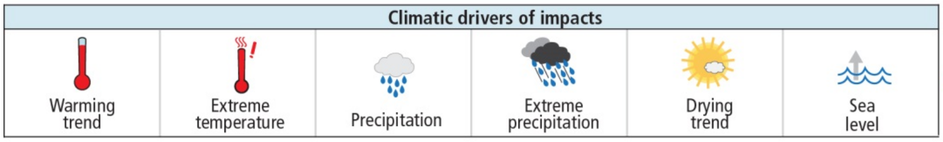
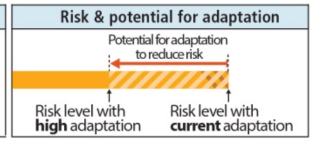
Climatic drivers of impacts



Risk & potential for adaptation



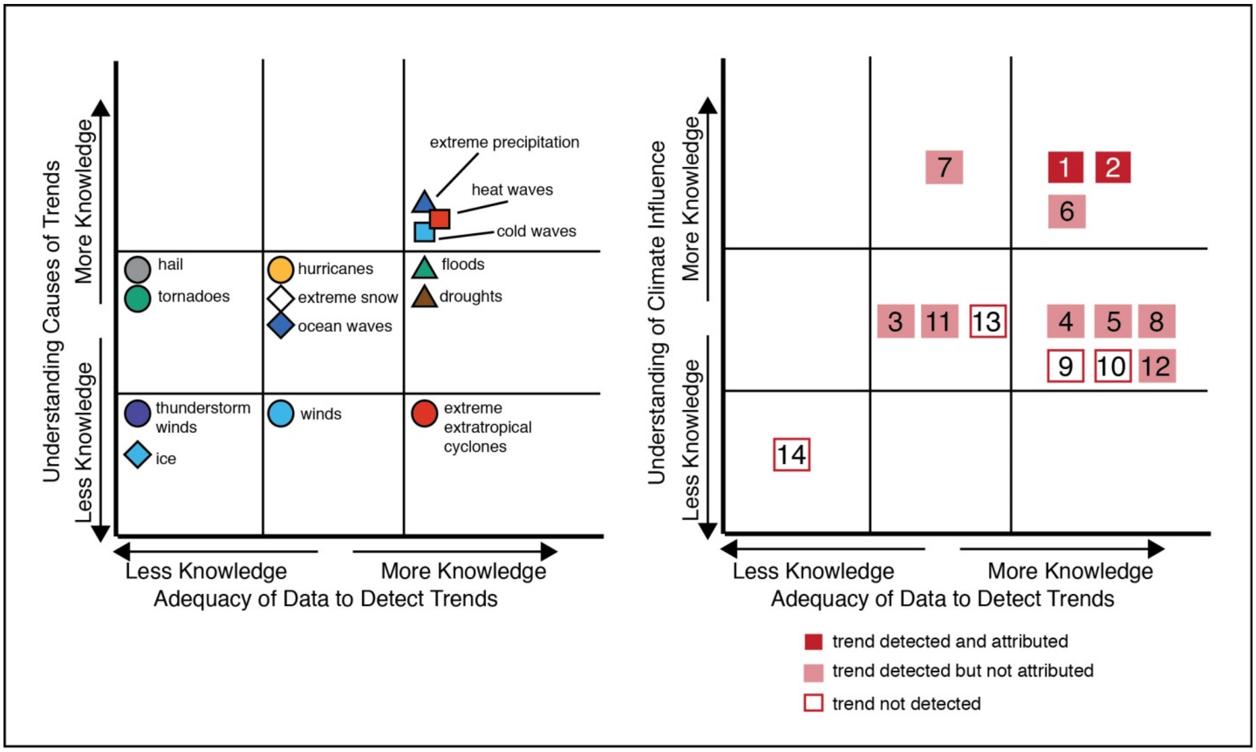


Figure 26-1 Detection and attribution of climate change impacts. Comparisons of the adequacy of currently available data to detect trends and the degree of understanding of causes of those changes in climatic extreme events in the United States (left; Peterson *et al.*, 2013) and degree of understanding of the climate influence in key impacts in North America (right). Note that "climate influence" means that the impact has been documented to be sensitive to climate, not that it has been attributed to climate change. Filled boxes indicate that formal detection and attribution to climate change has been performed for the given impact; shaded boxes indicate that a trend has been detected from background variability in the given impact, but formal attribution to climate change has not occurred and the trend could be due to other drivers; and open boxes indicate that a trend has not currently been detected. Key impacts are: 1) earlier peak flow of snowmelt run-off in snow-dominated streams and rivers in western North America [26.3.1], 2) declines in the amount of water stored in spring snowpack in snow-dominated areas of western North America [26.3.1], 3) northward and upward shifts in species' distributions in multiple taxa of terrestrial species, although not all taxa and regions [26.4.1], 4) increases in coastal flooding [26.8.1], 5) increases in wildfire activity, including fire season length and area burned by wildfires in the western United States and boreal Canada [Box 26-2], 6) storm-related disaster losses in the United States (most of the increase in insurance claims paid has been attributed to increasing exposure of people and assets in areas of risk) [26.7.6.1, 26.8.1], 7) increases in bark beetle infestation levels in pine tree species in western North America [26.4.2.1], 8) yield increases due in part to increasing temperatures in Canada and higher precipitation in the US; yield variances attributed to climate variability in Ontario and Quebec; yield losses attributed to climate-related extremes across North America [26.5.1], 9) changes in storm-related mortality in the United States [26.6.1.2], 10) changes in heat-related mortality in the United States [26.6.1.2], 11) increases in tree mortality rates in old-growth forests in the western United States and western Canada from 1960-2007 [26.4.2.1], 12) changes in flooding in some urban areas due to extreme rainfall [26.3.1, 26.8.2.1], 13) increase in water supply shortages due to drought [26.8.1, 26.3], and 14) changes in cold-related heat mortality [26.6.1.2]. **[Illustration to be redrawn to conform to IPCC publication specifications.]**

Figure 26-2: Extreme events illustrating vulnerabilities for Mexico, the United States, and Canada. This figure offers a graphic illustration of location of extreme events and relevant vulnerability trends. The observed extreme events have not been attributed to anthropogenic climate change, yet they are climate-sensitive sources of impact illustrating vulnerability of exposed systems, particularly if projected future increases in the frequency and/or intensity of such events should materialize. The figure includes:

a) A map (bottom) with population density at 1km resolution highlighting exposure and represented using 2011 Landscan data (Bright *et al.*, 2012).
b) A map (top) with significant weather events taking place during 1993-2012. The map only includes disasters with overall losses of more than $1 billion US dollars in US, or more than $500 million US dollars in Mexico and Canada, adjusted to 2012 values (Source: (NatCatSERVICE, 2010). Hence, it does not include the occurrence of disasters of small and medium impact, and it does not capture the impacts of disasters on populations' livelihoods and wellbeing. Disasters represented by points that are located at the approximate geographic center of affected regions, frequently span more than one subnational jurisdiction (e.g., the 2012 drought affected 12 Mexican states, Annex Table).
c) Four panels (right) with trends in socio-demographic indicators used in the literature to measure vulnerability to hazards (Romero-Lankao *et al.*, 2012): poverty rates, percentage of elderly, GDP per capita and total population (Sources: Comisión Económica para América Latina y el Caribe; U.S. Census Bureau, 2011; Statistics Canada, 2012).

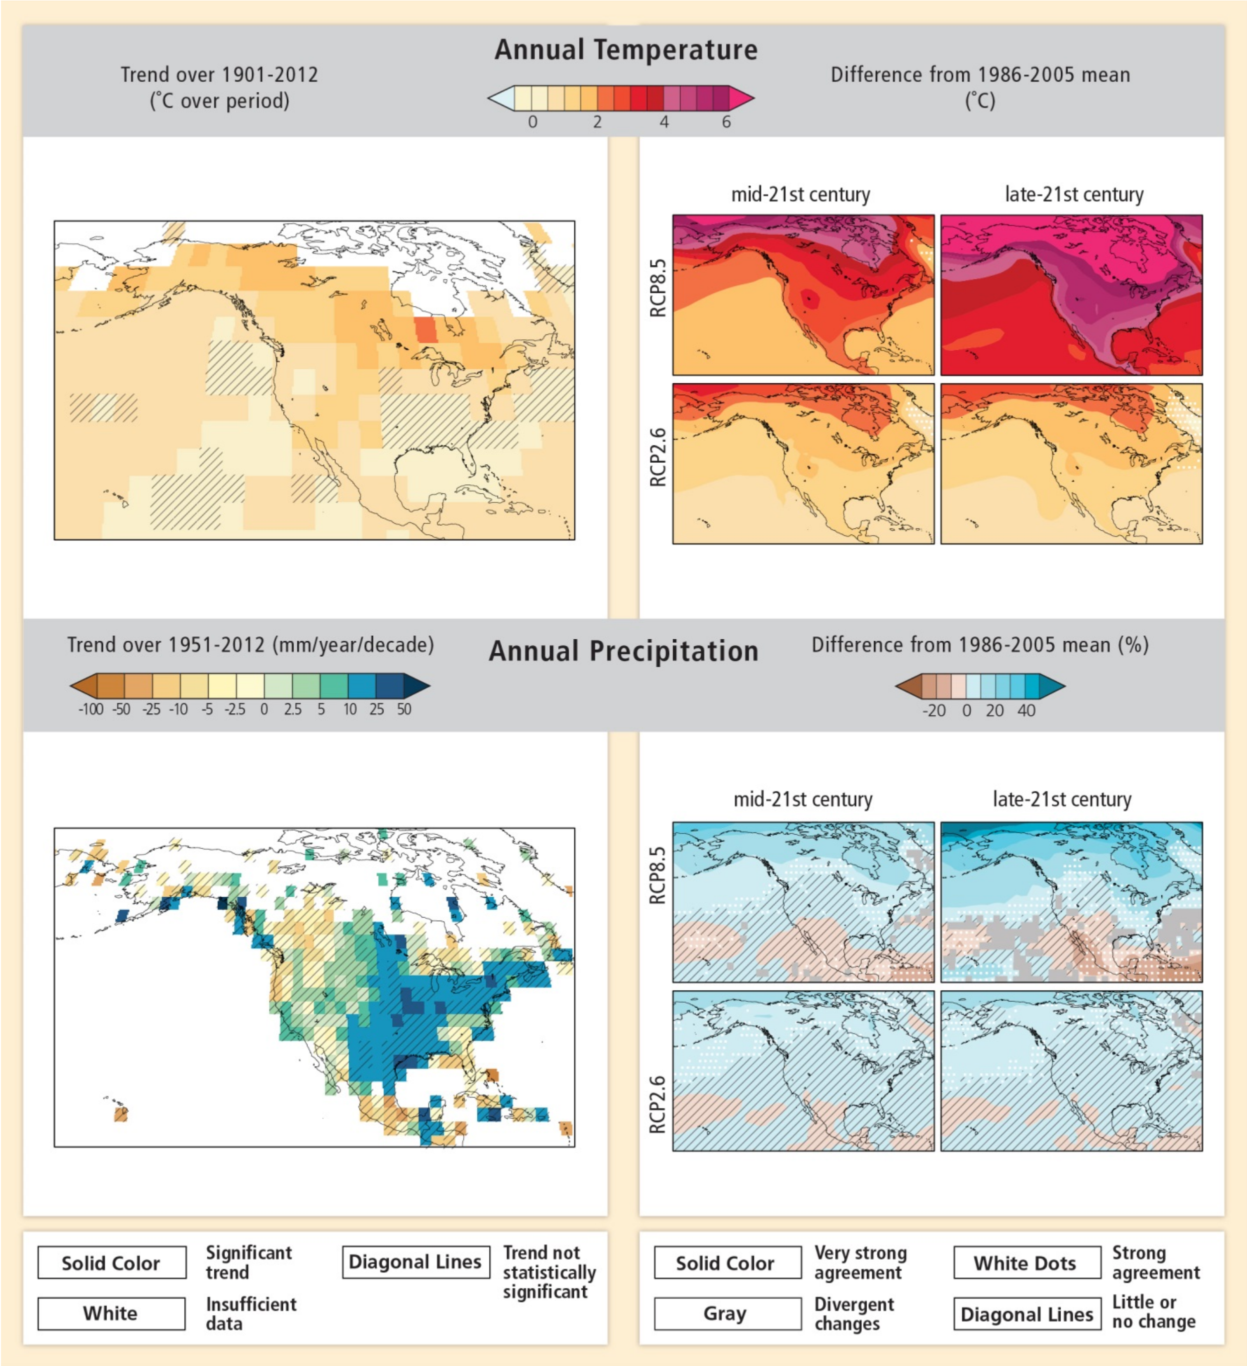

Figure 26-3: Observed and projected Changes in annual temperature and precipitation. (Top panel, left) observed temperature trends from 1901-2012 determined by linear regression [WGI AR5 Figures SPM.1 and 2.21]. (Bottom panel, left) Observed precipitation change from 1951-2010 determined by linear regression. [WGI AR5 Figure SPM.2] For observed temperature and precipitation, trends have been calculated where sufficient data permits a robust estimate (i.e., only for grid boxes with greater than 70% complete records and more than 20% data availability in the first and last 10% of the time period). Other areas are white. Solid colors indicate areas where change is significant at the 10% level. Diagonal lines indicate areas where change is not significant (Top and bottom panel, right) CMIP5 multi-model mean projections of annual average temperature changes and average percent change in annual mean precipitation for 2046-2065 and 2081-2100 under RCP2.6 and 8.5. Solid colors indicate areas with very strong agreement, where the multi-model mean change is greater than twice the baseline

variability, and >90% of models agree on sign of change. Colors with white dots indicate areas with strong agreement, where >66% of models show change greater than the baseline variability and >66% of models agree on sign of change. Gray indicates areas with divergent changes, where >66% of models show change greater than the baseline variability, but <66% agree on sign of change. Colors with diagonal lines indicate areas with little or no change, less than the baseline variability in >66% of models. (There may be significant change at shorter timescales such as seasons, months, or days.). Analysis uses model data and methods building from WGI AR5 Figure SPM.8. See also Annex I of WGI AR5. [Boxes 21-3 and CC-RC]

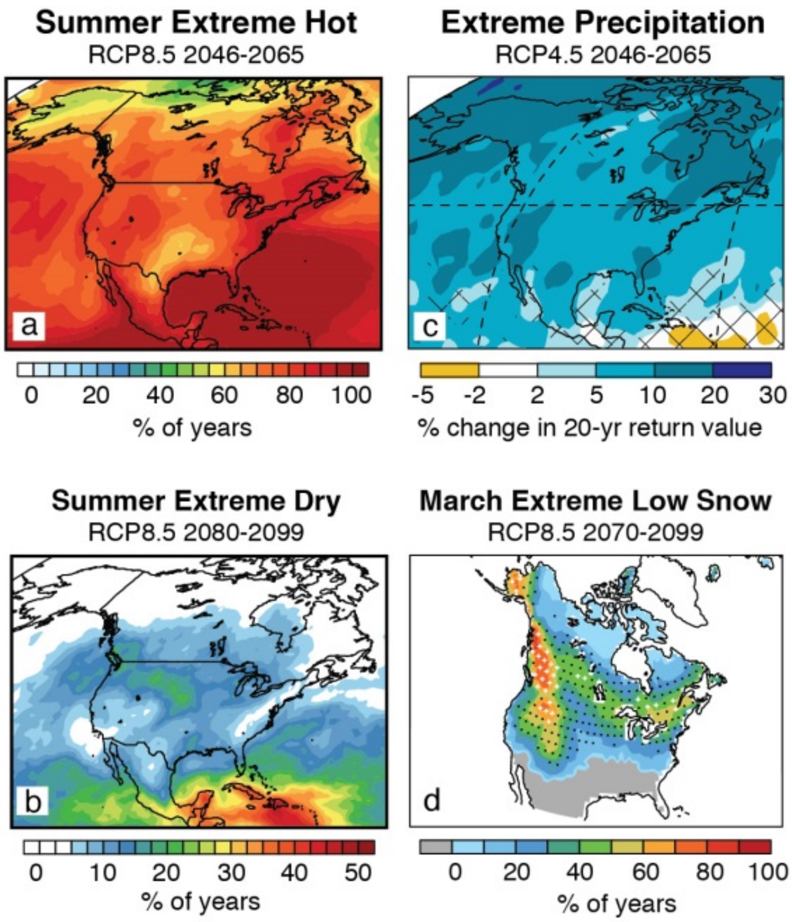

Figure 26-4: Projected changes in extremes in North America. (a) The percentage of years in the 2046–2065 period of RCP8.5 in which the summer temperature is greater than the respective maximum summer temperature of the 1986–2005 baseline period (Diffenbaugh and Giorgi, 2012). (b) The percentage of years in the 2080-2099 period of RCP8.5 in which the summer precipitation is less than the respective minimum summer precipitation of the 1986-2005 baseline period (Diffenbaugh and Giorgi, 2012) (c) The percentage difference in the 20-year return value of annual precipitation extremes between the 2046-2065 period of RCP4.5 and the 1986-2005 baseline period (from (Kharin *et al.*, 2013). The hatching indicates areas where the differences are not significant at the 5% level. (d) The percentage of years in the 2070-2099 period of RCP8.5 in which the March snow water equivalent is less than the respective minimum March snow water equivalent of the 1976–2005 period (Diffenbaugh *et al.*, 2012). The black (white) stippling indicate areas where the multimodel mean exceeds 1.0 (2.0) standard deviations of the multi-model spread. (a-d) The RCPs and time periods are those used in the peer-reviewed studies in which the panels appear. The 2046-2065 period of RCP8.5 and the 2046-2065 period of RCP4.5 exhibit global warming in the range of 2-3˚C above the pre-industrial baseline (WGI Fig. 12.40). The 2080-2099 and 2070-2099 periods of RCP8.5 exhibit global warming in the range of 4-5˚C above the pre-industrial baseline (WGI Fig. 12.40).

Executive Summary

Significant trends in precipitation and temperature have been observed in Central America (CA) and South America (SA) (*high confidence*). Besides, changes in climate variability and in extreme events have severely affected the region (*medium confidence*). Increasing trends in annual rainfall in Southeastern South America (SESA; 0.6 mm/day/50years during 1950-2008) contrast with decreasing trends in CA and Central-Southern Chile (-1mm/day /50 years during 1950-2008). Warming has been detected throughout CA and SA (near to 0.7-1°C/40 years since the mid-1970’s), except for a cooling off the Chilean coast of about -1 C°/40 years. Increases in temperature extremes have been identified in CA and most of tropical and subtropical SA (*medium confidence*), while more frequent extreme rainfall in SESA has favoured the occurrence of landslides and flash floods (*medium confidence*). (27.2.1.1, Table 27-1, Box 27-1)

Climate projections suggest increases in temperature, and increases or decreases in precipitation for CA and SA by 2100 (*medium confidence*). Post-AR4 climate projections, derived from dynamic downscaling forced by CMIP3 models for various SRES scenarios, and to different global climate models from the CMIP5 for various

RCPs (4.5 and 8.5), warming varies from +1.6°C to +4.0°C in CA, and +1.7°C to +6.7°C in SA (*medium confidence*). Rainfall changes for CA range between -22% to +7% by 2100, while in SA rainfall varies geographically, most notably showing a reduction of -22% in Northeast Brazil, and an increase of +25% in SESA (*low confidence*). By 2100 projections show an increase in dry spells in tropical SA east of the Andes, and in warm days and nights in most of SA (*medium confidence*) (27.2.1.2, Table 27-2).

Changes in stream flow and water availability have been observed and projected to continue in the future in CA and SA, affecting already vulnerable regions (*high confidence*). The Andean cryosphere is retreating affecting the seasonal distribution of streamflows (Table 27-3) (*high confidence*). Increasing runoffs in the La Plata River basin and decreasing ones in the Central Andes (Chile, Argentina) and in CA in the second half of the 20th century were associated with changes in precipitation (*high confidence*). Risk of water supply shortages will increase owing to precipitation reductions and evapotranspiration increases in semi-arid regions (*high confidence*) (Table 27-4), thus affecting water supply for cities (*high confidence*) (27.3.1.1; 27.3.5), hydropower generation (*high confidence*) (27.3.6; 27.6.1) and agriculture (27.3.1.1). Current practices to reduce the mismatch between water supply and demand could be used to reduce future vulnerability (*medium confidence*). Ongoing constitutional and legal reforms towards more efficient and effective water resources management and coordination constitute another adaptation strategy (*medium confidence*) (27.3.1.2).

Land use change contributes significantly to environmental degradation exacerbating the negative impacts of climate change (*high confidence*). Deforestation and land degradation are mainly attributed to increased extensive and intensive agriculture. The agricultural expansion, in some regions associated with increases in precipitation, has affected fragile ecosystems, such as the edges of the Amazon forest and the tropical Andes. Even though deforestation rates in the Amazon have decreased substantially since 2004 to a value of 4,656 km^2/yr in 2012, other regions like the Cerrado still present high levels of deforestation with average rates as high as 14,179 km^2/yr for the period 2002-2008 (27.2.2.1).

Conversion of natural ecosystems is the main cause of biodiversity and ecosystem loss in the region, and is a driver of anthropogenic CC (*high confidence*). CC is expected to increase the rates of species extinction (*medium confidence*). For instance, vertebrate species turnover until 2100 will be as high as 90% in specific areas of CA and the Andes Mountains. In Brazil, distribution of some groups of birds and plants will be dislocated southwards, where there are less natural habitats remaining. However, CA and SA have still large extensions of natural vegetation cover for which the Amazon is the main example (27.3.2.1). Ecosystem-based adaptation practices are increasingly common across the region, such as the effective management and establishment of protected areas, conservation agreements and community management of natural areas (27.3.2.2).

Socioeconomic conditions have improved since AR4; however there is still a high and persistent level of poverty in most countries resulting in high vulnerability and increasing risk to climate variability and change (*high confidence*). Poverty levels in most countries remain high (45% for CA and 30% for SA for year 2010) in spite of the sustained economic growth observed in the last decade. Human Development Index varies greatly between countries, from Chile and Argentina with the highest values, and Guatemala and Nicaragua with the lowest values in 2007. The economic inequality translates into inequality in access to water, sanitation and adequate housing, particularly for the most vulnerable groups translating into low adaptive capacities to climate change (27.2.2.2).

Sea-level rise (SLR) and human activities on coastal and marine ecosystems pose threats to fish stocks, corals, mangroves, recreation and tourism, and control of diseases (*high confidence*). SLR varied from 2 to 7 mm/yr between 1950 and 2008**.** Frequent coral bleaching events associated to ocean warming and acidification occur in the Mesoamerican Coral Reef. In CA and SA, the main drivers of mangrove loss are deforestation and land conversion to agriculture and shrimp ponds (27.3.3.1). Brazilian fisheries' co-management (a participatory multi-stakeholder process) is an example of adaptation since it favours a balance between conservation of marine biodiversity, the improvement of livelihoods, and the cultural survival of traditional populations (27.3.3.2).

Changes in agricultural productivity with consequences for food security associated to CC are expected to exhibit large spatial variability (*medium confidence*). In SESA, where projections indicate more rainfall, average productivity could be sustained or increased until the mid-century (SRES: A2, B2) (Table 27-5) (*medium confidence*). In CA, northeast of Brazil and parts of the Andean region increases in temperature and decreases in rainfall could decrease the productivity in the short-term (by 2030), threatening the food security of the poorest population (Table 27-5) (*medium confidence*). Considering that SA will be a key food producing region in the future, one of the challenges will be to increase the food and bioenergy quality and production while maintaining environmental sustainability under CC (27.3.4.1). Some adaptation measures include crop, risk, and water use management along with genetic improvement (27.3.4.2) (*high confidence*).

Renewable energy (RE) based on biomass has a potential impact on land use change and deforestation and could be affected by CC (*medium confidence*). Sugarcane and soy are likely to respond positively to CO_2 and temperature changes, even with a decrease in water availability, with an increase in productivity and production (*high confidence*). The expansion of sugarcane, soy and oil palm may have some effect on land use, leading to deforestation in parts of Amazon, CA among other regions, and loss of employment in some countries (*medium confidence*) (27.3.6.1). Advances in second-generation bioethanol from sugarcane and other feedstocks will be important as a measure of mitigation (27.3.6.2).

Changes in weather and climatic patterns are negatively affecting human health in CA and SA, either by increasing morbidity, mortality, and disabilities (*high confidence*), and through the emergence of diseases in previously non-endemic areas (*high confidence*). With *very high confidence* climate-related drivers are associated with respiratory and cardiovascular diseases, vector- and water-borne diseases (malaria, dengue, yellow fever, leishmaniasis, cholera, and other diarrheal diseases), Hantaviruses and Rotaviruses, chronic kidney diseases, and psychological trauma. Air pollution is associated with pregnancy-related outcomes and diabetes, among others (27.3.7.1). Vulnerabilities vary with geography, age, gender, race, ethnicity, and socio-economic status, and are rising in large cities (27.3.7.2) (*very high confidence*). Climate change will exacerbate current and future risks to health, given the region's population growth rates and vulnerabilities in existing health, water, sanitation and waste collection systems, nutrition, pollution and food production in poor regions (*medium confidence*).

In many CA and SA countries, a first step toward adaptation to future climate changes is to reduce the vulnerability to present climate. Long-term planning and the related human and financial resource needs may be seen as conflicting with present social deficit in the welfare of the CA and SA population. Various examples demonstrate possible synergies between development, adaptation and mitigation planning, which can help local communities and governments to allocate efficiently available resources in the design of strategies to reduce vulnerability. However, the generalization of such actions at continental scale requires that both the CA and SA citizens and governments are faced with the challenge of building a new governance model, where imperative development needs, vulnerability reduction and adaptation strategies to climate stresses will be truly intertwined. (27.3.4, 27.4.1, 27.4.2, 27.4.3, 27.4.4, 27.5).

27.1. Introduction

27.1.1. The Central and South America Region

The CA and SA region harbors unique ecosystems, the highest biodiversity in the planet and has a variety of eco-climatic gradients. Unfortunately, this natural wealth is threatened by advancing agricultural frontiers resulting from a rapidly growing agricultural and cattle production (Grau and Aide, 2008). The region experienced a steady economic growth in the last decade, accelerated urbanization and important demographic changes; poverty and inequality are decreasing continuously, but at a low pace (ECLAC, 2011c). Adaptive capacity is improving in part thanks to poverty alleviation and development initiatives (McGray *et al.*, 2007).

The region has multiple stressors on natural and human systems derived in part from significant land use changes and exacerbated by climate variability/climate change. Climate variability at various time scales has been affecting social and natural systems, and extremes in particular have affected large regions. During 2000-2010, almost 630 weather and climate extreme events occurred in CA and SA, leaving near to 16,000 fatalities and 46.6 million people affected; and generating economical losses amounting to US$ 208 million (CRED, 2011). Land is facing increasing pressure from competing uses like cattle ranching, food production and bioenergy.

The region is regarded as playing a key role in future world economy because countries like Brazil, Chile, Colombia and Panama, among others, are rapidly developing and becoming economically important in the world scenario. The region is bound to be exposed to the pressure related to increasing land use and industrialization. Therefore, it is expected to have to deal with increasing emission potentials. Thus, science-based decision-making is thought to be an important tool to control innovation and development of the countries in the region.

Two other important contrasting features characterize the region: having the biggest tropical forest of the planet on the one side, and possessing the largest potential for agricultural expansion and development during the next decades on the other. This is the case because the large countries of SA, especially, would have a major role in food and bioenergy production in the future, as long as policies towards adaptation to global climate change (GCC) will be strategically designed. The region is already one of the top producers and user of bioenergy and this experience will serve as an example to other developing regions as well as developed regions.

27.1.2. Summary of the AR4 and SREX Findings

27.1.2.1. AR4 Findings

According to AR4-Chapter 13 (Latin America), during the last decades of the 20th century, unusual extreme weather events have been severely affecting the LA region contributing greatly to the strengthening of the vulnerability of human systems to natural disasters. In addition, increases in precipitation were observed in SESA, northwest Peru and Ecuador; while decreases were registered in southern Chile, southwest Argentina, southern Peru and western CA since 1960. Mean warming was near to 0.1ºC/decade. The rate of SLR has accelerated over the last 20 years reaching 2-3mm/year. The glacier-retreat trend has intensified, reaching critical conditions in the Andean countries. Rates of deforestation have been continuously increasing mainly due to agricultural expansion, and land degradation has been intensified for the entire region.

Mean warming for LA at the end of 21st century could reach 1ºC to 4ºC (SRES B2) or 2ºC to 6ºC (SRES A2) (*medium confidence*) (AR4-Ch13-pp583). Rainfall anomalies (positive or negative) will be larger for the tropical part of LA. The frequency and intensity of weather and climate extremes is *likely* to increase (*medium confidence*).

Future impacts include: “Significant species extinctions, mainly in tropical LA” (*high confidence*). “Replacement of tropical forest by savannas, and semi-arid vegetation by arid vegetation” (*medium confidence*). “Increases in the number of people experiencing water stress” (*medium confidence*). “Probable reductions in rice yields and possible increases of soy yield in SESA (AR4-Ch13-pp583); and increases in crop pests and diseases” (*medium confidence*) (AR4-Ch13-pp607). “Some coastal areas affected by sea level rise, weather and climatic variability and extremes” (*high confidence*) (AR4-Ch13-pp584).

Some countries have made efforts to adapt to climate change and variability, for example through the conservation of key ecosystems (e.g. biological corridors in Mesoamerica, Amazonia, and Atlantic forest; compensation for ecosystem services in Costa Rica,), the use of early warning systems and climate forecast (e.g. fisheries in eastern Pacific, subsistence agriculture in NE Brazil), and the implementation of disease surveillance systems (e.g. Colombia) (AR4-Ch13-pp 591). However, several constraints like the lack of basic information, observation and monitoring systems; the lack of capacity-building and appropriate political, institutional and technological frameworks; low income; and settlements in vulnerable areas, outweigh the effectiveness of these efforts.

27.1.2.2. SREX Findings

As reported *on Chapter 3.4 of* the IPCC *Special* Report on Managing the Risks of Extreme Events and Disasters to Advance Climate Change Adaptation (SREX) (IPCC, 2012b), a changing climate leads to changes in the frequency, intensity, spatial extent or duration of weather and climate extremes, and can result in unprecedented extremes. Levels of confidence in historical changes depend on the availability of high quality and homogeneous data, and relevant model projections. This has been a major problem in CA and SA, where a lack of long-term homogeneous and continuous climate and hydrological records, and of complete studies on trends have not allowed for an identification of trends in extremes, particularly in CA. Recent observational studies and projections from global and regional models suggest changes in extremes. With *medium confidence*, increases in warm days and decreases in cold days, as well as increases on warm nights and decreases in cold nights have been identified in CA, Northern SA, NEB, SESA and west coast of SA. In CA, there is *low confidence* that any observed long-term increase in tropical cyclone activity is robust, after accounting for past changes in observing capabilities. In other regions, such as the Amazon region, *insufficient evidence*, inconsistencies among studies and detected trends result in *low confidence* of observed rainfall trends. While it *is likely* that there has been an anthropogenic influence on extreme temperature in the region, there is *low confidence* in attribution of changes in tropical cyclone activity to anthropogenic influences.

Projections for the end of the 21st century for differing emissions scenarios (SRES A2 and A1B) show that for all CA and SA, models project substantial warming in temperature extremes. It is *likely* that increases in the frequency and magnitude of warm daily temperature extremes and decreases in cold extremes will occur in the 21st century on the global scale. With *medium confidence*, it is *very likely* that the length, frequency and/or intensity of heat waves will experience a large increase over most of SA, with weaker tendency towards increasing in SESA. With *low confidence*, the models also project an increase of the proportion of total rainfall from heavy falls for SESA and the West coast of SA; while for Amazonia and the rest of SA and CA there are not consistent signals of change. In some regions, there is *low confidence* in projections of changes in fluvial floods. Confidence is low due to limited evidence and because the causes of regional changes are complex. There *is medium confidence* that droughts will intensify along the 21st century in some seasons and areas due to reduced precipitation and/or increased evapotranspiration in Amazonia and NEB.

The character and severity of the impacts from climate extremes depend not only on the extremes themselves but also on exposure and vulnerability. These are influenced by a wide range of factors, including anthropogenic climate change, natural climate variability, and socioeconomic development.

27.2. Major Recent Changes and Projections in the Region

27.2.1. Climatic Stressors

27.2.1.1. Climate Trends, Long-term Changes in Variability, and Extremes

In CA and SA, decadal variability and changes in extremes have been affecting large sectors of the population, especially those more vulnerable and exposed to climate hazards. Observed changes in some regions have been attributed to natural climate variability, while in other regions they have been attributed to land use change, e.g. increase urbanization, meaning that land use change is a result of anthropogenic drivers. Table 27-1 summarizes observed trends in the region's climate.

[INSERT TABLE 27-1 HERE
Table 27-1: Regional observed changes in temperature, precipitation and climate extremes in various sectors of CA and SA. Additional information on changes in observed extremes can be found in the IPCC SREX (Seneviratne *et al.*, 2012) and Chapter 2 IPCC WGI AR5 [2.4, 2.5, 2.6]]

Since around 1950, in CA and the North American Monsoon System (NAMS), rainfall has been starting increasingly later and has become more irregular in space and time, while rainfall has been increasing and the intensity of rainfall has been increasing during the onset season (see references in Table 27-1). Arias *et al.* (2012) relate those changes to decadal rainfall variations in NAMS.

The West coast of SA experienced a prominent but localized coastal cooling of about 1 C during the past 30-50 years extending from central Peru down to central Chile. This occurs in connection with an increased upwelling of coastal waters favored by the more intense trade winds (Falvey and Garreaud, 2009; Gutiérrez *et al.*, 2011a; Gutiérrez *et al.*, 2011b; Kosaka and Xie, 2013; Narayan *et al.*, 2010; Schulz *et al.*, 2012). In the extremely arid northern coast of Chile, rainfall, temperature and cloudiness show strong interannual and decadal variability, and since the mid-70s, the minimum daily temperature, cloudiness and precipitation have decreased. In central Chile, a negative precipitation trend was observed over the period 1935-1976, and an increase after 1976, while further south, the negative trend in rainfall that prevailed since the 1950s has intensified by the end of the 20th century (Quintana and Aceituno, 2012).

To the east of the Andes, northeast Brazil (NEB) exhibits large interannual rainfall variability, with a slight decrease since the 1970s (Marengo *et al*. 2013a). Droughts in this region (e.g. 1983, 1987, 1998) have been associated with El Niño and/or a warmer Tropical North Atlantic Ocean. However, not all El Nino years result on drought in NEB, as the drought 2012-2013 occurred during La Niña (Marengo *et al.*, 2013a).

In the La Plata Basin in SESA, various studies have documented interannual and decadal scale circulation changes that have led to decreases in the frequency of cold nights in austral summer, as well as to increases in warm nights and minimum temperatures during the last 40 years. Simultaneously, a reduction in the number of dry months in the warm season is found since the mid-1970s, while heavy rain frequency is increasing in SESA (references in Table 27-1). In SESA, increases in precipitation are responsible for changes in soil moisture (Collini *et al.*, 2008; Saulo *et al.*, 2010), and although feedback mechanisms are present at all scales, the effect on atmospheric circulation is detected at large scales. Moreover, land use change studies in the Brazilian southern Amazonia for the last decades showed that the impact on the hydrological response is time lagged at larger scales (Rodriguez *et al.*, 2010)

In the central Andes, in the Mantaro Valley (Peru), precipitation shows a strong negative trend, while warming is also detected (SENAMHI, 2007). In the southern Andes of Peru air temperatures have increased during 1964-2006, but no clear signal on precipitation changes has been detected (Marengo *et al.*, 2009a). In the northern Andes (Colombia, Ecuador), changes in temperature and rainfall in 1961-90 have been identified by Villacís (2008). In the Patagonia region, Masiokas *et al.* (2008) have identified an increase of temperature together with precipitation reductions during 1912-2002. Vuille *et al.* (2008a) found that climate in the tropical Andes has changed significantly over the past 50–60 years. Temperature in the Andes has increased by approximately 0.1 °C/ decade, with only two of the last 20 years being below the 1961–90 average. Precipitation has slightly increased in the second half of the 20th century in the inner tropics and decreased in the outer tropics. The general pattern of moistening in the inner tropics and drying in the subtropical Andes is dynamically consistent with observed changes in the large-scale circulation, suggesting a strengthening of the tropical atmospheric circulation. Moreover, a positive significant trend in mean temperature of 0.09 ^{o}C per decade during 1965-2007 has been detected over the Peruvian Andes by Lavado *et al.* (2012).

For the Amazon basin, Marengo (2004) and Satyamurty *et al.* (2010) concluded that no systematic unidirectional long-term trends towards drier or wetter conditions in both the northern and southern Amazon have been identified since the 1920s. Rainfall fluctuations are more characterized by inter-annual scales linked to ENSO or decadal variability. Analyzing a narrower time period, Espinoza *et al.* (2009a; 2009b) found that mean rainfall in the Amazon basin for 1964–2003 has decreased, with stronger amplitude after 1982, especially in the Peruvian western Amazonia (Lavado *et al.*, 2012), consistent with reductions in convection and cloudiness in the same region (Arias *et al.*, 2011). Recent studies by Donat *et al.* (2013) suggest that heavy rains are increasing in frequency in Amazonia. Regarding seasonal extremes in the Amazon region, two major droughts and three floods have affected the region from 2005 to 2012, although these events have been related to natural climate variability rather than to deforestation (Espinoza *et al.*, 2013; Espinoza *et al.*, 2011; Espinoza *et al.*, 2012; Lewis *et al.*, 2011; Marengo *et al.*, 2008; Marengo *et al.*, 2012; Marengo *et al.*, 2013a; Satyamurty *et al.*, 2013). On the impacts of land use changes on changes in the climate and hydrology of Amazonia, Zhang *et al.* (2009) suggest that biomass-burning aerosols can work against the seasonal monsoon circulation transition, thus re-inforce the dry season rainfall pattern for Southern Amazonia, while Wang *et al.* (2011) suggests the importance of deforestation and vegetation dynamics on decadal variability of rainfall in the region. Costa and Pires (2010) have suggested a possible decrease in precipitation due to soybean expansion in Amazonia, mainly as a consequence of its very high albedo. In the SAMS region, positive trends in rainfall extremes have been identified in the last 30 years with a pattern of increasing frequency and intensity of heavy rainfall events, and earlier onsets and late demise of the rainy season (see Table 27-1).

______START BOX 27-1 HERE______

Box 27-1. Extreme Events, Climate Change Perceptions, and Adaptive Capacity in Central America

Central America has traditionally been characterized as a region with high exposure to geo-climatic hazards derived from its location and topography and with high vulnerability of its human settlements (ECLAC, 2010c). It has also been identified as the most responsive tropical region to climate change (Giorgi, 2006). Evidence for this has been accumulating particularly in the last 30 years with a steady increase in extreme events including storms, floods and droughts. In the period 2000-2009, 39 hurricanes occurred in the Caribbean basin compared to 15 and 9 in the decade of 1980 and 1990 respectively (UNEP-ECLAC, 2010). The impacts of these events on the population and the economy of the region have been tremendous: the economic loss derived from 11 recent hydrometereological events evaluated added to US $13,642 millions and the number of people impacted peaked with hurricane Mitch in 1998 with over 600,000 persons affected (ECLAC, 2010c). A high percentage of the population in CA live on or near highly unstable steep terrain with sandy, volcanic soils prone to mudslides which are the main cause of casualties and destruction (Restrepo and Alvarez, 2006).

The increased climatic variability in the past decade certainly changed the perception of people in the region with respect to climate change. In a survey to small farmers in 2003, Tucker *et al.* (2010) found that only 25% of respondents included climate events as a major concern. A subsequent survey in 2007 (Eakin *et al.*, 2013) found that over 50% of respondents cited drought conditions and torrential rains as their greatest concern. Interestingly, there was no consensus on the direction in climate change pattern: the majority or households in Honduras reported an increase in the frequency of droughts but in Costa Rica and Guatemala a decrease or no trend at all was reported; a similar discrepancy in answers was reported with the issue of increase rainfall. But there was general agreement in all countries that rainfall patterns were more variable resulting in higher difficulty in recognizing the start of the rainy season.

The high levels of risk to disasters in CA are the result of high exposure to hazards and the high vulnerability of the population and its livelihoods derived from elevated levels of poverty and social exclusion (Programa Estado de la Nación-Región, 2011). Disaster management in the region has focused on improving early warning systems and emergency response for specific extreme events (Saldaña-Zorrilla, 2008) but little attention has been paid to strengthening existing social capital in the form of local organizations and cooperatives. These associations can be central in increasing adaptive capacity through increased access to financial instruments and strategic information on global markets and climate (Eakin *et al.*, 2011). There is a need to increase the communication of the knowledge from local communities involved in processes of autonomous adaptation to policy makers responsible for strengthening the adaptive capacities in CA (Castellanos *et al.*, 2013).

______END BOX 27-1 HERE______

27.2.1.2. Climate Projections

Since the AR4, substantial additional regional analysis has been carried out using the CMIP3 model ensemble. In addition, projections from CMIP5 models and new experiences using regional models (downscaling) have allowed for a better description of future changes in climate and extremes in CA and SA. Using CMIP3 and CMIP5 models, Giorgi (2006), Diffenbaugh *et al.* (2008), Xu *et al.* (2009), Diffenbaugh and Giorgi (2012) and Jones and Carvalho (2013) have identified areas of CA/western North America and the Amazon as persistent regional climate change hotspots throughout the 21st century of the RCP8.5 and RCP4.5. Table 27-2 summarizes projected climatic changes derived from global and regional models for the region, indicating the projected change, models, emission scenarios, time spans and references.

[INSERT TABLE 27-2 HERE
Table 27-2: Regional projected changes in temperature, precipitation, and climate extremes in different sectors of CA and SA. Various studies used A2 and B2 scenarios from CMIP3 and various RCPs scenarios for CMIP5, and different time slices from 2010 to 2100. In order to make results comparable, the CMIP3 and CMIP5 at the time slice ending in 2100 are included. Additional information on changes in projected extremes can be found in the IPCC SREX (see IPCC, 2012b), and Chapters 9 and 14 from IPCC WG1AR5 [9.5, 9.6 and 14.2, 14.7]]

In CA and Northern Venezuela, projections from CMIP3 models and from downscaling experiments suggest precipitation reductions and warming together with an increase in evaporation, and reductions in soil moisture for most of the land during all seasons by the end of the 21th century (see references in Table 27-2). However, the spread of projections is high for future precipitation.

Analyses from global and regional models in tropical and subtropical SA show common patterns of projected climate in some sectors of the continent. Projections from CMIP3 regional and high resolution global models show by the end of the 21st century for the A2 emission scenario, a consistent pattern of increase of precipitation in SESA, Northwest of Peru and Ecuador and western Amazonia, while decreases are projected for northern SA, Eastern Amazonia, central eastern Brazil, NEB, the Altiplano and southern Chile (Table 27-2). For some regions, projections show mixed results in rainfall projections for the Amazonia and the SAMS region suggesting high uncertainties on the projections (Table 27-2).

As for extremes, CMIP3 models and downscaling experiments show increases in dry spells are projected for Eastern Amazonia and NEB, while rainfall extremes are projected to increase in SESA, in western Amazonia, Northwest Peru and Ecuador, while over southern Amazonia, northeastern Brazil and eastern Amazonia, the maximum number of consecutive dry days tends to augment, suggesting a longer dry season. Increases in warm nights throughout SA are also projected by the end of the 21st century (see references in Table 27-2). Shiogama *et al.* (2011) suggest that although the CMIP3 ensemble mean assessment suggested wetting across most of SA, the observational constraints indicate a higher probability of drying in the eastern Amazon basin.

The CMIP5 models project an even larger expansion of the monsoon regions in NAMS in future scenarios (Jones and Carvalho, 2013; Kitoh *et al.*, 2013). A comparison from eight models from CMIP3 and CMIP5 identifies some improvements in the new generation models. For example, CMIP5 inter-model variability of temperature in summer was lower over northeastern Argentina, Paraguay and northern Brazil, in the last decades of the 21st century, as compared to CMIP3. Although no major differences were observed in both precipitation datasets, CMIP5 inter-model variability was lower over northern and eastern Brazil in summer by 2100 (Blázquez and Nuñez, 2013; Jones and Carvalho, 2013).

The projections from the CMIP5 models at regional level for CA and SA (using the same regions from the IPCC SREX) are shown in Figure 27-1, and update some of these previous projections based on SRES A2 and B2 emission scenarios from CMIP3. Figure 27-1 shows that in relation to the baseline period 1986-2005, for CA and northern South America-Amazonia, temperatures are projected to increase approximately by 0.6 °C and 2 °C for the RCP2.6 scenario, and by 3.6 C and 5.2 °C for the RCP8.5 scenario. For the rest of South America, increases by about 0.6 °C to 2 °C are projected for the RCP4.5 and by about 2.2 °C to 7 °C for the RCP8.5 scenario. The observed records show increases of temperature from 1900 to 1986 by about 1 °C. For precipitation, while for CA and northern South America-Amazonia precipitation is projected to vary between +10% to -25% (with large spread among models). For NEB, there is a spread among models between +30 to -30% making hard to identify any projected rainfall change. This spread is much lower in the western coast of South America and SESA, where the spread is between +20 and -10% (IPCC WG2 Chapter 21, Box 21-3).

Figure 27-2 shows that by late-21st century, the CMIP5 derived projections for RCP8.5 projected: CA: mean annual warming of 2.5ºC and rainfall reduction of 10%, and reduction in summertime precipitation. SA: mean warming of 4ºC, with rainfall reduction up to 15% in tropical SA east of the Andes, and an increase of about 15-20% in SESA, and in other regions of the continent. Changes in mid-21st century are small. Both Figures 27-1 and 27-2 show that there is some degree of uncertainty on climate change projections for regions, particularly for rainfall in CA and tropical SA.

[INSERT FIGURE 27-1 HERE
Figure 27-1: Observed and simulated variations in past and projected future annual average temperature over the Central and South American regions defined in IPCC (2012a). Black lines show various estimates from observational measurements. Shading denotes the 5-95 percentile range of climate model simulations driven with "historical" changes in anthropogenic and natural drivers (63 simulations), historical changes in "natural" drivers only (34), the "RCP2.6" emissions scenario (63), and the "RCP8.5" (63). Data are anomalies from the 1986-2006 average of the individual observational data (for the observational time series) or of the corresponding historical all-forcing simulations. Further details are given in Box 21-3.]

[INSERT FIGURE 27-2 HERE
Figure 27-2: Projected changes in annual average temperature and precipitation. CMIP5 multi-model mean projections of annual average temperature changes (left panel) and average percent change in annual mean precipitation (right panel) for 2046-2065 and 2081-2100 under RCP2.6 and 8.5. Solid colors indicate areas with very strong agreement, where the multi-model mean change is greater than twice the baseline variability, and>90% of models agree on sign of change. Colors with white dots indicate areas with strong agreement, where>66% of models show change greater than the baseline variability and>66% of models agree on sign of change. Gray indicates areas with divergent changes, where>66% of models show change greater than the baseline variability, but<66% agree on sign of change. Colors with diagonal lines indicate areas with little or no change, less than the baseline variability in>66% of models. (There may be significant change at shorter timescales such as seasons, months, or days.). Analysis uses model data and methods building from WGI AR5 Figure SPM.8. See also Annex I of WGI AR5. [Boxes 21-3 and CC-RC]]

27.2.2. Non-Climatic Stressors

27.2.2.1. Trends and Projections in Land Use and Land Use Change

Land use change is a key driver of environmental degradation for the region that exacerbates the negative impacts from climate change (Lopez-Rodriguez and Blanco-Libreros, 2008; Sampaio *et al.*, 2007). The high levels of deforestation observed in most of the countries in the region have been widely discussed in the literature as a deliberate development strategy based on the expansion of agriculture to satisfy the growing world demand for food, energy and minerals (Benhin, 2006; Grau and Aide, 2008; Mueller *et al.*, 2008). Land is facing increasing pressure from competing uses, among them cattle ranching, food and bioenergy production. The enhanced competition for land increases the risk of land use changes, which may lead to negative environmental and socio-economic impacts. Agricultural expansion has relied in many cases on government subsidies, which have often resulted in lower land productivity and more land speculation (Bulte *et al.*, 2007; Roebeling and Hendrix, 2010). Some of the most affected areas due to the expansion of the agricultural frontier are fragile ecosystems such as the edges of the Amazon forest in Brazil, Colombia, Ecuador and Peru, and the tropical Andes including the Paramo, where activities such as deforestation, agriculture, cattle ranching and gold mining are causing severe environmental degradation (ECLAC, 2010d), and the reduction of environmental services provided by these ecosystems.

Deforestation rates for the region remain high in spite of a reducing trend in the last decade (Fearnside, 2008; Ramankutty *et al.*, 2007). Brazil is by far the country with the highest area of forest loss in the world according to the latest FAO statistics (2010): 21,940 km^2 per year equivalent to 39% of the world deforestation for the period 2005-2010. Bolivia, Venezuela and Argentina follow in deforested area (Figure 27-3) with 5.5%, 5.2% and 4.3% of the total world deforestation respectively. The countries of CA and SA lost a total of 38,300 km^2 of forest per year in that period (69% of the total world deforestation) (FAO, 2010). These numbers are limited by the fact that many countries do not have comparable information through time, particularly for recent years. Aide *et al.* (2013) completed a wall-to-wall analysis for the region for the period 2001-2010 analyzing not only deforestation but also reforestation and reported very different results than FAO (2010) for some countries where reforestation seems to be higher than deforestation, particularly in Honduras, El Salvador, Panama, Colombia and Venezuela. For Colombia and Venezuela, these results are contradictory with country analyses that align better with the FAO data (Armenteras *et al.*, 2013; Rodríguez *et al.*, 2010).

[INSERT FIGURE 27-3 HERE
Figure 27-3: Area deforested per year for selected countries in CA and SA (2005-2010). Notice three countries listed with a positive change in forest cover (based on data from FAO, 2010).]

Deforestation in the Amazon forest has received much international attention in the last decades, both because of its high rates, and its rich biodiversity. Brazilian Legal Amazon is now one of the best-monitored ecosystems in terms of deforestation since 1988 (INPE, 2011). Deforestation for this region peaked in 2004 and has steadily declined since then to a lowest value of 4,656 Km^2/yr for the year 2012 (see Figure 27-4). Such reduction results from a series of integrated policies to control illegal deforestation particularly enforcing protected areas, which now shelter 54% of the remaining forests of the Brazilian Amazon (Soares-Filho *et al.*, 2010). Deforestation in Brazil is now highest in the Cerrado (drier ecosystem south of Amazon) with an average value of 14,179 Km^2/yr for the period 2002-2008 (FAO, 2009).

[INSERT FIGURE 27-4 HERE
Figure 27-4: Deforestation rates in the Brazilian Amazonia (km^2/year) based on measurements by the PRODES project (INPE, 2011).]

The area of forest loss in CA is considerably less than in SA, owing to smaller country sizes (Carr *et al.*, 2009), but when relative deforestation rates are considered, Honduras and Nicaragua show the highest values for CA and SA (FAO, 2010). At the same time, CA includes some countries where forest cover shows a small recovery trend in the last years: Costa Rica, El Salvador, Panama and possibly Honduras where data is conflicting in the literature (Aide *et al.*, 2013; FAO, 2010). This forest transition is the result of: (1) economies less dependent on agriculture, and more on industry and services (Wright and Samaniego, 2008); (2) processes of international migration with the associated remittances (Hecht and Saatchi, 2007), and (3) a stronger emphasis on the recognition of environmental services of forest ecosystems (Kaimowitz, 2008). The same positive trend is observed in some SA countries (Figure 27-3). However, a substantial amount of forest is gained through (single-crop) plantations, most noticeably in Chile (Aguayo *et al.*, 2009), which has a much lower ecological value than the depleted natural forests (Echeverría *et al.*, 2006; Izquierdo *et al.*, 2008).

Land degradation, is also an important process compromising extensive areas of CA and SA very rapidly. According to data from the Global Land Degradation Assessment and Improvement (GLADA) project of the Global Environmental Facility (GEF), additional degraded areas reached 16.4% of the entire territory of Paraguay, 15.3% of Peru and 14.2% of Ecuador for the period 1982-2002. In CA, Guatemala shows the highest proportion of degraded land, currently at 58.9% of the country’s territory, followed by Honduras (38.4%) and Costa Rica (29.5%); only El Salvador shows a reversal of the land degradation process, probably due to eased land exploitation following intensive international migratory processes (ECLAC, 2010d).

Deforestation and land degradation are mainly attributed to increased extensive and intensive agriculture. Two activities have traditionally dominated the agricultural expansion: soy production (only in SA) and beef; but more recently, biomass for biofuel production has become as important (Nepstad and Stickler, 2008) with some regions also affected by oil and mining extractions. Deforestation by small farmers, mainly coming from families who migrate in search for land is relatively low: extensive cattle production is the predominant land use in deforested areas of tropical and subtropical Latin America (Wassenaar *et al.*, 2007). Cattle is the only land use variable correlated with deforestation in Colombia (Armenteras *et al.*, 2013) and in the Brazilian Amazon the peak of deforestation in 2004 (Figure 27-4) was primarily the result of increased cattle ranching (Nepstad *et al.*, 2006). Mechanized farming, agro-industrial production and cattle ranching are the major land use change drivers in eastern Bolivia but subsistence agriculture by indigenous colonists is also important (Killeen *et al.*, 2008).

In recent years, soybean croplands have expanded continuously in SA, becoming increasingly more important in the agricultural production of the region. Soybean-planted area in Amazonian states (mainly Mato Grosso) in Brazil expanded 12.1% per year during the 1990s, and 16.8% per year from 2000 to 2005 (Costa *et al.*, 2007). This landscape-scale conversion from forest to soy and other large-scale agriculture can alter substantially the water balance for large areas of the region resulting in important feedbacks to the local climate (Hayhoe *et al.*, 2011; Loarie *et al.*, 2011) (see section 27.3.4.1).

Soybean and beef production have also impacted other ecosystems next to the Amazon, such as the Cerrado (Brazil) and the Chaco dry forests (Bolivia, Paraguay, Argentina and Brazil). Gasparri *et al.* (2008) estimated carbon emissions from deforestation in Northern Argentina, and concluded that deforestation in the Chaco forest has accelerated in the past decade from agricultural expansion and is now the most important source of carbon emission for that region. In northwest Argentina (Tucumán and Salta provinces) 14,000 km^2 of dry forest were cleared from 1972 to 2007 as a result of technological improvements and increasing rainfall (Gasparri and Grau, 2009). Deforestation continued during the 1980s and 1990s resulting in cropland area covering up to 63% of the region by 2005 (Viglizzo *et al.*, 2011). In central Argentina (northern Córdoba province), cultivated lands have increased from 3% to 30% (between 1969 and 1999); and the forest cover has decreased from 52.5% to 8.2%. This change has also been attributed to the synergistic effect of climatic, socioeconomic, and technological factors (Zak *et al.*, 2008). Losses in the Atlantic forest are estimated in 29% of the original area in 1960, and in 28% of the Yunga forest area, mainly due to cattle ranching migration from the Pampas and Espinal (Viglizzo *et al.*, 2011).

Oil palm is a significant biofuel crop also linked to recent deforestation in tropical CA and SA. Its magnitude is still small compared with deforestation related to soybean and cattle ranching, but it is considerable for specific countries and expected to increase due to increasing demands for biofuels (Fitzherbert *et al.*, 2008). The main producers of palm oil in the region are Colombia and Ecuador, followed by Costa Rica, Honduras, Guatemala and Brazil; this country has the largest potential for expansion, as nearly half of the Amazonia is suitable for oil palm cultivation (Butler and Laurance, 2009). Oil palm production is also growing in the Amazonian region of Peru, where 72% of new plantations have expanded into forested areas representing 1.3% of the total deforestation for that country for the years 2000-2010 (Gutiérrez-Vélez *et al.*, 2011).

However, forests are not the only important ecosystems threatened in the region. An assessment of threatened ecosystems in SA by Jarvis *et al.* (2010) concluded that grasslands, savannas and shrublands are more threatened than forests, mainly from excessively frequent fires (>1/year) and grazing pressure. An estimation of burned land in Latin America by Chuvieco *et al.* (2008) also concluded that herbaceous areas presented the highest occurrence of fires. In the Río de la Plata region (Central-East Argentina, southern Brazil, and Uruguay), grasslands decreased from 67.4% to 61.4% between 1985 and 2004. This reduction was associated with an increase in annual crops, mainly soybean, sunflower, wheat, and maize (Baldi and Paruelo, 2008).

Even with technological changes that might result in agricultural intensification, the expansion of pastures and croplands is expected to continue in the coming years (Kaimowitz and Angelsen, 2008; Wassenaar *et al.*, 2007), particularly from an increasing global demand for food and biofuels (Gregg and Smith, 2010) with the consequent increase in commodity prices. This agricultural expansion will be mainly in Latin America and Sub-Saharan Africa as these regions hold two-thirds of the global land with potential to expand cultivation (Nepstad and Stickler, 2008). It is important to consider the policy and legal needs to keep this process of large-scale change under control as much as possible; Takasaki (2007) showed that policies to eliminate land price distortions and promote technological transfers to poor colonists could reduce deforestation. It is also important to consider the role of indigenous groups; there is a growing acknowledgment that recognizing the land ownership and authority of indigenous groups can help central governments to better manage many of the natural areas remaining in the region (Larson, 2010; Oltremari and Jackson, 2006). The impact of indigenous groups on land use change can vary: Oliveira *et al.* (2007) found that only 9% of the deforestation in the Peruvian Amazon between 1999 and 2005 happened in indigenous territories but Killeen *et al.* (2008) found that Andean indigenous colonists in Bolivia were responsible for the largest land cover changes in the period 2001-2004. Indigenous groups are important stakeholders in many territories in the region and their well-being should be considered when designing responses to pressures on the land by a globalized economy (Gray *et al.*, 2008; Killeen *et al.*, 2008).

27.2.2.2. Trends and Projections in Socioeconomic Conditions

Development in the region has traditionally displayed four characteristics: low growth rates, high volatility, structural heterogeneity and a very unequal income distribution (Bárcena, 2010; ECLAC, 2008). This combination of factors has generated high and persistent poverty levels (45% for CA and 30% for SA for year 2010), with the rate of poverty being generally higher in rural than urban areas (ECLAC, 2009b). SA has based its economic growth in natural resource exploitation (mining, energy, agricultural), which involves direct and intensive use of land and water, and in energy-intensive and, in many cases, highly polluting natural-resource-based manufactures. In turn, CA has exploited its proximity to the North American market and its relatively low labor costs (ECLAC, 2010e). The region shows a marked structural heterogeneity, where modern production structures coexist with large segments of the population with low productivity and income levels (ECLAC, 2010g). The GDP per capita in SA is twice that of CA; in addition, in the latter poverty is 50% higher (see Figure 27-5).

[INSERT FIGURE 27-5 HERE
Figure 27-5: Evolution of GDP per capita and poverty (income below US$ 2 per day) from 1990-2010: CA and SA (US-Dollars per inhabitant at 2005 prices and percentages) (ECLAC on the basis of CEPALSTAT (2012) and ECLAC (2011c)).]

The 2008 financial crisis reached CA and SA through exports and credits, remittances and worsening expectations by consumers and producers (Bárcena, 2010; Kacef and López-Monti, 2010). This resulted in the sudden stop of six consecutive years of robust growth and improving social indicators (ECLAC, 2010e), which contributed to higher poverty in 2009 after six years where poverty had declined by 11%. Poverty rates fell from 44% to 33% of the total population from 2003 to 2008 (Figure 27-5), leaving 150 million people in this situation while extreme poverty diminished from 19.4% to 12.9% (which represents slightly more than 70 million people) (ECLAC, 2009b).

In the second half of 2009 industrial production and exports began to recover and yielded a stronger economic performance (GDP growth of 6.4% in SA and 3.9% in CA in 2010) (ECLAC, 2012). SA benefited the most because of the larger size of their domestic markets and the greater diversification of export markets. Conversely, slower growth was observed in CA with more open economies and a less diversified portfolio of trading partners and a greater emphasis on manufacturing trade (ECLAC, 2010g).

The region is expected to continue to grow in the short term, albeit at a pace that is closer to potential GDP growth, helped by internal demand as the middle class becomes stronger and as credit becomes more available. In SA, this could be boosted by external demand from the Asian economies as they continue to grow at a rapid pace. The macroeconomic challenge is to act counter cyclically creating conditions for productive development that is not based solely on commodity exports (ECLAC, 2010f).

In spite of its economic growth, CA and SA still display high and persistent inequality: most countries have Gini coefficients between 0.5 and 0.6, whereas the equivalent figures in a group of 24 developed countries vary between under 0.25 and around 0.4. The average per capita income of richest 10% of households is approximately 17 times that of the poorest 40% of households (ECLAC, 2010g). Nevertheless, during the first decade of the century, prior to the financial crisis, the region has shown a slight but clear trend towards a more equitable distribution of income and a stronger middle class population resulting in a higher demand for goods (ECLAC, 2010g; ECLAC, 2011b; UN, 2010). Latin American countries also reported gains in terms of human development, although these gains have slowed down slightly over recent years. In comparative terms, the performance of countries as measured by the Human Development Index (HDI) varied greatly in 2007 (from Chile with 0.878 and Argentina with 0.866 to Guatemala with 0.704 and Nicaragua with 0.699) although those with lower levels of HDI showed notably higher improvements than countries with the highest HDI (UNDP, 2010).

Associated with inequality are disparities in access to water, sanitation and adequate housing for the most vulnerable groups - for example indigenous peoples, Afro-descendants, children and women living in poverty- and in their exposure to the effects of climate change. The strong heterogeneity of subnational territorial entities in the region takes the form of high spatial concentration and persistent disparities in the territorial distribution of wealth (ECLAC, 2010g; ECLAC, 2011b; UN, 2010).

The region faces significant challenges in terms of environmental sustainability and adaptability to a changing climate (UN, 2010), resulting from the specific characteristics of its population and economy already discussed and aggravated with a significant deficit in infrastructure development. The countries in CA and SA have made progress in incorporating environmental protection into decision-making processes, and particularly in terms of environmental institutions and legislation, but there are still difficulties to effectively incorporate environmental issues into relevant public policies (UN, 2010). While climate change imposes new challenges, it also provides an opportunity to shift development and economic growth patterns towards a more environmentally friendly course.

27.3. Impacts, Vulnerabilities, and Adaptation Practices

27.3.1. Freshwater Resources

CA and SA are regions with a high average but unevenly distributed water resources availability (Magrin *et al.*, 2007a). The main user of water is agriculture followed by the region's 580 million inhabitants (including the Caribbean), of which 86% had access to water supply by 2006 (ECLAC, 2010b). According to the International Energy Agency (IEA), the region meets 60% of its electricity demand through hydropower generation, which contrast with the 20% average contribution of other regions (see Table 27-6 and case study 27.6.1).

27.3.1.1. Observed and Projected Impacts and Vulnerabilities

In CA and SA there are many evidences of changing hydrologic related conditions. The most robust trend for major rivers is found in the sub-basins of the La Plata River basin (*high confidence* based on *high agreement, robust evidence*). This basin, second only to the Amazon in size, shows a positive trend in streamflow in the second half of the 20th century at different sites (Amsler and Drago, 2009; Conway and Mahé, 2009; Dai *et al.*, 2009; Dai, 2011; Doyle and Barros, 2011; Krepper *et al.*, 2008; Krepper and Zucarelli, 2010a; Pasquini and Depetris, 2007; Saurral *et al.*, 2008). An increase in precipitation and a reduction in evapotranspiration from land use changes have been associated with the trend in streamflows (Doyle and Barros, 2011; Saurral *et al.*, 2008), with the former being more important in the southern sub-basins and the latter in the northern ones (Doyle and Barros, 2011) (see section 27.2.1). Increasing trends in streamflows have also been found in the Patos Lagoon in southern Brazil (Marques, 2012) and Laguna Mar Chiquita (a closed lake), and in the Santa Fe Province, both in Argentina, with ecological and erosive consequences (Bucher and Curto, 2012; Pasquini *et al.*, 2006; Rodrigues Capítulo *et al.*, 2010; Troin *et al.*, 2010; Venencio and García, 2011).

There is no clear long-term trend for the Amazon River. Espinoza *et al.* (2009a; 2011) showed that the 1974-2004 apparent stability in mean discharge at the main stem of the Amazon in Obidos is explained by opposing regional features of Andean rivers (e.g. increasing trends during the high-water period in Peruvian and Colombian Amazons and decreasing trend during the low-water period in Peruvian and Bolivian Amazons (Lavado *et al.*, 2012). In recent years extremely low levels were experienced during the droughts of 2005 and 2010, while record high levels were detected during the 2009 and 2012 floods (see section 27.2.1). Major Colombian rivers draining to the Caribbean Sea (Magdalena and Cauca) exhibit decreasing trends along their main channels (Carmona and Poveda, 2011), while significant trends are absent for all other major large rivers in the Brazilian North East, and northern SA (Dai *et al.*, 2009). Dai (2011) showed a drying trend in CA rivers.

A rapid retreat and melting of the tropical Andes glaciers of Venezuela, Colombia, Ecuador, Peru and Bolivia has been further reported following the IPCC AR4, through use of diverse techniques (*high confidence* based on *high agreement* and *robust evidence*). Rabatel *et al*. (2013) provides a synthesis of these studies (specific papers are presented in Table 27-3a). Tropical glaciers' retreat has accelerated in the second half of the 20th century (area loss between 20-50%), especially since the late 1970s in association with increasing temperature in the same period (Bradley *et al.*, 2009). In early stages of glacier retreat associated streamflow tends to increase due to an acceleration of glacier melt, but after a peak in streamflow as the glacierized water reservoir gradually empties, runoff tends to decrease, as evidenced in the Cordillera Blanca of Peru (Baraer *et al.*, 2012; Chevallier *et al.*, 2011), where seven out of nine river basins have probably crossed a critical threshold, exhibiting a decreasing dry-season discharge

(Baraer *et al.*, 2012). Likewise, glaciers and icefields in the extra tropical Andes located in Central-South Chile and Argentina face significant reductions (see review in Masiokas *et al.* (2009) and details in Table 27-3b), with their effect being compounded by changes in snowpack extent, thus magnifying changes in hydrograph seasonality by reducing flows in dry seasons and increasing them in wet seasons (Pizarro *et al.*, 2013; Vicuña *et al.*, 2013). Central-South Chile and Argentina also face significant reductions in precipitation as shown in section 27.2.1, contributing to runoff reductions in the last decades of the 20th century (Rubio-Álvarez and McPhee, 2010; Seoane and López, 2007; Urrutia *et al.*, 2011; Vicuña *et al.*, 2013), corroborated with long-term trends found through dendrochronology (Lara *et al.*, 2007; Urrutia *et al.*, 2011). Trends in precipitation and runoff are less evident in the Central-North region in Chile (Fiebig-Wittmaack *et al.*, 2012; Souvignet *et al.*, 2012).

[INSERT TABLE 27-3 HERE
Table 27-3: Observed trends related to Andean cryosphere: a) Andean tropical glacier trends, and b) extra tropical Andean cryosphere (glaciers, snowpack, runoff effects) trends.]

As presented in Table 27-4, the assessment of future climate scenarios implications in hydrologic related conditions shows a large range of uncertainty across the spectrum of climate models (mostly using CMIP3 simulations with the exception of Demaria *et al.* (2013) and scenarios considered. Nohara *et al.* (2006) studied climate change impacts on 24 of the main rivers in the world considering a large number of GCMs, and found no robust change for the Paraná (La Plata Basin) and Amazon Rivers. Nevertheless, in both cases the average change showed a positive value consistent at least with observations for the La Plata Basin. In a more recent work Nakaegawa *et al.* (2013a) showed statistically significant increase for both basins in a study that replicated that of Nohara *et al.* (2006) but with different hydrologic model. Focusing in extreme flows Guimberteau *et al.* (2013) show that by the middle of the century no change is found in high flow on the main stem of the Amazon River but there is a systematic reduction in low-flow streamflow. In contrast the northwestern part of the Amazon River shows a consistent increase in high flow and inundated area (Guimberteau *et al.*, 2013; Langerwisch *et al.*, 2013). On top of such climatic uncertainty, future streamflows and water availability projections are confounded by the potential effects of land use changes (Coe *et al.*, 2009; Georgescu *et al.*, 2013; Moore *et al.*, 2007).

[INSERT TABLE 27-4 HERE
Table 27-4: Synthesis of projected climate change impacts on hydrologic related variables in CA and SA basins and major glaciers.]

The CA region shows a consistent future runoff reduction. Maurer *et al.* (2009)studied climate change projections for the Lempa River basin, one of the largest basins in CA, covering portions of Guatemala, Honduras and El Salvador. They showed that future climate projections (increase in evaporation and reduction in precipitation) imply a reduction of 20% in inflows to major reservoirs in this system (see Table 27-4). Imbach *et al.* (2012) found similar results using a modeling approach that also considered potential changes in vegetation. These effects could have large hydropower generation implications as discussed in the case study (see section 27.6.1).

The evolution of tropical Andes glaciers associated future climate scenarios has been studied using trend (e.g. Poveda and Pineda (2009), regression (e.g. Juen *et al.* (2007) and Chevallier *et al.* (2011) and explicit modeling (e.g. Condom *et al.*, 2012) analysis. These studies indicate that glaciers will continue their retreat (Vuille *et al.*, 2008a) and even disappear as glacier Equilibrium Line Altitudes rises, with larger hydrological effects during the dry season (Gascoin *et al.*, 2011; Kaser *et al.*, 2010). This is expected to happen during the next 20-50 years (Chevallier *et al.*, 2011; Juen *et al.*, 2007) (see Table 27-4). After that period water availability during the dry months is expected to diminish. A projection by Baraer *et al.* (2012) for the Santa River in the Peruvian Andes finds that once the glaciers are completely melt, annual discharge would decrease by 2%–30%, depending on the watershed. Glacier retreat can exacerbate current water resources related vulnerability (Bradley *et al.*, 2006; Casassa *et al.*, 2007; Mulligan *et al.*, 2010; Vuille *et al.*, 2008b), diminishing the mountains' water regulation capacity, making it more expensive and less reliable the supply of water for diverse purposes, as well as for ecosystems integrity (Buytaert *et al.*, 2011). Impacts on economic activities associated with conceptual scenarios of glacier melt reduction have been monetized (Vergara *et al.*, 2007), representing about US$100 million in the case of water supply for Quito, and between US$212 million to US$ 1.5 billion in the case of the Peruvian electricity sector due to losses of hydropower generation (see case study 27.6.1). Andean communities will face an important increase in their vulnerability, as documented by Mark *et al.* (2010), Pérez *et al.* (2010) and Buytaert and De Bièvre (2012).

In Central Chile, Vicuña *et al.* (2011) project changes in the seasonality of streamflows of the upper snowmelt-driven watersheds of the Limarí River, associated with temperature increases and reductions in water availability owing to a reduction (increase) in precipitation (evapotranspiration). Similar conclusions are derived across the Andes on the Limay River in Argentina by Seoane and López (2007). Under these conditions, semiarid highly populated basins (e.g. Santiago, Chile) and with extensive agriculture irrigation and hydropower demands are expected to increase their current vulnerability (ECLAC, 2009a; Fiebig-Wittmaack *et al.*, 2012; Souvignet *et al.*, 2010; Vicuña *et al.*, 2012) (*high confidence*) (see Table 27-4). Projected changes in the cryosphere conditions of the Andes could affect the occurrence of extreme events, such as extreme low and high flows (Demaria *et al.*, 2013). Glacial-lake outburst floods occurring in the icefields of Patagonia (Dussaillant *et al.*, 2010; Marín *et al.*, 2013), volcanic collapse and debris flow associated with accelerated glacial melting in the tropical Andes (Carey, 2005; Carey *et al.*, 2012b; Fraser, 2012), and with volcanoes in southern Chile and Argentina (Tormey, 2010), as well as scenarios of water quality pollution by exposure to contaminants owing to glaciers retreat (Fortner *et al.*, 2011).

Another semiarid region that has been studied thoroughly is the NEBian (Hastenrath, 2012). De Mello *et al.* (2008), Gondim *et al.* (2008), Souza *et al.* (2010) and Montenegro and Ragab (2010) have shown that future climate change scenarios would decrease water availability for agriculture irrigation owing to reductions in precipitation and increases in evapotranspiration (*medium confidence*). Krol and Bronstert (2007) and Krol *et al.* (2006) presented an integrated modeling study that linked projected impacts on water availability for agriculture with economic impacts that could potentially drive full-scale migrations in the Brazilian northeast region.

27.3.1.2. Adaptation Practices

At an institutional level, a series of policies have been developed to reduce vulnerability to climate variability as faced today in different regions and settings. In 1997, Brazil instituted the National Water Resources Policy and created the National Water Resources Management System under the shared responsibility between the States and the Federal government. Key to this new regulation has been the promotion of decentralization and social participation through the creation of National Council of Water Resources and their counterparts in the states, the States Water Resources Councils. The challenges and opportunities dealing with water resources management in Brazil in the face of climate variability and climate change have been well studied (Abers, 2007; Engle *et al.*, 2011; Kumler and Lemos, 2008; Lorz *et al.*, 2012; Medema *et al.*, 2008). Other countries in the region are following similar approaches. In the last years, there have been constitutional and legal reforms towards more efficient and effective water resources management and coordination among relevant actors in Honduras, Nicaragua, Ecuador, Peru, Uruguay, Bolivia and Mexico; although in many cases, these innovations have not been completely implemented (Hantke –Domas, 2011). Institutional and governance improvements are required to assure an effective implementation of these adaptation measures (e.g. Halsnæs and Verhagen, 2007; Engle and Lemos, 2010; Lemos *et al.*, 2010; Zagonari, 2010; Pittock, 2011; and Kirchhoff *et al.* 2013).

With regards to region specific freshwater resources issues it is important to consider adaptation to reduce vulnerabilities in the communities along the tropical Andes and the semi-arid basins in Chile-Argentina, North East Brazil, and the northern CA basins. Different issues have been addressed in the assessment of adaptation strategies for tropical Andean communities such as the role of governance and institutions (Lynch, 2012; Young and Lipton, 2006), technology (Carey *et al.*, 2012a), and the dynamics of multiple stressors (Bury *et al.*, 2013; McDowell and Hess, 2012). Semiarid regions are characterized by pronounced climatic variability and often by water scarcity and related social stress (Krol and Bronstert, 2007; Scott *et al.*, 2012; 2013). Adaptation tools to face the threats of climate change for the most vulnerable communities in the Chilean semi-arid region are discussed by Young *et al.* (2010) and Debels *et al.* (2009). In CA, Benegas *et al.* (2009), Manuel-Navarrete *et al.* (2007) and Aguilar *et al.* (2009) provide different frameworks to understand vulnerability and adaptation strategies to climate change and variability in urban and rural contexts, although no specific adaptation strategies are suggested. The particular experience in NEB provides other examples of adaptation strategies to manage actual climate variability. Broad *et al.* (2007) and Sankarasubramanian *et al.* (2009) studied the potential benefits of streamflow forecast as a way to reduce the impacts of climate change and climate variability on water distribution under stress conditions. An historical review and analysis of drought management in this region are provided by Campos and Carvalho (2008). Souza Filho and Brown (2009) studied different water distribution policy scenarios finding that the best option depended on the degree of water scarcity. The study by Nelson and Finan (2009) provides a critical perspective of drought-related policies, arguing that they constitute an example of maladaptation as they do not try to solve the causes of vulnerability and instead undermine resilience. Tompkins *et al.* (2008) are also critical of risk reduction practices in this region because they have fallen short of addressing the fundamental causes of vulnerability needed for efficient longer-term drought management. Other types of adaptation options that stem from studies on arid and semiarid regions are related to: a) increase in water supply from groundwater pumping (Burte *et al.*, 2011; Döll, 2009; Kundzewicz and Döll, 2009; Nadal *et al.*, 2013; Zagonari, 2010); fog interception practices (Holder, 2006; Klemm *et al.*, 2012), and reservoirs and irrigation infrastructure (Fry *et al.*, 2010; Vicuña *et al.*, 2010; 2012); b) improvements in water demand management associated with increased irrigation efficiency and practices (Bell *et al.*, 2011; Geerts *et al.*, 2010; Jara-Rojas *et al.*, 2012; Montenegro and Ragab, 2010; Van Oel *et al.*, 2010), and changes towards less water intensive crops (Montenegro and Ragab, 2010).

Finally flood management practices also provide a suite of options to deal with actual and future vulnerabilities related to hydrologic extremes, such as the management of ENSO-related events in Peru via participatory (Warner and Oré, 2006) or risk reduction approaches (Khalil *et al.*, 2007), the role of land use management (Bathurst *et al.*, 2010; 2011; Coe *et al.*, 2011), and flood hazard assessment (Mosquera-Machado and Ahmad, 2006) (*medium confidence*).

27.3.2. Terrestrial and Inland Water Systems

27.3.2.1. Observed and Projected Impacts and Vulnerabilities

CA and SA house the largest biological diversity and several of the world's megadiverse countries (Guevara and Laborde, 2008; Mittermeier *et al.*, 1997). However, land use change has led to the existence of six biodiversity hotspots, i.e. places with a great species diversity that show high habitat loss and also high levels of species endemism: Mesoamerica, Chocó-Darien-Western Ecuador, Tropical Andes, Central Chile, Brazilian Atlantic forest, and Brazilian Cerrado (Mittermeier *et al.*, 2005). Thus, conversion of natural ecosystems is the main proximate cause of biodiversity and ecosystem loss in the region (Ayoo, 2008). Tropical deforestation is the second largest driver of anthropogenic climate change on the planet, adding up to 17%-20% of total greenhouse gas emissions during the 1990s (Gullison *et al.*, 2007; Strassburg *et al.*, 2010). In parallel, the region has still large extensions of wilderness areas for which the Amazon is the most outstanding example. Nevertheless, some of these areas are precisely the new frontier of economic expansion. For instance, between 1996 and 2005 Brazil deforested about 19,500 km^2 per year, which represented 2% to 5% of global annual CO_2 emissions (Nepstad *et al.*, 2009). Between 2005 and 2009, deforestation in the Brazilian Amazon dropped by 36%, which is partly related to the network of protected areas that now covers around 45.6% of the biome in Brazil (Soares-Filho *et al.*, 2010). Using LandSHIFT modeling framework for land use change and the IMPACT projections of crop/livestock production, Lapola *et al.* (2011) projected that zero deforestation in the Brazilian Amazon forest by 2020 (and of the Cerrado by 2025) would require either a reduction of 26%–40% in livestock production until 2050 or a doubling of average livestock density from 0.74 to 1.46 head per hectare. Thus, climate change may imply reduction of yields and entail further deforestation.

Local deforestation rates or rising greenhouse gases globally drive changes in the regional SA that during this century might lead the Amazon rainforest into crossing a critical threshold at which a relatively small perturbation can qualitatively alter the state or development of a system (Cox *et al.*, 2000; Lenton *et al.*, 2008; Nobre and Borma, 2009; Salazar *et al.*, 2007; Sampaio *et al.*, 2007). Various models are projecting a risk of reduced rainfall and higher temperatures and water stress, that may lead to an abrupt and irreversible replacement of Amazon forests by savanna-like vegetation, under a high emission scenario (A2), from 2050-2060 to 2100 (Betts *et al.*, 2004; 2008; Cox *et al.*, 2004; Malhi *et al.*, 2008; Malhi *et al.*, 2009; Marengo *et al.*, 2011c; Nobre and Borma, 2009; Salazar *et al.*, 2007; Sampaio *et al.*, 2007; Sitch *et al.*, 2008). The possible 'savannization' or 'die-back' of the Amazon region would potentially have large-scale impacts on climate, biodiversity and people in the region. The possibility of this die-back scenario occurring, however, is still an open issue and the uncertainties are still very high (Rammig *et al.*, 2010; Shiogama *et al.*, 2011).

Plant species are rapidly declining in CA, SA, Central and West Africa, and Southeast Asia (Bradshaw *et al.*, 2009). Risk estimates of plant species extinction in the Amazon, which do not take into account possible climate change impacts, range from 5%-9% by 2050 with a habitat reduction of 12%-24% (Feeley and Silman, 2009) to 33% by 2030 (Hubbell *et al.*, 2008). The highest percentage of rapidly declining amphibian species occurs in CA and SA. Brazil is among the countries with most threatened bird and mammal species (Bradshaw *et al.*, 2009).

A similar scenario is found in inland water systems. Among the components of aquatic biodiversity, fish are the best-known organisms (Abell *et al.*, 2008) with Brazil accounting for the richest icthyofauna of the planet (Nogueira *et al.*, 2010). For instance, the 540 Brazilian small microbasins host 819 fish species with restrict distribution. However, 29% of these microbasins have historically lost more than 70% of their natural vegetation cover and only 26% show a significant overlap with protected areas or indigenous reserves. Moreover, 40% of the microbasins overlap with hydrodams (see 27.6.1 and Chapter 3) or have few protected areas and high rates of habitat loss (Nogueira *et al.*, 2010).

The faster and more severe the rate of climate change, the more severe the biological consequences such as species decline (Brook *et al.*, 2008). Vertebrate fauna in North and South America is projected to suffer species losses until 2100 of at least 10%, as forecasted in over 80% of the climate projections based on low emissions scenario (Lawler *et al.*, 2009). Vertebrate species turnover until 2100 will be as high as 90% in specific areas of CA and the Andes Mountains for emission scenarios varying from low B1 to mid-high A2 (Lawler *et al.*, 2009). Elevational specialists, i.e. a small proportion of species with small geographic ranges restricted to high mountains, are most frequent in the Americas (e.g. Andes and Sierra Madre) and might be particularly vulnerable to global warming because of their small geographic ranges and high energetic and area requirements, particularly birds and mammals (Laurance *et al.*, 2011). In Brazil, projections for Atlantic forest birds (Anciães and Peterson, 2006), endemic bird species (Marini *et al.*, 2009), and plant species (by 2055, scenarios HHGSDX50 and HHGGAX50; Siqueira and Peterson, 2003) of the Cerrado indicate that distribution will dislocate towards the South and Southeast, precisely where fragmentation and habitat loss are worse. Global climate change is also predicted to increase negative impacts worldwide, including SA, on freshwater fisheries due to alterations in physiology and life histories of fish (Ficke *et al.*, 2007).

In addition to climate change impacts at individual species level, biotic interactions will be affected. Modifications in phenology, structure of ecological networks, predator-preys interactions and non-trophic interactions among organisms have been forecasted (Brooker *et al.*, 2008; Walther, 2010). The outcome of non-trophic interactions among plants is expected to shift along with variation in climatic parameters, with more facilitative interactions in more stressful environments, and more competitive interactions in more benign environments (Anthelme *et al.*, 2012; Brooker *et al.*, 2008). These effects are expected to have a strong influence of community and ecosystem (re-) organization given the key engineering role played by plants on the functioning of ecosystems (Callaway, 2007). High Andean ecosystems, especially those within the tropics, are expected to face exceptionally strong warming effects during the 21th century because of their uncommonly high altitude (Bradley *et al.*, 2006). At the same time they provide a series of crucial ecosystem services for millions people (Buytaert *et al.*, 2011). For these reasons shifts in biotic interactions are expected to have negative consequences on biodiversity and ecosystem services in this region.

Although in the region biodiversity conservation is largely confined to protected areas, with the magnitude of climatic changes projected for the century, it is expected that many species and vegetational types will lose representativeness inside such protected areas (Heller and Zavaleta, 2009).

27.3.2.2. Adaptation Practices

The sub-set of practices that are multi-sectoral, multi-scale, and based on the premise that ecosystem services reduce the vulnerability of society to climate change are known as Ecosystem-based Adaptation (EbA) (Vignola *et al.*, 2009; see also Glossary and CC-EA). Schemes such as the payment for environmental services (PES) and community management fit the concept of EbA that begins to spread in CA and SA (Vignola *et al.*, 2009). The principle behind these schemes is the valuation of ecosystem services that should reflect both the economic and cultural benefits derived from the human-ecosystem interaction and the capacity of ecosystems to secure the flow of these benefits in the future (Abson and Termansen, 2011).

Since PES schemes have developed more commonly in CA and SA than in other parts of the world (Balvanera *et al.*, 2012), this topic will be covered as a case study (see 27.6.2).

Ecological restoration, conservation in protected areas, and community management can all be important tools for adaptation. A meta-analysis of 89 studies by Benayas *et al.* (2009) (with timescale of restoration varying from <5 to 300 years), including many in SA, showed that ecological restoration enhances the provision of biodiversity and environmental services by 44% and 25%, respectively, as compared to degraded systems (Benayas *et al.*, 2009). Moreover, ecological restoration increases the potential for carbon sequestration and promotes community organization, economic activities and livelihoods in rural areas (Chazdon, 2008), as seen in examples of the Brazilian Atlantic Forest (Calmon *et al.*, 2011; Rodrigues *et al.*, 2011). In that sense, Locatelli *et al.* (2011) revised several ecosystem conservation and restoration initiatives in CA and SA that simultaneously help mitigate and adapt to climate change. Chazdon *et al.* (2009) also highlight the potential of restoration efforts to build ecological corridors (see Harvey *et al.*, 2008, for example in Central America).

The effective management of natural protected areas and the creation of new protected areas within national protected area systems and community management of natural areas are also efficient tools to adapt to climate change and to reconcile biodiversity conservation with socio-economic development (e.g., Bolivian Andes - Hoffmann *et al*., 2011; Panama – Oestreicher *et al*. 2009). Porter-Bolland *et al.* (2012) compared protected areas with areas under community management in different parts of the tropical world, including CA and SA, and found that protected areas have higher deforestation rates than areas with community management. Similarly, Nelson and Chomitz (2011) found for the region that (i) protected areas of restricted use reduced fire substantially, but multi-use protected areas are even more effective; and that (ii) in indigenous reserves the incidence of forest fire was reduced by 16% as compared to non-protected areas. This contrasts with the findings of Miteva *et al*. (2012) that found protected areas more efficient in constraining deforestation than other schemes. Other good examples of adaptive community management in the continent include community forest concessions (e.g., Guatemala; Radachowsky *et al.*, 2012), multiple-use management of forests (Guariguata *et al.*, 2012 ; see also examples in Brazil – Klimas *et al.*, 2012, Soriano *et al.*, 2012, and Bolívia – Cronkleton *et al.*, 2012); and local communities where research and monitoring protocols are in place to pay the communities for collecting primary scientific data (Luzar *et al.*, 2011).

27.3.3. Coastal Systems and Low-Lying Areas

27.3.3.1. Observed and Projected Impacts and Vulnerabilities

Climate change is altering coastal and marine ecosystems (Hoegh-Guldberg and Bruno, 2010). Coral reefs (Chapter 5, Cross-Chapter Box CC-CR), seagrass beds, mangroves, rocky reefs and shelves, and seamounts have few to no areas left in the world that remain unaffected by human influence (Halpern *et al.*, 2008). Anthropogenic drivers associated with climate change decreased ocean productivity, altered food web dynamics, reduced abundance of habitat-forming species, shifting species distributions, and greater incidence of disease (Hoegh-Guldberg and Bruno, 2010). Coastal and marine impacts and vulnerability are often associated with collateral effects of climate change such as sea-level rise, ocean warming and ocean acidification (Cross-Chapter Box CC-OA). Overfishing, habitat pollution and destruction, and the invasion of species also negatively impact biodiversity and the delivery of ecosystem services (Guarderas *et al.*, 2008; Halpern *et al.*, 2008). Such negative impacts lead to losses that pose significant challenges and costs for societies, particularly in developing countries (Hoegh-Guldberg and Bruno, 2010). For instance, the Ocean Health Index (Halpern *et al.*, 2012) that measures how healthy the coupling of the human-ocean system is for every coastal country (including parameters related to climate change), indicates that CA countries rank amongst the lowest values. For SA, Suriname stands out with one of the highest scores.

Coastal states of Latin America and the Caribbean have a human population of more than 610 million, 3/4 of who live within 200 km of the coast (Guarderas *et al.*, 2008). For instance, studying seven countries in the region (El Salvador, Nicaragua, Costa Rica, Panama, Colombia, Venezuela, Ecuador), Lacambra and Zahedi (2011) found that more than 30% of the population lives in coastal areas directly exposed to climatic events. Large coastal populations are related to the significant transformation marine ecosystems have been undergoing in the region. Fish stocks, places for recreation and tourism, and controls of pests and pathogens are all under pressure (Guarderas *et al.*, 2008; Mora, 2008). Moreover, SLR varied from 2 to 7 mm/yr between 1950 and 2008 in CA and SA. The Western equatorial border, influenced by the ENSO phenomenon, shows a lower variation (of about 1 mm yr^{-1}) and a range of variation under El Niño events of the same order of magnitude that the sustained past changes (Losada *et al.*, 2013). The distribution of population is a crucial factor for inundation impact, with coastal areas being non-homogeneously impacted. A scenario of 1m SLR would affect some coastal populations in Brazil and the Caribbean islands (see Figure 27-6). (ECLAC, 2011a)

[INSERT FIGURE 27-6 HERE
Figure 27-6: Current and predicted coastal impacts and coastal dynamics in response to climate change.]

Coastal impacts - based on trends observed and projections, the figure shows how potential impacts may be distributed in the region. Three cases: a) flooding: since flooding probability increases with increasing sea-level, one may expect a higher probability of flooding in locations showing >40% of change over the last 60 years in the 100-years total sea-level (excluding hurricanes). The figure also identifies urban areas where the highest increase in flooding level has been obtained.; b) beach erosion: it increases with potential sediment transport, thus locations where changes in potential sediment transport have increased over a certain threshold have a higher probability to be eroded; c) sea-ports and reliability of coastal structures: the figure shows locations where, in the case of having a protection structure in place, there is a reduction in the reliability of the structures due to the increase in the design wave height estimates (ECLAC, 2011a).
Coastal dynamics - information based on historical time series that have been obtained by a combination of data reanalysis, available instrumental information and satellite information. Advanced statistical techniques have been used for obtaining trends including uncertainties (Izaguirre *et al.*, 2013; Losada *et al.*, 2013).]

The greatest flooding levels (hurricanes not considered) in the region are found in Rio de La Plata area, which combine a 5 mm yr^{-1} change in storm surge with SLR changes in extreme flooding levels (ECLAC, 2011a; Losada *et al.*, 2013). Extreme flooding events may become more frequent since return periods are decreasing, and urban coastal areas in the eastern coast will be particularly affected, while at the same time beach erosion is expected to increase in southern Brazil and in scattered areas at the Pacific coast. (ECLAC, 2011a)

The majority of literature concerning climate change impacts for coastal and marine ecosystems considers coral reefs (see also Chapter 5, Cross-Chapter Box CC-CR), mangroves and fisheries. Coral reefs are particularly sensitive to climate-induced changes in the physical environment (Baker *et al.*, 2008) to an extent that 1/3 of the more than 700 species of reef-building corals worldwide are already threatened with extinction (Carpenter *et al.*, 2008). Coral bleaching and mortality are often associated with ocean warming and acidification (Baker *et al.*, 2008). If extreme sea surface temperatures are to continue, the projections of scenarios SRES (A1FI, 3ºC sensitivity, and A1B with 2ºC and 4.5ºC sensitivity) indicate that it is possible that the Mesoamerican coral reef will collapse by mid-century (between 2050 and 2070), causing major economic losses (WB, 2009). Extreme high sea surface temperatures have been increasingly documented in the western Caribbean near the coast of CA and have resulted in frequent bleaching events (1993, 1998, 2005, and again in 2010) of the Mesoamerican coral reef, located along the coasts of Belize, Honduras and Guatemala (Eakin *et al.*, 2010). Reef but also mangrove ecosystems are estimated to contribute greatly to goods and services in economic terms. In Belize, for example, this amount is approximately US$395-US$559 million annually, primarily through marine-based tourism, fisheries and coastal protection (Cooper *et al.*, 2008). In the Eastern Tropical Pacific, seascape trace abundance of cement and elevated nutrients in upwelled waters are factors that help explain high bioerosion rates of local coral reefs (Manzello *et al.*, 2008). In the southwestern Atlantic coast, eastern Brazilian reefs might suffer a massive coral cover decline in the next 50 years Francini-Filho *et al.* (2008). This estimate is based on coral disease prevalence and progression rate, along with growth rate of *Mussismilia braziliensis* - a major reef-building coral species that is endemic in Brazil. These authors also pointed out that coral diseases intensified between 2005 and 2007 based on qualitative observations since the

1980s and regular monitoring since 2001. They have also predicted that - the studied coral species will be nearly extinct in less than a century if the current rate of mortality due to disease is not reversed.

Mangroves are largely affected by anthropogenic activities whether or not they are climate driven. All mangrove forests, along with important ecosystem goods and services, could be lost in the next 100 years if the present rate of loss continues (1-2% a year) (Duke *et al.*, 2007). Moreover, estimates are that climate change may lead to a maximum global loss of 10–15% of mangrove forest by 2100 (Alongi, 2008). In CA and SA, some of the main drivers of loss are deforestation and land conversion, agriculture and shrimp ponds (Polidoro *et al.*, 2010). The Atlantic and Pacific coasts of CA are some of the most endangered in the planet with regards to mangroves, since approximately 40% of the present mangroves' species are threatened with extinction (Polidoro *et al.*, 2010). Approximately 75% of the mangrove extension of the planet is concentrated in 15 countries, among which Brazil is included (Giri *et al.*, 2011). The rate of survival of original mangroves lies between 12.8% and 47.6% in the Tumaco Bay (Colombia), resulting in ecosystem collapse, fisheries reduction and impacts on livelihoods (Lampis, 2010). Gratiot *et al.* (2008) project for the current decade an increase of mean high water levels of 6 cm followed by 90m shoreline retreat implying flooding of thousands of hectares of mangrove forest along the coast of French Guiana.

Peru and Colombia are two of the eight most vulnerable countries to climate change impacts on fisheries, due to the combined effect of observed and projected warming, to species and productivity shifts in upwelling systems, to the relative importance of fisheries to national economies and diets, and limited societal capacity to adapt to potential impacts and opportunities (Allison *et al.*, 2009). Fisheries production systems are already pressured by overfishing, habitat loss, pollution, invasive species, water abstraction and damming (Allison *et al.*, 2009). In Brazil, a decadal rate of 0.16 trophic level decline (as measured by the Marine Trophic Index, which refers to the mean trophic level of the catch) has been detected through most of the northeastern coast, between 1978 and 2000, which is one of the highest rates documented in the world (Freire and Pauly, 2010).

Despite the focus in the literature on corals, mangroves and fisheries, there is evidence that other benthic marine invertebrates that provide key services to reef systems, such as nutrient cycling, water quality regulation, and herbivory, are also threatened by climate change (Przeslawski *et al.*, 2008). The same applies for seagrasses for which a worldwide decline has accelerated from a median of 0.9% yr^{-1} before 1940 to 7% yr^{-1} since 1990, which is comparable to rates reported for mangroves, coral reefs, tropical rainforests and place seagrass meadows among the most threatened ecosystems on earth (Waycott *et al.*, 2009).

A major challenge of particular relevance at local and global scales will be to understand how these physical changes will impact the biological environment of the ocean (e.g., Gutiérrez *et al.*, 2011b), as the Humboldt Current system -flowing along the west coast of SA- is the most productive upwelling system of the world in terms of fish productivity.

27.3.3.2. Adaptation Practices

Designing marine protected areas (MPAs) that are resilient to climate change is a key adaptation strategy in coastal and marine environments (McLeod *et al.*, 2009). By 2007, Latin America and the Caribbean (which includes CA and SA countries) had over 700 MPAs established covering around 1.5% of the coastal and shelf waters, most of which allow varying levels of extractive activities (Guarderas *et al.*, 2008). This protected area cover, however, is insufficient to preserve important habitats or connectivity among populations at large biogeographic scales (Guarderas *et al.*, 2008).

Nevertheless, examples of adaptation in CA and SA are predominantly related to MPAs. In Brazil, a protected area type known as "Marine Extractive Reserves" currently benefits 60,000 small-scale fishermen along the coast (Moura *et al.*, 2009). Examples of fisheries' co-management, a form of a participatory process involving local fishermen communities, government, academia and NGOs, are reported to favor a balance between conservation of marine fisheries, coral reefs and mangroves on the one hand (Francini-Filho and Moura, 2008), and the improvement of livelihoods, as well as the cultural survival of traditional populations on the other (Hastings, 2011; Moura *et al.*, 2009).

Significant financial and human resources are expended annually in the marine reserves to support reef management efforts. These actions, including the creation of marine reserves to protect from overfishing, improvement of watershed management, and protection or replanting of coastal mangroves, are proven tools to improve ecosystem functioning. In Mesoamerican reefs, (Carilli *et al.*, 2009) found out that such actions may also actually increase the thermal tolerance of corals to bleaching stress and thus the associated likelihood of surviving future warming.

In relation to mangroves, in addition to marine protected areas that include mangroves and functionally linked ecosystems, Gilman *et al.* (2008) list a number of other relevant adaptation practices: coastal planning to facilitate mangrove migration with sea-level rise, management of activities within the catchment that affect long-term trends in the mangrove sediment elevation, better management of non-climate stressors, and the rehabilitation of degraded areas. However, such types of practices are not frequent in the region.

On the other hand, the implementation of adaptation strategies to sea level rise or to address coastal erosion is more commonly seen in many countries in the region (Lacambra and Zahedi, 2011). For instance, redirecting new settlements to better-protected locations and to promote investments in appropriate infrastructure shall be required in the low elevation coastal zones (LECZ) of the region, particularly in lower income countries with limited resources, which are especially vulnerable. The same applies to countries with high shares of land (e.g., Brazil ranking 7th worldwide of the total land area in the LECZ) and/or population (e.g., Guyana and Suriname rank 2nd and 5th by the share of population in the LECZ, having respectively 76% and 55% of their populations in such areas (McGranahan *et al.*, 2007). Adaptation will demand effective and enforceable regulations and economic incentives, all of which require political will as well as financial and human capital (McGranahan *et al.*, 2007). Adaptive practices addressing river flooding are also being made available as in the study of Casco *et al.* (2011) for the low Parana river, in Argentina; (see also Chapters 5 and 6 for coastal and marine adaptation).

27.3.4. Food Production Systems and Food Security

27.3.4.1. Observed and Projected Impacts and Vulnerabilities

Increases in the global demand for food and biofuels promoted a sharp increase in agricultural production in SA and CA mainly associated with the expansion of planted areas (see Chapter 7), and this trend is predicted to continue in the future (see 27.2.2.1). Ecosystems are being and will be affected in isolation and synergistically by climate variability/change and land use changes, which are comparable drivers of environmental change (see 27.2.2.1; 27.3.2.1). By the end of 21th century (13 GCMs, under SRES A1B and B1) SA could lose between 1% and 21% of its arable land due to CC and population growth (Zhang and Cai, 2011).

Optimal land management could combine efficient agricultural and biofuels production with ecosystem preservation under CC, however current practices are leading to a deterioration of ecosystems throughout the continent (see section 27.3.2). In southern Brazilian Amazonia water yields (mean daily discharge (mm.day^{-1})) were near four times higher in soy than forested watersheds, and showed greater seasonal variability (Hayhoe *et al.*, 2011). In the Argentinean Pampas current land use changes disrupt water and biogeochemical cycles and may result in soil salinization, altered C and N storage, surface runoff and stream acidification (Berthrong *et al.*, 2009; Farley *et al.*, 2009; Nosetto *et al.*, 2008). In central Argentina flood extension was associated with the dynamics of groundwater level that has been influenced by precipitation and land use change (Viglizzo *et al.*, 2009).

Observed impacts: The SESA region has shown significant increases in precipitation and wetter soil conditions during the 20th century (Giorgi, 2002) (see Table 27-1) that benefited summer crops and pastures productivity, and contributed to the expansion of agricultural areas (Barros, 2010; Hoyos *et al.*, 2012). Wetter conditions observed during 1970-2000 (in relation to 1930-1960) led to increases in maize and soybean yields (9% to 58%) in Argentina, Uruguay and Southern Brazil (Magrin *et al.*, 2007b). Even if rainfall projections estimate increases of about 25% in SESA for 2100, agricultural systems could be threatened if climate reverts to a drier situation due to interdecadal variability. This could put at risk the viability of continuous agriculture in marginal regions of the Argentina's Pampas (Podestá *et al.*, 2009). During the 30's and 40's, dry and windy conditions together with deforestation, overgrazing, overcropping, and non-suitable tillage produced severe dust storms, cattle mortality, crop failure, and rural migration (Viglizzo and Frank, 2006).

At the global scale (see Chapter 7), warming since 1981 has reduced wheat, maize and barley productivity, although the impacts were small compared with the technological yield gains over the same period (Lobell and Field, 2007). In central Argentina, simulated potential wheat yield –without considering technological improvements- has been decreasing at increasing rates since 1930 (1930-2000: -28 kg/ha/year; 1970-2000: -53 kg/ha/year) in response to increases in minimum temperature during October-November (1930-2000: +0.4°C/decade; 1970-2000: +0.6°C/decade) (Magrin *et al.*, 2009). The observed changes in the growing season temperature and precipitation between 1980 and 2008 have slowed the positive yield trends due to improved genetics in Brazilian wheat, maize and soy, as well as Paraguayan soy. In contrast, rice in Brazil and soybean in Argentina have benefited from precipitation and temperature trends (2011). In Argentina, increases in soybean yield may be associated with weather types that favour the entry of cold air from the south reducing thermal stress during flowering and pod set, and weather types that increase the probability of dry days at harvest (Bettolli *et al.*, 2009).

Projected impacts: The assessment of future climate scenarios implications in food production and food security (see Table 27-5) shows a large range of uncertainty across the spectrum of climate models and scenarios. One of the uncertainties is related to the effect of CO_2 on plant physiology. Many crops (such as soybean, common bean, maize and sugarcane) can probably respond with an increasing productivity as a result of higher growth rates and better water use efficiency. However, food quality could decrease due to higher sugar contents in grain and fruits, and decreases in the protein content in cereals and legumes (DaMatta *et al.*, 2010). Uncertainties associated with climate and crop models, as well as with the uncertainty in human behavior, potentially lead to large error bars on any long-term prediction of food output. However, the trends presented here represent the current available information.

In SESA, some crops could be benefited until mid-21st-century if CO_2 effects are considered (see Table 27-5), although interannual and decadal climate variability could provoke important damages. In Uruguay and Argentina productivity could increase or remain almost stable until the 2030s-2050s depending on the SRES scenario (ECLAC, 2010c). Warmer and wetter conditions may benefit crops towards the southern and western zone of the Pampas (ECLAC, 2010c; Magrin *et al.*, 2007c). In South Brazil, irrigated rice yield (Walter *et al.*, 2010) and bean productivity (Costa *et al.*, 2009) is expected to increase. If technological improvement is considered, the productivity of common bean and maize could increase between 40% and 90% (Costa *et al.*, 2009). Sugarcane production could benefit as warming could allow the expansion of planted areas towards the south, where low temperatures are a limiting factor (Pinto *et al.*, 2008). Increases in crop productivity could reach 6% in São Paulo state towards 2040 (Marin *et al.*, 2009). In Paraguay the yields of soybean, maize and wheat could have slight variations (-1.4% to +3.5%) until 2020 (ECLAC, 2010a).

In Chile and western Argentina, yields could be reduced by water limitation. In central Chile (30ºS to 42ºS) temperature increases, reduction in chilling hours and water shortages may reduce productivity of winter crops, fruits, vines and radiata pine. Conversely, rising temperatures, more moderate frosts and more abundant water will *very likely* benefit all species towards the South (ECLAC, 2010a; Meza and Silva, 2009). In northern Patagonia (Argentina) fruit and vegetable growing could be negatively affected because of a reduction in rainfall and in average flows in the Neuquén River basin. In the north of the Mendoza basin (Argentina) increases in water demand, due to population growth, may compromise the availability of subterranean water for irrigation, pushing up irrigation costs and forcing many producers out of farming towards 2030. Also, water quality could be reduced by the worsening of existing salinization processes (ECLAC, 2010a).

In CA, NEB and parts of the Andean region (Table 27-5) CC could affect crop yields, local economies and food security. It is *very likely* that growing season temperatures in parts of tropical SA, east of the Andes and CA exceed the extreme seasonal temperatures documented from 1900 to 2006 at the end of this century (23 GCMs), affecting regional agricultural productivity and human welfare (Battisti and Naylor, 2009). For NEB, declining crop yields in subsistence crops such as beans, corn and cassava are projected (Lobell *et al.*, 2008; Margulis *et al.*, 2010). In addition, increases in temperature could reduce the areas currently favorable to cowpea bean (Silva *et al.*, 2010). The highest warming foreseen for 2100 (5.8 °C, under SRES A2 scenario) could make the coffee crop unfeasible in Minas Gerais and São Paulo (SE Brazil) if no adaptation action is accomplished. Thus, the coffee crop may have to be transferred to southern regions where temperatures are lower and the frost risk will be reduced (Camargo, 2010). With +3ºC, Arabica coffee is expected to expand in the extreme south of Brazil, the Uruguayan border and North of Argentina (Zullo *et al.*, 2011). Brazilian potato production could be restricted to a few months in currently warm areas, which today allow potato production all around the year (Lopes *et al.*, 2011). Large losses of suitable environments for the "Pequi" tree (*Caryocar brasiliense*; an economically important Cerrado fruit tree) are projected by 2050, mainly affecting the poorest communities in Central Brazil (Nabout *et al.*, 2011). In the Amazon region soybean yields would be reduced by 44% in the worst scenario (HadCM3 and no CO_2 fertilization) by 2050 (Lapola *et al.* (2011). By 2050, according to 17GCMs under SRES A2 scenario, 80% of crops will be impacted in more than 60% of current areas of cultivation in Colombia, with severe impacts in perennial and exportable crops (Ramirez-Villegas *et al.*, 2012).

Teixeira *et al.* (2013) identified hot spots for heat stress towards 2071-2100 under the A1B scenario and suggest that rice in South East Brazil, maize in CA and SA, and soybean in Central Brazil will be the crops and zones most affected by increases in temperature.

In CA, changes projected in climate could severely affect the poorest population and specially their food security increasing the current rate of chronic malnutrition. Currently, Guatemala is the most food insecure country by percentage of the population (30.4%) and the problem has been increasing in recent years (FAO, 2012). The impact of climate variability and change is a great challenge in the region. As an example, the recent rust problem on the coffee sector of 2012/2013 has affected near to 600.000 ha (55% of the total area) (ICO, 2013) and will reduce employment by 30% to 40% for the harvest 2013/2014 (FEWS NET, 2013). At least 1.4 million people in Guatemala, El Salvador, Honduras and Nicaragua depend on the coffee sector, which is very susceptible to climate variations. In Panamá, the large interannual climate variability will continue to be the dominant influence on seasonal maize yield into the coming decades (Ruane *et al.*, 2013). In the future, warming conditions combined with more variable rainfall are expected to reduce maize, bean and rice productivity (ECLAC, 2010c); rice and wheat yields could decrease up to 10% by 2030 (Lobell *et al.,* 2008 (*medium confidence*) (see Table 26-7). In CA, near to 90% of agricultural production destined to internal consumption is composed by maize (70%), bean (25%) and rice (6%) (ECLAC, 2011d).

[INSERT TABLE 27-5 HERE
Table 27-5: Impacts on agriculture.]

CC may also alter the current scenario of plant diseases and their management, having effects on productivity (Ghini *et al.*, 2011). In Argentina, years with severe infection of late cycle diseases in soybean could increase; severe outbreaks of the Mal de Rio Cuarto virus in maize (natural vectors: D*elphacodes kuscheli* and *Delphacodes hayward*) could be more frequent; and wheat head fusariosis will increase slightly in the south of the Pampas region by the end of the century (ECLAC, 2010a). In Brazil favorable areas for soybean and coffee rusts will move toward the south, particularly for the hottest scenario of 2080 (Alves *et al.*, 2011). Potato late blight (*Phytophtora infestans*) severity is expected to increase in Perú (Giraldo *et al.*, 2010).

The choice of livestock species could change in the future. For example, by 2060, under a hot and dry scenario, beef and dairy cattle, pigs and chickens production choice could decrease between 0.9 and 3.2%, while sheep election could increase by 7% mainly in the Andean countries (Seo *et al.*, 2010). Future climate could strongly affect milk production and feed intake in dairy cattle in Brazil, where substantial modifications in areas suitable for livestock, mainly in the Pernambuco region, are expected (Silva *et al.*, 2009). Warming and drying conditions in Nicaragua could reduce milk production, mainly among farmers that are already seriously affected under average dry season conditions (Lentes *et al.*, 2010).

CC impact on regional welfare will depend not only on changes in yield, but also in international trade. According to Hertel *et al.* (2010), by 2030, global cereal price could change between increases of 32% (low-productivity scenario) or decreases of 16% (optimistic yield scenario). A rise in prices could benefit net exporting countries like Brazil, where gains from terms of trade shifts could outweigh the losses due to CC. Despite experiencing significant negative yield shocks, some countries tend to gain from higher commodity prices. However, most poor household are food purchasers and rising commodity prices tend to have a negative effect on poverty (von Braun, 2007). According to Chapter 7, increases in prices during 2007-2009 led to rising poverty in Nicaragua.

27.3.4.2. Adaptation Practices

Genetic advances and suitable soil and technological management may induce an increase in some crops' yield despite unfavorable future climate conditions. In Argentina, genetic techniques, specific scientific knowledge and land-use planning are viewed as promising sources of adaptation (Urcola *et al.*, 2010). Adjustments in sowing dates and fertilization rates could reduce negative impacts or increase yields in maize and wheat crops in Argentina and Chile (Magrin *et al.*, 2009; Meza and Silva, 2009; Travasso *et al.*, 2009b). Furthermore, in central Chile and southern Pampas in Argentina warmer climates could allow performing two crops per season increasing productivity per unit land (Meza *et al.*, 2008; Monzon *et al.*, 2007). In Brazil, adaptation strategies for coffee crops include: planting at high densities, vegetated soil, accurate irrigation and breeding programs, and shading management system (arborization) (Camargo, 2010). Shading is also used in Costa Rica and Colombia. In South Brazil, a good option for irrigated rice could be to plant early cultivars (Walter *et al.*, 2010).

Water management is other option for a needed better preparedness regarding water scarcity (see section 27.3.1). In Chile, the adoption of water conservation practices depends on social capital, farm size and land use; and the adoption of technologies that require investment depend on the accesses to credit and irrigation water subsidies (Jara-Rojas *et al.*, 2012). Deficit irrigation could be an effective measure for water savings in dry areas such as the Bolivian Altiplano (quinoa), central Brazil (tomatoes) and northern Argentina (cotton) (Geerts and Raes, 2009). In rainfed crops adaptive strategies might need to look at the harvest, storage, temporal transfer and efficient use of rainfall water. In addition, some agronomic practices like: fallowing, crop sequences, groundwater management, no-till operations, cover crops and fertilization could improve the adaptation to water scarcity (Quiroga and Gaggioli, 2011).

One approach to adapting to future CC is by assisting people to cope with current climate variability (Baethgen, 2010), for which the use of climatic forecasts in agricultural planning presents a measure. Increased access and improvement of climate forecast information enhances the ability of the farmers in the Brazilian Amazon to cope with El Niño impacts (Moran *et al.*, 2006). The Southern Oscillation Index for maize, and the South Atlantic Sea Surface Temperature for soybean and sunflower were the best indicators of annual crop yield variability in Argentina (Travasso *et al.*, 2009a). Another possibility to cope with extreme events consists in transferring weather-related risks by using different types of rural insurance (Baethgen, 2010). Index insurance is one mechanism that has been recently introduced to overcome obstacles to traditional agricultural and disaster insurance markets (see chapter 15). For the support of such parametric agricultural insurance, a Central American climate database was recently established (SICA, 2013).

Local and indigenous knowledge have the potential to bring solutions even in the face of rapidly changing climatic conditions (Altieri and Koohafkan, 2008; Folke *et al.*, 2002); although, migration, climate change, and market integration are reducing indigenous capacity for dealing with weather and climate risk (Pérez *et al.*, 2010; Valdivia *et al.*, 2010). Crop diversification is used in the Peruvian Andes to suppress pest outbreaks and dampen pathogen transmission (Lin, 2011). In Honduras, Nicaragua and Guatemala traditional practices have proven more resilient to erosion and runoff and have helped retain more topsoil and moisture (Holt-Gimenez, 2002). In El Salvador, if local sustainability efforts continue the future climate vulnerability index could only slightly increase by 2015 (Aguilar *et al.*, 2009). Studies with indigenous farmers in highland Bolivia and Peru indicate that constraints on access to key resources must be addressed for reducing vulnerability over time (McDowell and Hess, 2012; Sietz *et al.*, 2012). In Guatemala and Honduras adaptive response between coffees farmers is mainly related to land availability, while participation in organized groups and access to information contribute to adaptive decision-making (Tucker *et al.*, 2010). Otherwise, adaptation may include an orientation towards non-farming activities to sustain their livelihoods and be able to meet their food requirements (Sietz, 2011). In NEB increasing vulnerability related to degradation of natural resources (due to over use of soil and water) encouraged farmers toward off-farm activities, however they could not improve their well-being (Sietz *et al.*, 2006; Sietz *et al.*, 2011). Migration is other strategy in ecosystems and regions at high risk of climate hazards (see Section 27.3.1.1). During 1970-2000 LAC has had the great rate of net migration per population in the dryland zones (Sherbinin *et al.*, 2012). In CA near to 25% of the surveyed households reported some type of migration during the coffee crisis (Tucker *et al.*, 2010). Some migrations, e.g. Guatemala 1960s-1990s; El Salvador 1950s-1980s; NEB 1960s-present, have provoked conflict in receiving areas (Reuveny, 2007).

Shifting in agricultural zoning has been an autonomous adaptation observed in SA. In Argentina e.g., increases in precipitation promoted the expansion of the agricultural frontier to the West and North of the traditional agricultural area, resulting in environmental damage that could be aggravated in the future (Barros, 2008; República Argentina, 2007). Adjustment of production practices, like farmers in the semi-arid zones of mountain regions of Bolivia have begun as they noticed strong changes in the climate since the 1980s, including upward migration of crops, selection of more resistant varieties and water capturing, presents a further adaptation measure (PNCC, 2007).

Organic systems could enhance adaptive capacity due to the application of traditional skills and farmers' knowledge, soil fertility-building techniques and a high degree of diversity (ITC, 2007). As mentioned previously, crop diversity, local knowledge, soil conservation, and economic diversity are all documented strategies for managing risk in CA and SA. A controversial, but important issue in relation to adaptation is the use of genetically modified plants to produce food, with biotech crops being a strategy to cope with the needed food productivity increase considering global population trend (see Chapter 7). Brazil and Argentina are the 2nd and 3rd fastest growing biotech crop producers in the world after the US (Marshall, 2012). However, this option is problematic for the small farms (Mercer *et al.*, 2012), which are least favorable towards GMO (??) (Soleri *et al.*, 2008). According to Eakin and Wehbe (2009) some practices could be an adaptive option for specific farm enterprises, but may have maladaptive implications at regional scales, and over time, become maladaptive for individual enterprises.

27.3.5. Human Settlements, Industry, and Infrastructure

According to the World Bank database (WB, 2012) CA and SA are the geographic regions with the second highest urban population (79%), behind North America (82%) and well above the world average (50%). Therefore this section focuses on assessing the literature on climate change impacts and vulnerability of *urban* human settlements. The information provided should be complemented with other sections of the chapter (see 27.2.2.2; 27.3.1; 27.3.3; and 27.3.7)

27.3.5.1. Observed and Projected Impacts and Vulnerabilities

Urban human settlements suffer from many of the vulnerabilities and impacts already presented in several sections of this chapter. The provision of critical resources and services as already discussed in the chapter –water, health and energy– and of adequate infrastructure and housing remain determinants of urban vulnerability that are enhanced by climate change (Roberts, 2009; Romero-Lankao *et al.*, 2013b; Romero-Lankao *et al.*, 2012b; Smolka and Larangeira, 2008; Winchester, 2008).

Water resource management for example (see section 27.3.1), is a major concern for many cities that need to provide both drinking water and sanitation (Henríquez Ruiz, 2009). More than 20% of the population in the region are concentrated in the largest city in each country (WB, 2012), hence water availability for human consumption in the region's megacities (e.g. São Paulo, Santiago, Lima, Buenos Aires) is of great concern. In this context, reduction in glacier and snowmelt related runoff in the Andes poses important adaptation challenges for many cities, e.g. the metropolitan areas of Lima, La Paz/El Alto and Santiago de Chile (Bradley *et al.*, 2006; Hegglin and Huggel, 2008; Melo *et al.*, 2010). Flooding is also a preoccupation in several cities. In São Paulo for example, according to Marengo *et al.* (2009b; 2013b) the number of days with rainfall above 50 mm were almost zero during the 1950s and now they occur between 2 to 5 times per year (2000-2010). The increase in precipitation is one of the expected risks affecting the city of São Paulo as presented in Box 27-2. Increases in flood events during 1980-2000 have been observed also in the Buenos Aires province and Metropolitan Area (Andrade and Scarpati, 2007; Barros *et al.*, 2008; Hegglin and Huggel, 2008; Nabel *et al.*, 2008). There are also the combined effects of climate change impacts, human settlements' features and other stresses, such as more intense pollution events (Moreno, 2006; Nobre *et al.*, 2011; Nobre, 2011; Romero-Lankao *et al.*, 2013b) and more intense hydrological cycles from urban heat-island effects. In terms of these combined effects, peri-urban areas and irregular settlements pose particular challenges to urban governance and risk management given their scale, lack of infrastructure and socio-economic fragility (Romero-Lankao *et al.*, 2012).

______START BOX 27-2 HERE______

Box 27-2. Vulnerability of South American Megacities to Climate Change: The Case of the Metropolitan Region of São Paulo (MRSP)

Research in the Metropolitan Region of São Paulo (MRSP), between 2009 and 2011, represents a comprehensive and interdisciplinary project on the impacts of climate variability and change, and vulnerability of Brazilian megacities. Studies derived from this project (Marengo *et al.*, 2013b; Nobre *et al.*, 2011) identify the impacts of climate extremes on the occurrence of natural disasters and human health. These impacts are linked to a projected increase of 38% in the extension of the urban area of the MRSP by 2030, accompanied by a projected increase in rainfall extremes. These may induce an intensification of urban flash floods and landslides, affecting large populated areas already vulnerable to climate extremes and variability. The urbanization process in the MRSP has been affecting the local climate, and the intensification of the heat island effect to a certain degree may be responsible for the 2°C warming detected in the city during the last 50 years (Nobre *et al.*, 2011). This warming has been further accompanied by an increase in heavy precipitation as well as more frequent warm nights (Marengo *et al.*, 2013b; Silva Dias *et al.*, 2012). By 2100, climate projections based on data from 1933-2010 show an expected warming between 2-3°C in the MRSP, together with a possible doubling of the number of days with heavy precipitation in comparison to the present (Marengo *et al.*, 2013b; Silva Dias *et al.*, 2012).

With the projected changes in climate and in the extension of the MRSP (Marengo *et al.*, 2013b) more than 20% of the total area of the city could be potentially affected by natural disasters. More frequent floods may increase the risk of leptospirosis, which, together with increasing air pollution and worsening environmental conditions that trigger the risk of respiratory diseases, would leave the population of the MRSP more vulnerable. Potential adaptation measures include a set of strategies that need to be developed by the MRSP and its institutions to face these environmental changes. These include improved building controls to avoid construction in risk areas, investment in public transportation, protection of the urban basins and the creation of forest corridors in the collecting basins and slope regions. The lessons learned suggest that the knowledge on the observed and projected environmental changes, as well as on the vulnerability of populations living in risk areas is of great importance for defining adaptation policies that in turn constitute a first step towards building resilient cities that in turn improve urban quality of life in Brazil.

______END BOX 27-2 HERE______

Changes in prevailing urban climates have led to changing patterns of disease vectors, and water-borne disease issues linked to water availability and subsequent quality (see section 27.3.7). The influence of climate change on particulate matter and other local contaminants is another concern (Moreno, 2006; Romero-Lankao *et al.*, 2013b). It is important to highlight the relationship between water and health, given the problems of water stress and intense precipitation events affecting many urban centers. Both relate to changing disease risks, as well as wider problems of event-related mortalities and morbidity, and infrastructure and property damage. These risks are compounded for low-income groups in settlements with little or no service provision, e.g. waste collection, piped drinking water, sanitation, (ECLAC, 2008). Existing cases of flooding, air pollution and heat waves reveal that not only low-income groups are at risk, but also that wealthier sectors are not spared. Factors such as high-density settlement (Barros *et al.*, 2008) and the characteristics of some hazards explain this – e.g., poor and wealthy alike are at risk from air pollution and temperature in Santiago de Chile and Bogota (2013b; Romero-Lankao *et al.*, 2012a).

There are also other climate change risks in terms of economic activity location and impacts on urban manufacturing and service workers, e.g. thermal stress (Hsiang, 2010), and the forms of urban expansion or sprawl into areas where ecosystem services may be compromised and risks enhanced, e.g. floodplains. Both processes are also related to rising motorization rates that facilitate suburban development and new regional agglomerations that bring pressure to bear on land uses that favor infiltration, surface cooling and biodiversity; the number of light vehicles in Latin America and the Caribbean is expected to double between 2000 and 2030, and be three times the 2000 figure by 2050 (ECLAC, 2009c).

While urban populations face diverse social, political, economic and environmental risks in daily life, climate change adds a new dimension to these risk settings (Pielke Jr *et al.*, 2003; Roberts, 2009; Romero-Lankao and Qin, 2011). Since urban development remains fragile in many cases, with weak planning responses, climate change can compound existing challenges. The probabilities and magnitudes of these events in each urban center will differ significantly according to socioeconomic, institutional and physical contexts.

27.3.5.2. Adaptation Practices

The direct and indirect effects of climate change as flooding, heat islands and food insecurity present cities with a set of challenges and opportunities for mainstreaming flood management, warning systems and other adaptation responses with sustainability goals (Bradley *et al.*, 2006; Hardoy and Pandiella, 2009; Hegglin and Huggel, 2008; Romero-Lankao, 2010; Romero-Lankao *et al.*, 2013a; Romero-Lankao, 2012).

Urban populations, economic activities and authorities have a long experience of responding to climate-related hazards, particularly through disaster risk management (e.g., Tucuman and San Martin, Argentina (Plaza and Pasculi, 2007; Sayago *et al.*, 2010)), and land use and economic development planning to a limited extent (Barton, 2009). Climate policies can build on these. Local administrations participate in the ICLEI, C40, IDB Emerging and Sustainable Cities Initiative (ESCI) (IDB, 2013), and other networks, demonstrating their engagement in the generation of more climate-resilient cities. In smaller settlements, there is less capacity for adequate responses (e.g., climate change and vulnerability information (Hardoy and Romero-Lankao, 2011). Policies, plans and programs are required to reduce social vulnerability, and identify and reduce potential economic effects of climate on the local economy. Rio de Janeiro, for example, with its coastline property and high dependence on tourists (and their perceptions of risk), cannot ignore these climate-related hazards (Gasper *et al.*, 2011).

Poverty and vulnerability, as interlinked elements of the adaptation challenge in CA and SA, remain pivotal to understanding how urban climate policies can be streamlined with broader development issues and not solely the capacity to respond to climate change (Hardoy and Pandiella, 2009; Hardoy and Romero-Lankao, 2011; Winchester and Szalachman, 2009). These broader links include addressing the determinants of vulnerability (e.g., access to education, health and infrastructure, and to emergency response systems (Romero-Lankao, 2007a; Romero-Lankao and Qin, 2011). Among these response options, a focus on social assets has been highlighted by Rubin and Rossing (2012), rather than a, purely, physical asset focus.

Much urbanisation involves in-migrating or already resident, low-income groups and their location in risk-prone zones (Costa Fereira *et al.*, 2011). The need to consider land use arrangements, particularly urban growth on risk-prone zones, as part of climate change adaptation highlights the role of green areas that mitigate the heat island effect and reduce risks from landslides and flooding (Krellenberg *et al.*, 2013; Rodríguez Laredo, 2011).

In the case of governance frameworks, there is clear evidence that incorporation of climate change considerations into wider city planning is still a challenge, as are more inter-sectoral and participative processes that have been linked to more effective policies (Barton, 2009; Barton, 2013; De Oliveira, 2009; Romero-Lankao *et al.*, 2013a). Several metropolitan adaptation plans have been generated over the last five years, e.g. Bogotá, Buenos Aires, Esmeraldas, Quito, and São Paulo, although for the most part they have been restricted to the largest conglomerations and are often included as an addition to mitigation plans (Carmin *et al.*, 2009; Luque *et al.*, 2013; Romero-Lankao, 2007b; Romero-Lankao *et al.*, 2013a; Romero-Lankao *et al.*, 2012b).

27.3.6. Renewable Energy

27.3.6.1. Observed and Projected Impacts and Vulnerabilities

Table 27-6 shows the relevance of RE in the Latin America energy matrix as compared to the world for 2009 according to the International Energy Agency statistics (IEA, 2012). Hydropower is the most representative source of RE and therefore analyzed separately from this section and all other RE sources (see case study in section 27.6.1.). Geothermal energy will be not discussed as it is assumed that there is no impact of climate change on the effectiveness of this energy type (Arvizu *et al.*, 2011).

[INSERT TABLE 27-6 HERE
Table 27-6: Comparison of consumption of different energetics in Latin America and the world (in thousand tons of oil equivalent (ktoe) on a net calorific value basis).]

Hydro, wind energy and biofuel production might be sensitive to climate change in Brazil (Lucena *et al.*, 2009). With the vital role that RE plays in mitigating the effects of GCC, being by far the most important sources of non-hydro RE in SA and CA, this sensitivity demands the implementation of RE projects that will increase knowledge on the crops providing bioenergy.

For historical reasons, CA and SA developed sugarcane as bioenergy feedstock. Brazil accounts for the most intensive RE production as bioethanol, which is used by the majority of the cars in the country (Goldemberg, 2008) whereas biodiesel comprises 5% of all diesel nationwide. With the continent's long latitudinal length, the expected impacts of climate change on plants will be complex due to a wide variety of climate conditions, so that different crops would have to be used in different regions. In Brazil, most of the biodiesel comes from soybeans, but there are promising new sources such as palm oil (Lucena *et al.*, 2009). The development of palm oil as well as soybean are important factors that induce land use change, with a potential to influence stability of forests and biodiversity in certain key regions in SA, such as the Amazon (section 27.2.2.1).

Biofuels can help CA and SA to decrease emissions from energy production and use. However, RE might imply potential problems such as those related to positive net emissions of greenhouse gases, threats to biodiversity, an increase in food prices and competition for water resources (section 27.2.3), some of which can be reverted or attenuated (Koh and Ghazoul, 2008). For example, the sugarcane agro-industry in Brazil combusts bagasse to produce electricity, providing power for the bioethanol industry and increasing sustainability. The excess heat energy is then used to generate bioelectricity, thus allowing the biorefinery to be self-sufficient in energy utilization (Amorim *et al.*, 2011; Dias *et al.*, 2012). In 2005/2006 the production of bioelectricity was estimated to be 9.2 kWh per ton of sugarcane (Macedo *et al.*, 2008), approximately 2% of Brazil's total energy generation production.

Most bioenergy feedstocks at present in production in CA and SA are grasses. In the case of sugarcane, the responses to the elevation of CO_2 concentration up to 720 ppmv have been shown to be positive in terms of biomass production and principally regarding water use efficiency (De Souza *et al.*, 2008).

The production of energy from renewable sources such as hydro- and wind power is greatly dependent on climatic conditions and therefore may be impacted in the future by GCC. Lucena *et al.* (2010a) suggests an increasing energy vulnerability of the poorest regions of Brazil to GCC together with a possible negative influence on biofuels production and electricity generation, mainly biodiesel and hydropower respectively. (JAM: we use CC and GCC, I believe that we use should use CC only).

Expansion of biofuel crops in Brazil might cause both direct and indirect land use changes (e.g., biofuel crops replacing rangelands, which previously replaced forests) with the direct land use changes, according to simulation performed by Lapola *et al.* (2010) of the effects for 2020. The same study shows that sugarcane ethanol and biodiesel derived from soybean each contribute with about one half of the indirect deforestation projected for 2020 (121.970 km^2) (Lapola *et al.*, 2010). Thus, indirect land use changes, especially those causing the rangeland frontier to move further into the Amazonian forests, might potentially offset carbon savings from biofuels production.

The increase in global ethanol demand is leading to the development of new hydrolytic processes capable of converting cellulose into ethanol (Dos Santos *et al.*, 2011). The expected increase in the hydrolysis technologies is *very likely* to balance the requirement of land for biomass crops. Thus, the development of these technologies has a strong potential to diminish social (e.g. negative health effects due the burning process, poor labor conditions) and environmental impacts (e.g. loss of biodiversity, water and land uses) whereas at it can improve the economic potential of sugarcane. One adaptation measure will be to increase the productivity of bioenergy crops due to planting in high productivity environments with highly developed technologies, in order to use less land. As one of the main centers of biotech agriculture application in the world (Gruskin, 2012), the region has a great potential to achieve this goal.

As the effects previously reported on crops growing in SESA might prevail (see 27.3.4.1), i.e. that an increase in productivity may happen due to increasing precipitation, future uncertainty will have to be dealt with by preparing adapted varieties of soybean in order to maintain food and biodiesel production, mainly in Argentina as it is one of the main producers of biodiesel from soybean in the world (Chum *et al.*, 2011).

Other renewable energy sources—such as wind power generation—may also be vulnerable, raising the need for further research. According to Lucena *et al.* (2009; 2010b) the projections of changes in wind power in Brazil, may favor the use of this kind of energy in the future.

27.3.6.2. Adaptation Practices

RE will become increasingly more important over time as this is closely related with the emissions of GHG (Fischedick *et al.*, 2011). Thus, RE could have an important role as adaptation means to provide sustainable energy for development in the region (see also *27.6.1*). However, the production of RE requires large available areas for agriculture, which is the case of Argentina, Bolivia, Brazil, Chile, Colombia, Peru and Venezuela, that together represent 90% of the total area of CA and SA. However, for small countries it might not be possible to use bioenergy. Instead, they could benefit in the future from other types of RE, such as geothermal, eolic, photovoltaic etc., depending on policies and investment in different technologies. This is important because economic development is thought to be strongly correlated with an increase in energy use (Smil, 2000), which is itself associated with an increase in emissions (Sathaye *et al.*, 2011).

Latin America is second to Africa in terms of technical potential for bioenergy production from rain-fed lignocellulosic feedstocks on unprotected grassland and woodlands (Chum *et al.*, 2011). Among the most important adaptation measures regarding RE are: (1) management of land use change (LUC); and (2) development of policies for financing and management of science and technology for all types of RE in the region.

If carefully managed, biofuel crops can be used as a means to regenerate biodiversity as proposed by Buckeridge *et al.* (2012) highlighting that the technology for tropical forest regeneration has become available and that forests could share land with biofuel crops (such as sugarcane) taking advantage of forests' mitigating potential. A possible adaptation measure could be to expand the use of reforestation technology to other countries in CA and SA.

One of the main adaptation issues is related to the food *vs*. fuel issues (Valentine *et al.*, 2012). This is important because an increase in bioenergy feedstocks might threaten primary food production in a scenario expected to feed future populations with an increase of 70% in production (Gruskin, 2012; Valentine *et al.*, 2012). This is particularly important in the region as it has one of the highest percentages of arable land available for food production in the world (Nellemann *et al.*, 2009). As CA and SA develop new strategies to produce more RE there might be a pressure for more acreage to produce bioenergy. Because climate change will affect bioenergy and food crops at the same time, their effects, as well as the adaptation measures related to agriculture will be similar. The main risks identified by Arvizu *et al.* (2011) are: (1) business as usual; (2) un-reconciled growth, and (3) environment and food *vs*. fuel. Thus, the most important adaptation measures will be the ones related to the control of economic growth, environmental management and agriculture production. The choice for lignocellulosic feedstocks (e.g. sugarcane second generation technologies) will be an important mitigation/adaptation measure because these feedstocks do not compete with food (Arvizu *et al.*, 2011). In the case of sugarcane, for instance, an increase of ca. 40% in the production of bioethanol is expected as a result of the implantation of second generation technologies coupled with the first generation ones already existent in Brazil (De Souza *et al.*, 2013; Dias *et al.*, 2012).

Biodiesel production has the lowest costs in Latin America (Chum *et al.*, 2011) due to the high production of soybean in Brazil and Argentina. The use of biodiesel to complement oil-derived diesel is a productive choice for adaptation measures regarding this bioenergy source. Also, the cost of ethanol, mainly derived from sugarcane, is the lowest in CA, SA and Latin America (Chum *et al.*, 2011) and as an adaptation measure, such costs, as well as the one of biodiesel, should be lowered even more by improving technologies related to agricultural and industrial production of both. Indeed, it has been reported that in LA the use of agricultural budgets by governments for investment in public goods induces faster growth, decreasing poverty and environmental degradation (López and Galinato, 2007). The pressure of soy expansion due to biodiesel demand can lead to land use change and consequently to economic teleconnections, as suggested by Nepstad *et al.* (2006). These teleconnections may link Amazon deforestation derived from soy expansion to the economic growth in some developing countries due to changes in the demand of soy. These effects may possibly mean a decrease in jobs related to small to big farms in agriculture in Argentina (Tomei and Upham, 2009) on the one hand, and deforestation in the Amazon due to the advance of soybean cropping in the region on the other (Nepstad and Stickler, 2008).

27.3.7. Human Health

27.3.7.1. Observed and Projected Impacts and Vulnerability

Changes in weather extremes and climatic patterns are affecting human health (*high confidence*), by increasing morbidity, mortality, and disabilities, and through the emergence of diseases in previously non-endemic regions (*high confidence*) (Rodríguez-Morales, 2011; Winchester and Szalachman, 2009). Heat waves and cold spells have increased urban mortality rates (Bell *et al.*, 2008; Hajat *et al.*, 2010; Hardoy and Pandiella, 2009; McMichael *et al.*, 2006; Muggeo and Hajat, 2009). Outbreaks of vector- and water-borne diseases were triggered in CA by hurricane Mitch in 1998 (Costello *et al.*, 2009; Rodríguez-Morales *et al.*, 2010), while the 2010-2012 Colombian floods caused hundreds of deaths and thousands of displaced people (Hoyos *et al.*, 2013).

The number of cases of malaria have increased in Colombia during the last five decades alongside air temperatures (Arevalo-Herrera *et al.*, 2012; Poveda *et al.*, 2011), but also in urban and rural Amazonian regions undergoing large environmental changes (Cabral *et al.*, 2010; Da Silva-Nunes *et al.*, 2012; Gil *et al.*, 2007; Tada *et al.*, 2007). Malaria transmission has reached 2,300 m in the Bolivian Andes, and vectors are found at higher altitudes from Venezuela to Bolivia (Benítez and Rodríguez-Morales, 2004; Lardeux *et al.*, 2007; Pinault and Hunter, 2011). Although the incidence of malaria has decreased in Argentina, its vector density has increased in the northwest along with climate variables (Dantur Juri *et al.*, 2011; Dantur Juri *et al.*, 2010). El Niño drives malaria outbreaks in Colombia (Mantilla *et al.*, 2009; Poveda *et al.*, 2011) amidst other factors (Osorio *et al.*, 2007; Restrepo-Pineda *et al.*, 2008; Rodríguez-Morales *et al.*, 2006). Linkages between ENSO and malaria are also reported in Ecuador and Peru (Anyamba *et al.*, 2006; Kelly-Hope and Thomson, 2010), French Guiana (Hanf *et al.*, 2011), Amazonia (Olson *et al.*, 2009), and Venezuela (Moreno *et al.*, 2007).

Unlike malaria, dengue fever (DF) and its hemorrhagic variant (DHF) are mostly urban diseases whose vector is affected by climate conditions. Their incidence have risen in tropical America in the last 25 years, causing annual economic losses of US$ 2.1+[1 to 4] billion (Shepard *et al.*, 2011; Tapia-Conyer *et al.*, 2009; Torres and Castro, 2007). Environmental and climatic variability affect their incidence in CA (Fuller *et al.*, 2009; Mena *et al.*, 2011; Rodríguez-Morales *et al.*, 2010), in Colombia (Arboleda *et al.*, 2009), and in French Guiana alongside malaria (Carme *et al.*, 2009; Gharbi *et al.*, 2011). In Venezuela, DF increases during La Niña (Herrera-Martinez and Rodríguez-Morales, 2010; Rodríguez-Morales and Herrera-Martinez, 2009). Weather and climate variability are also associated with DF in southern SA (Costa *et al.*, 2010; De Carvalho-Leandro *et al.*, 2010; Degallier *et al.*, 2010; Honório *et al.*, 2009; Lowe *et al.*, 2011), involving also demographic and geographic factors in Argentina (Carbajo *et al.*, 2012). In Rio de Janeiro a 1°C increase in monthly minimum temperature led to a 45% increase of DF in the next month, and 10 mm increase in rainfall to a 6% increase (Gomes *et al.*, 2012). Despite large vaccination campaigns, the risk of Yellow Fever (YF) outbreaks has increased mostly in tropical America's densely populated poor urban settings (Gardner and Ryman, 2010), alongside climate conditions (Jentes *et al.*, 2011).

Schistosomiasis (SCH) is endemic in rural areas of Suriname, Venezuela, the Andean highlands, and rural and peripheral urbanized regions of Brazil (Barbosa *et al.*, 2010; Igreja, 2011; Kelly-Hope and Thomson, 2010). It is highly likely that SCH will increase in a warmer climate (Lopes *et al.*, 2010; Mangal *et al.*, 2008; Mas-Coma *et al.*, 2009). Vegetation indices are associated with human fascioliasis in the Andes (Fuentes, 2004).

Hantaviruses (HV) have been recently reported throughout the region (Jonsson *et al.*, 2010; MacNeil *et al.*, 2011), and El Niño and climate change augment their prevalence (Dearing and Dizney, 2010). Variation in HV reservoirs in Patagonia is strongly dependent on climate and environmental conditions (Andreo *et al.*, 2012; Carbajo *et al.*, 2009). In Venezuela, Rotavirus (RV) is more frequent and more severe in cities with minimal seasonality (Kane *et al.*, 2004). The peak of RV in Guatemala occurs in the dry season, causing 60% of total diarrhoea cases (Cortes *et al.*, 2012).

In spite of its rapid decline, climate-sensitive Chagas disease is still a major public health issue (Abad-Franch *et al.*, 2009; Araújo *et al.*, 2009; Gottdenker *et al.*, 2011; Moncayo and Silveira, 2009; Tourre *et al.*, 2008). Climate also affects the most prevalent mycosis (Barrozo *et al.*, 2009), and ENSO is associated with outbreaks of bartonellosis in Peru (Payne and Fitchett, 2010).

The high incidence of cutaneous leishmaniasis (CL) in Bolivia is exacerbated during La Niña (García *et al.*, 2009; Gomez *et al.*, 2006). CL is affected in Costa Rica by temperature, forest cover and ENSO (Chaves *et al.*, 2008), and in Colombia by land cover, altitude, climatic variables, and El Niño (Cárdenas *et al.*, 2006; 2007; 2008; Valderrama-Ardila *et al.*, 2010), and decreases during La Niña in Venezuela (Cabaniel *et al.*, 2005). CL in Suriname peaks during the March dry season (35%) (Van der Meide *et al.*, 2008), and in French Guiana is intensified after the October-December dry season (Rotureau *et al.*, 2007). Incidence of visceral leishmaniasis (VL) has increased in Brazil (highest in LA) in association with El Niño and deforestation (Cascio *et al.*, 2011; Ready, 2008; Sortino-Rachou *et al.*, 2011), as in Argentina, Paraguay, and Uruguay (Bern *et al.*, 2008; Dupnik *et al.*, 2011; Fernández *et al.*, 2012; Salomón *et al.*, 2011). VL transmission in Venezuela is associated with rainfall seasonality (Feliciangeli *et al.*, 2006; Rodríguez-Morales *et al.*, 2007). Besides, the incidence of skin cancer in Chile has increased in recent years, concomitantly with climate and geographic variables (Salinas *et al.*, 2006).

Onchocerciasis (river blindness) vector exhibits seasonal biting rates (Botto *et al.*, 2005; Rodríguez-Pérez *et al.*, 2011), and leptospirosis is prevalent in CA's warm-humid tropical regions (Valverde *et al.*, 2008). Other climate-driven infectious diseases are ascariasis and gram-positive cocci in Venezuela (Benítez *et al.*, 2004; Rodríguez-Morales *et al.*, 2010), and Carrion's disease in Peru (Huarcaya *et al.*, 2004).

Sea water temperature affects the abundance of cholera's bacteria (Hofstra, 2011; Jutla *et al.*, 2010; Koelle, 2009; Marcheggiani *et al.*, 2010), which explains the outbreaks during El Niño in Peru, Ecuador, Colombia and Venezuela (Cerda Lorca *et al.*, 2008; Gavilán and Martínez-Urtaza, 2011; Holmner *et al.*, 2010; Martínez-Urtaza *et al.*, 2008; Murugaiah, 2011; Salazar-Lindo *et al.*, 2008).

The worsening of air quality and higher temperatures in urban settings are increasing chronic respiratory and cardiovascular diseases, and morbidity from asthma and rhinitis (Grass and Cane, 2008; Gurjar *et al.*, 2010; Jasinski *et al.*, 2011; Martins and Andrade, 2008; Rodriguez *et al.*, 2011), but also artherosclerosis, pregnancy-related outcomes, cancer, cognitive deficit, otitis, and diabetes (Olmo *et al.*, 2011). Dehydration from heatwaves increases hospitalizations for chronic kidney diseases (Kjellstrom *et al.*, 2010), affecting construction, sugarcane and cotton workers in CA (Crowe *et al.*, 2009; 2010; Kjellstrom and Crowe, 2011; Peraza *et al.*, 2012).

Extreme weather/climate events affect mental health in Brazil (depression, psychological distress, anxiety, mania and bipolar disorder), in particular in drought-prone areas of NEB (Coêlho *et al.*, 2004; Volpe *et al.*, 2010). Extreme weather, meager crop yields, and low GDP are also associated with increased violence (McMichael *et al.*, 2006).

Multiple factors increase the region's vulnerability to climate change: precarious health systems, malnutrition, inadequate water and sanitation services, poor waste collection and treatment systems, air, soil and water pollution, lack of social participation, and inadequate governance (Luber and Prudent, 2009; Rodríguez-Morales, 2011; Sverdlik, 2011). Human health vulnerabilities in the region depend on geography, age (Graham *et al.*, 2011; Martiello and Giacchi, 2010; Perera, 2008; Åstrom *et al.*, 2011), gender (Oliveira *et al.*, 2011), race, ethnicity, and socio-economic status (Diez Roux *et al.*, 2007; Martiello and Giacchi, 2010). Neglected Tropical Diseases in LA cause 1.5-5.0 million disability-adjusted life years (DALYs) (Hotez *et al.*, 2008). Vulnerability of mega-cities (see 27.3.5) is aggravated by access to clean water, rapid spread of diseases (Borsdorf and Coy, 2009), and migration from rural areas forced by disasters (Borsdorf and Coy, 2009; Campbell-Lendrum and Corvalán, 2007; Hardoy and Pandiella, 2009). Human health vulnerabilities have been assessed in Brazil through composite indicators involving downscaled climate scenarios, epidemiological variables and socio-economic projections (Barbieri and Confalonieri, 2011; Confalonieri *et al.*, 2009; ; FIOCRUZ, 2011). The Andes and CA are among the regions of highest predicted losses [1% to 27%] in labor productivity from future climate scenarios (Kjellstrom *et al.*, 2009).

27.3.7.2. Adaptation Strategies and Practices

Adaptation efforts in the region ((Blashki *et al.*, 2007; Costello *et al.*, 2011) are hampered by lack of political commitment, gaps in scientific knowledge, and institutional weaknesses (Keim, 2008; Lesnikowski *et al.*, 2011; Olmo *et al.*, 2011) (see 27.4.3). Research priorities and current strategies must be reviewed (Halsnæs and Verhagen, 2007; Karanja *et al.*, 2011; Romero and Boelaert, 2010), and preventive/responsive systems must be put in place (Bell, 2011) to foster adaptive capacity (Campbell-Lendrum and Bertollini, 2010; Huang *et al.*, 2011). Colombia established a pilot adaptation program to cope with changes in malaria transmission and exposure (Poveda *et al.*, 2011). The city of São Paulo has implemented local pollution control measures, with the co-benefit of reducing GHG emissions (De Oliveira, 2009; Nath and Behera, 2011).

Human wellbeing indices must be explicitly stated as adaptation policies in LA (e.g., Millennium Development Goals) (Franco-Paredes *et al.*, 2007; Halsnæs and Verhagen, 2007; Mitra and Rodriguez-Fernandez, 2010). South-south cooperation and multidisciplinary research are required to design relevant adaptation and mitigation strategies (Team and Manderson, 2011; Tirado *et al.*, 2010).

27.4. Adaptation Opportunities, Constraints, and Limits

27.4.1. Adaptation Needs and Gaps

During the last years, the study of adaptation to climate change has progressively switched from an impact-focused approach (mainly climate-driven) to include a vulnerability-focused vision (Boulanger *et al.*, 2011). As a consequence, the development and implementation of systemic adaptation strategies, involving institutional, social, ecosystem, environmental, financial and capacity components (see Chapter 14), to cope with present climate extreme events is a key step toward climate change adaptation, especially in SA and CA countries. While different frameworks and definitions of vulnerability exist, a general tendency aims at studying vulnerability to climate change especially in SA and CA focusing on the following aspects: urban vulnerability (e.g. Hardoy and Pandiella, 2009; Heinrichs and Krellenberg, 2011), rural community (McSweeney and Coomes, 2011; Ravera *et al.*, 2011), rural farmer vulnerability (Oft, 2010), and sectoral vulnerability (see 27.3). The approach used can be holistic or systemic (Carey *et al.*, 2012b; Ison, 2010), where climate drivers are actually few with respect to all other drivers related to human and environment interactions including physical, economic, political and social context, as well as local characteristics such as occupations, resource uses, accessibility to water, etc. (Manuel-Navarrete *et al.*, 2007; Young *et al.*, 2010).

In developing and emergent countries, there exists a general consensus that the adaptive capacity is low, strengthened by the fact that poverty is key determinant of vulnerability in Latin America (to climate related natural hazards, see Rubin and Rossing, 2012) and thus a limit to resilience (Pettengell, 2010) leading to a "low human development trap" (UNDP, 2007). However, Magnan (2009) suggests that this analysis is biased by a "relative immaturity of the science of adaptation to explain what are the processes and the determinants of adaptive capacity". Increasing research efforts on the study of adaptation is therefore of great importance to improve our understanding of the actual societal, economical, community and individual drivers defining the adaptive capacity. Especially, a major focus on traditions and their transmission (Young and Lipton, 2006) may actually indicate potential adaption potentials in remote and economically poor regions of SA and CA. Such a potential does not dismiss the fact that the nature of future challenges may actually not be compared to past climate variability (e.g. glacier retreat in the Andes).

Coping with new situations may require new approaches such as a multilevel risk governance (Corfee-Morlot *et al.*, 2011; Young and Lipton, 2006) associated with decentralization in decision-making and responsibility. While the multilevel risk governance and the local participatory approach are interesting frameworks for strengthening adaptation capacity, perception of local and national needs is diverging, challenging the implementation of adaptation strategies in CA/SA (Salzmann *et al.*, 2009). At present, despite an important improvement during the last years, there still exists a certain lack of awareness of environmental changes and mainly their implications for livelihoods and businesses (Young *et al.*, 2010). Moreover, considering the limited financial resources of some states in CA and SA, long-term planning and the related human and financial resource needs may be seen as conflicting with present social deficit in the welfare of the population. This situation weakens the importance of adaptation planning to climate change in the political agenda (Carey *et al.*, 2012b), and requires therefore international involvement as one facilitating factor in natural hazard management and climate change adaptation, in accordance with the respect to sovereignty, the international conventions including the United Nations Framework Convention on Climate Change. In addition, as pointed out by McGray *et al.* (2007), development, adaptation and mitigation issues are not separate issues. Especially, development and adaptation strategies should be tackled together in developing countries such as SA and CA, focusing on strategies to reduce vulnerability. The poor level of adaptation of present-day climate in SA and CA countries is characterized by the fact that responses to disasters are mainly reactive rather than preventive. Some early warning systems are being implemented, but the capacity of responding to a warning is often limited, particularly among poor populations. Finally, actions combining public communication (and education), public decision-maker capacity-building and a synergetic development-adaptation funding will be key to sustain the adaptation process that CA and SA require to face future climate change challenges.

27.4.2. Practical Experiences of Autonomous and Planned Adaptation, including Lessons Learned

Adaptation processes in many cases have been initiated a few years ago, and there is still a lack of literature to evaluate their efficiency in reducing vulnerability and building resilience of the society against climate change. However, experiences of effective adaptation and maladaptation are slowly being documented (see also 27.4.3), some lessons have already been learned from these first experiences (see section 27.3), and tools, such as the Index of Usefulness of Practices for Adaptation (IUPA) to evaluate adaptation practices have been developed for the region (Debels *et al.*, 2009). Evidenced by these practical experiences, there is a wide range of options to foster adaptation and thus adaptive capacity in CA and SA. In CA and SA, many societal issues are strongly connected to development goals and are often considered priority in comparison to adaptation efforts to climate change. However, according to the 135 case studies analyzed by McGray *et al.* (2007), 21 of which were in CA and SA, the synergy between development and adaptation actions allows to ensuring a sustainable result of the development projects.

Vulnerability and disaster risk reduction may not always lead to long-term adaptive capacity (Nelson and Finan, 2009; Tompkins *et al.*, 2008), except when structural reforms based on good governance (Tompkins *et al.*, 2008) and negotiations (Souza Filho and Brown, 2009) are implemented. While multi-level governance can help to create resilience and reduce vulnerability (Corfee-Morlot *et al.*, 2011; Roncoli, 2006; Young and Lipton, 2006), capacity-building (Eakin and Lemos, 2006), good governance and enforcement (Lemos *et al.*, 2010; Pittock, 2011) are key components.

Autonomous adaptation experience are mainly realized at local levels (individual or communitarian) with examples found for instance for rural communities in Honduras (McSweeney and Coomes, 2011), indigenous communities in Bolivia (Valdivia *et al.*, 2010) and coffee agroforestry systems in Brazil (De Souza *et al.*, 2012). However, such adaptation processes do not always respond specifically to climate forcing. For instance, the agricultural sector adapts rapidly to economic stressors, while, despite a clear perception of climate risks, it may last longer before responding to climate changes (Tucker *et al.*, 2010). In certain regions or communities, such as Anchioreta in Brazil (Bonatti *et al.*, 2012), adaptation is part of a permanent process and is actually tackled through a clear objective of vulnerability reduction, maintaining and diversifying a large set of natural varieties of corn allowing the farmers to diversify their planting. Another kind of autonomous adaptation is the southward displacement of agriculture activities (e.g. wine, coffee) though the purchase of lands, which will become favorable for such agriculture activities in a warmer climate. In Argentina, the increase of precipitation observed during the last 30 years contributed to a westward displacement of the annual crop frontier. However, local adaptation to climate and non-climate drivers may undermine long-term resilience of socio-ecological systems when local, short-term strategies designed to deal with specific threats or challenges do not integrate a more holistic and long-term vision of the system at threat (Adger *et al.*, 2011). Thus, policy should identify the sources of and conditions for local resilience and strengthen their capacities to adapt and learn (Adger *et al.*, 2011; Borsdorf and Coy, 2009; Eakin *et al.*, 2011), as well as to integrate new adapted tools (Oft, 2010). This sets the question of convergence between the local-scale/short-term and broad scale/long-term visions in terms of perceptions of risks, needs to adapt and appropriate policies to be implemented (Eakin and Wehbe, 2009; Salzmann *et al.*, 2009). Even if funding for adaptation is available, the overarching problem is the lack of capacity and/or willingness to address the risks, especially those threatening lower income groups (Satterthwaite, 2011a). Adaptation to climate change cannot eliminate the extreme weather risks, and thus efforts should focus on disaster preparedness and post-disaster response (Sverdlik, 2011). Migration is the last resort for rural communities facing water stress problems in CA and SA (Acosta-Michlik *et al.*, 2008).

In natural hazard management contributing to climate change adaptation, specific cases such as the one in Lake 513 in Peru (Carey *et al.*, 2012b) clearly allowed to identify facilitating factors for a successful adaptation process (technical capacity, disaster events with visible hazards, institutional support, committed individuals, and international involvement) as well as impediments divergent risk perceptions, imposed government policies, institutional instability, knowledge disparities, and invisible hazards). In certain cases, forward-looking learning (anticipatory process), as a contrast to learning by shock (reactive process), has been found as a key element for adaptation and resilience (Tschakert and Dietrich, 2010) and should be promoted as a tool for capacity-building at all levels (stakeholders, local and national governments). Its combination with role-playing game and agent-based models (Rebaudo *et al.*, 2011) can strengthen and accelerate the learning process.

Planned adaptation policies promoted by governments have been strengthened by the participation in international networks, where experience and knowledge can be exchanged. As an example, the C40 Cities- Climate Leadership Group or ICLEI include Bogota (Colombia), Buenos Aires (Argentina), Caracas (Venezuela), Curitiba, Rio de Janeiro and Sao Paulo (Brazil), Lime (Peru) and Santiago de Chile (Chile). Most of these cities have come up with related action and strategy plans (e.g. Action Plan Buenos Aires 2030, Plan of Caracas 2020 or the Metropolitan Strategy to CCA of Lima) (C40 Cities, 2011).

At a regional policy level, an example of intergovernmental initiatives in SA and CA is the ‘Ibero-American Programme on Adaptation to Climate Change’ (PIACC), developed by the Ibero-American Network of Climate Change Offices (RIOCC) (Keller *et al.*, 2011b). For CA specifically, the Central American Commission for Environment and Development (CCAD) brings together the environmental ministries of the Central American Integration System (Sistema de la Integración Centroamericana (SICA)) that released its climate change strategy in 2010 (CCAD-SICA, 2010; Keller *et al.*, 2011a).

These initiatives demonstrate that there has been a growing awareness of CA and SA governments on the need to integrate climate change and future climate risks in their policies. Up to date, in total 18 regional Non-Annex countries, including Argentina, Belize, Bolivia, Brazil, Chile, Colombia, Costa Rica, Ecuador, El Salvador, Guatemala, Honduras, Nicaragua, Guyana, Panama, Paraguay, Peru, Suriname, Uruguay and Venezuela, have already published their first and/or second National Communication to the UNFCCC (see UNFCCC, 2012) allowing to measure the country’s emissions and to assess its present and future vulnerability.

27.4.3. Observed and Expected Barriers to Adaptation

Adaptation is a dynamic process, which to be efficient requires a permanent evolution and even transformation of the vulnerable system. Such transformation process can be affected by several constraints, including constraints affecting the context of adaptation as well as the implementation of policies and measures (see 16.3.2).

Major constraints related to the capacity and resources needed to support the implementation of adaptation policies and processes comprehend access to (Lemos *et al.*, 2010) and exchange of knowledge (e.g. adaptive capacity can be enhanced by linking indigenous knowledge and scientific knowledge; Valdivia, 2010), the access to and quality of natural resources (López-Marrero, 2010), the access to financial resources, especially for poor households (Hickey and Weis, 2012; Rubin and Rossing, 2012; Satterthwaite, 2011b) as well as for institutions (Pereira *et al.*, 2009), technological resources (López-Marrero, 2010), technical assistance (Eakin *et al.*, 2011; Guariguata, 2009) , as well as the fostering of public-private technology transfer (La Rovere *et al.*, 2009a; Ramirez-Villegas *et al.*, 2012) and promotion of technical skills (Hickey and Weis, 2012), and social asset-based formation at the local level (Rubin and Rossing, 2012).

In terms of framing adaptation, as constraint to affect the adaptation context, it is usually considered that a major barrier to adaptation is the perception of risks and many studies focused on such an issue (Bonatti *et al.*, 2012). Also, new studies (Adger *et al.*, 2009) identified social limits to possible adaptation to climate change in relation with issues of values and ethics, risk, knowledge and culture, even though such limits can evolve in time. Indeed, while being a necessary condition, perception may not be the main driver for initiating an adaptation process. As pointed out by Tucker *et al.* (2010) with a specific focus on CA, exogenous factors (economic, land tenure, cost, etc.) may actually strongly constrain the decision-making process involved in possible adaptation process. In that sense, efficient governance and management are key components in the use of climate and non-climate information in the decision-making and adaptation process. As a consequence, it is difficult to describe adaptation without defining at which level it is thought. Indeed, while a lot of efforts are invested in national and regional policy initiatives, most of the final adaptation efforts will be local. National and international (transborder) governance is key to build adaptive capacity (Engle and Lemos, 2010) and therefore to strengthen (or weaken) local adaptation through efficient policies and delivery of resources. At a smaller scale (Agrawal, 2008), local institutions can strongly contribute to vulnerability reduction and adaptation. However, at all levels, the efficiency in national and local adaptation activities strongly depend on the capacity-building and information transmission to decision-makers (Eakin and Lemos, 2006).

27.5 Interactions between Adaptation and Mitigation

Synergies between adaptation and mitigation strategies on the local level can be reached due to self-organization of communities in cooperatives (see 'The SouthSouthNorth Capacity Building Module on Poverty Reduction" (see SSN, 2006), which manages recycling or renewable energy production, leading to an increase in energy availability, thus production capacity and therefore new financial resources. Moreover, Venema and Cisse (2004) support also the development of decentralized renewable energy solutions for the growth of renewable energy in CA and SA (see also section 27.3.6) next to large infrastructure project (see their case studies for Argentina and Brazil).

In spite of their smaller size (individual or communitarian), these solutions offer adaptation and mitigation benefits. On one hand, fossil-based energy consumption is reduced, while energy availability is increased. On the other hand, reduction of energy precariousness is key in any development strategy. Thus, it allows local community and individuals to growing socially and economically; and therefore to reducing its vulnerability avoiding the poverty trap (UNDP, 2007), and to initiating an adaptation process based on non-fossil fuel energy sources. Such initiatives also depend on local and organizational leaderships (UN-Habitat, 2011).

Such integrated strategies of income generation as adaptation measures as well as production of renewable energy are also identified for vulnerable, small farmers diversifying their crops towards crops for vegetable oil and biodiesel production in Brazil. Barriers identified concern capacity building and logistical requirements making policy tools, credit mechanism, and organization into cooperatives, and fostered research necessary (La Rovere *et al.*, 2009b).

Other promising interactions of mitigation and adaptation are identified e.g. for the management of Brazilian tropical natural and planted forest (Guariguata, 2009).

At national and regional scales, CA and SA countries will require the allocation of human and financial resources to adapt to climate change. While resources are limited, too large an economic dependence of these countries to fossil fuels will reduce their adaptive capacity. The reduction in energy consumption and the integration of renewable energies in their energetic matrix is therefore a key issue for all these countries in order to sustain their development and growth and therefore increase their adaptive capacity (see also section 27.3.6).
Reforestation and avoided deforestation are important practices that contribute to both mitigation and adaptation efforts in the region as in other parts of the world. Maintaining forest cover can provide a suite of environmental services including local climate regulation, water regulation, reduced soil erosion, all of which can reduce the vulnerability of communities to variable climate (see section 27.3.2.2 on Ecosystem-based adaptation) (Vignola *et al.*, 2009).

27.6. Case Studies

27.6.1. Hydropower

Hydropower is the main source of renewable energy in CA and SA (see section 27.3.6). The region is only second to Asia in terms of hydropower energy generation in the world, displaying a 20% share of total annual generation and an average regional capacity factor of over 50% (Table 5-1 SRREN; IPCC, 2011). As a result, the region has by far the largest proportion of electricity generated through hydropower facilities (Table 27-6 in section 27.3.6.1). The hydropower proportion of total electricity production is over 40% in the region, and in some cases is near or close to 80%, as in the case of Brazil, Colombia and Costa Rica (IEA, 2012). Although there is debate, especially in tropical environments, about GHG emissions from hydropower reservoirs (Fearnside and Pueyo, 2012), this form of electricity generation is often seen as a major contributor to mitigating GHG emissions worldwide (see IPCC SRREN [5]; Kumar *et al.*, 2011). But on the other hand, hydropower is a climate-related sector, thus making it prone to the potential effects of changing climate conditions (see section 27.3.1.1). In this regards the CA and SA region constitute a unique example to study these relations between climate change mitigation and adaptation in relation to hydropower generation.

Diverse studies have analyzed the potential impacts of climate change on hydropower generation (see details in Table 27-4 in section 27.3.1.1). Maurer *et al.* (2009) studied future conditions for the Lempa River (El Salvador, Honduras and Guatemala) showing a potential reduction in hydropower capacity of 33% to 53% by 2070-2099 (Maurer *et al.*, 2009). A similar loss is expected for the Sinu-Caribe basin in Colombia were, despite a general projection of increased precipitation, losses due to evaporation enhancement reduces inflows to hydroelectric systems, thus reducing electricity generation up to 35% (Ospina-Noreña *et al.*, 2009a). Further studies (Ospina-Noreña *et al.*, 2011a; 2011b) have estimated vulnerability indices for the hydropower sector in the same basin, and identified reservoir operation strategies to reduce this vulnerability. Overall reductions in hydropower generation capacity are also expected in Chile for the main hydropower generation river basins: Maule, Laja and Biobio (ECLAC, 2009a; McPhee *et al.*, 2010; Stehr *et al.*, 2010), and also in the Argentinean Limay River basin (Seoane and López, 2007). Ecuador, on the other hand, faces an increase in generation capacity associated with an increment in precipitation on its largest hydroelectric generation Paute River basin (Buytaert *et al.*, 2010). Brazil, although being the country with the largest installed hydroelectric capacity in the region, still has unused generation capacity in sub-basins of the Amazon River (Soito and Freitas, 2011). However, future climate conditions plus environmental concerns pose an important challenge for the expansion of the system (Andrade *et al.*, 2012; Finer and Jenkins, 2012; Freitas and Soito, 2009). According to Lucena *et al.* (2009), hydropower systems in southern Brazil (most significantly the Parana River system) could face a slight increase in energy production under an A2 scenario. However, the rest of the country's hydropower system, and especially those located in NEB, could face a reduction in power generation, thus reducing the reliability of the whole system (Lucena *et al.*, 2009).

An obvious implication of the mentioned impacts is the need to replace the energy lost through alternative (see 27.3.6.2) or traditional sources. Adaptation measures have been studied for Brazil (Lucena *et al.*, 2010a), with results implying an increase in natural gas and sugarcane bagasse electricity generation in the order of 300 TWh, increase in operation costs in the order of 7 billion USD annually and 50 billion USD in terms of investment costs by 2035. In Chile, the study by ECLAC (2009a) assumed that the loss in hydropower generation, in the order of 18 TWh for the 2011-2040 period (a little over 10% of actual total hydropower generation capacity) would be compensated by the least operating cost source available, coal-fired power plant, implying an increase of 2 $MTCO_2e$ of total GHG emissions (emissions for the electricity sector in Chile totaled 25 $MTCO_2e$ in 2009). Ospina-Noreña (2011a; 2011b) studied some adaptation options, such as changes in water use efficiency or demand growth that could mitigate the expected impacts on hydropower systems in the Colombian Sinú-Caribe River basin. Changes in seasonality and total availability could also increase complexities in the management of multiple-use dedicated basins in Peru (Condom *et al.*, 2012; Juen *et al.*, 2007), Chile (ECLAC, 2009a), and Argentina (Seoane and López, 2007), that could affect the relationship between different water users within a basin. It is worth noting that those regions which are projected to face an increase in streamflow and associated generation capacity, such as Ecuador or Costa Rica, also share difficulties in managing deforestation, erosion and sedimentation which limits the useful life of reservoirs (see section 27.3.1.1). In these cases it is important to consider these effects in future infrastructure operation (Ferreira and Teegavarapu, 2012) and planning, and also to enhance the on-going process of recognizing the value of the relation between ecosystem services and hydropower system operations (Leguía *et al.*, 2008) (see more on PES in section 27.3.2.2 and 27.6.2).

27.6.2. Payment for Ecosystem Services

Payment for ecosystem services (PES) is commonly described as a set of transparent schemes for securing a well-defined ecosystem service (or a land use capable to secure that service) through conditional payments or compensations to voluntary providers (Engel *et al.*, 2008; Tacconi, 2012). Van Noordwijk *et al.* (2012) provides a broader definition to PES by arguing that it encompasses three complementary approaches, (i) the one above, i.e., commodification of pre-defined ecosystem services so that prices can be negotiated between buyers and sellers; plus (ii) compensation for opportunities forgone voluntarily or by command and control decisions; and (iii) coinvestment in environmental stewardships. Therefore, the terms ´conservation agreements´, ´conservation incentives´ and ´community conservation´ are often used as synonyms or as something different or broader than PES (Cranford and Mourato, 2011; Milne and Niesten, 2009). For simplicity, we refer to PES in its broadest sense (sensu Van Noordwijk *et al.*, 2012).

Services subjected to such types of agreements often include regulation of freshwater flows, carbon storage, provision of habitat for biodiversity, and scenic beauty (De Koning *et al.*, 2011; Montagnini and Finney, 2011). Since the ecosystems that provide the services are mostly privately owned, policies often aim at supporting landowners to maintain the provision of services over time (Kemkes *et al.*, 2010). Irrespective of the debate of as to whether payments or compensations should be designed to focus on actions or results (Gibbons *et al.*, 2011), experiences in Colombia, Costa Rica and Nicaragua show that PES can finance conservation, ecosystem restoration, and better land use practices (Montagnini and Finney, 2011; see also Table 27-5). However, based on examples from Ecuador and Guatemala, Southgate *et al.* (2010) argue that uniformity of payment for beneficiaries can be inefficient if recipients accept less compensation in return for conservation measures, or if recipients that promote greater environmental gains receive only the prevailing payment. Other setbacks to PES schemes might include cases where there is a perception of commoditization of nature and its intangible values (e.g. Bolivia, Cuba, Ecuador and Venezuela); other cases where mechanisms are inefficient to reduce poverty; slowness to build trust between buyers and sellers, as well as gender and land tenure issues that might arise (Asquith *et al.*, 2008; Balvanera *et al.*, 2012; Peterson *et al.*, 2010; Van Noordwijk *et al.*, 2012).

Table 27-7 lists selected examples of PES schemes in Latin America, but a more complete and detailed list is given in Balvanera *et al.* (2012).

[INSERT TABLE 27-7 HERE
Table 27-7: Cases of government-funded PES schemes in CA and SA.]

The PES concept (or ´fishing agreements´) also applies to coastal and marine areas, although only a few cases have been reported. Begossi (2011) argues that this is due to three factors: origin (the mechanism was originally designed for forests), monitoring (marine resources such as fish are more difficult to monitor than terrestrial resources) and definition of resource boundaries in offshore water. One example of a compensation mechanism in the region is the so-called *defeso*, in Brazil. It consists of a period (reproductive season) when fishing is forbidden by the government and fishermen receive a financial compensation. It applies to shrimp, lobster and both marine and freshwater fisheries (Begossi *et al.*, 2011).

27.7. Data and Research Gaps

The scarcity and difficult availability of high resolution high quality and continuous climate, oceanic and hydrological data, together with the availability of only very few complete regional studies, pose challenges for the region to address changes in climate variability and the identification of trends in extremes, in particular for CA. This situation hampers studies on frequency and variability of extremes, as well as impacts and vulnerability analyses of the present and future climates, and the development of vulnerability assessments and adaptation actions.

Related to observed impacts in most sectors, there is an imbalance in information availability among countries. While more studies have been performed for Brazil, Southern SA and SESA region, much less are available for CA and for some regions of tropical SA. An additional problem is poor dissemination of results in peer-reviewed publications since most information is available only as grey literature. There is a need for studies focused on current impacts and vulnerabilities across sectors throughout CA and SA, with emphasis on extremes to improve risk management assessments.

The complex interactions between climate and non-climate drivers difficult the assessment of impacts and projections, as is the case for water availability and streamflows owing to current and potential deforestation; overfishing and pollution regarding the impacts on fisheries, or impacts on hydroenergy production. The lack of interdisciplinary integrated studies limits our understanding of the complex interactions between natural and socio-economic systems. In addition, accelerating deforestation and land use changes, as well as changes in economic conditions, impose a continuous need for updated and available data sets that feed basic and applied studies.

To address the global challenge of food security and food quality, both important issues in CA and SA, investment in scientific agricultural knowledge need to be reinforced, mainly with regard to the integration of agriculture with organic production; and the integration of food and bioenergy production. It is necessary to consider ethical aspects when the competition for food and bioenergy production is analyzed to identify which activity is most important at a given location and time and whether bioenergy production would affect food security for a particular population.

Sea level rise and coastal erosion are also relevant issues; the lack of comparable measurements of sea level rise in CA and SA difficult the present and future integrated assessment of the impacts of SLR in the region. Of local and global importance will be improving our understanding of the physical oceanic processes, in particular of the Humboldt Current system flowing along the west coast of SA, being this one of the most fish productive system worldwide.

More information and research about the impacts of climate variability and change on human health is needed. One problem is the difficulty in accessing health data that are not always archived and ready to be used in integrated studies. Another need refers to building the necessary critical mass of transdisciplinary scientists to tackle the climate change-human health problems in the region. The prevailing gaps in scientific knowledge hamper the implementation of adaptation strategies, thus demanding a review of of research priorities towards better disease control. With the aim of further studying the health impacts of climate change and identifying resilience, mitigation and adaptation strategies, South-South cooperation and multidisciplinary research are considered to be relevant priorities.

In spite of the uncertainty that stems from global and regional climatic projections, the region needs to act in preparation of a possible increase in climate variability and in extremes. It is necessary to undertake research activities leading to public policies to assist societies in coping with current climate variability, as for example, risk assessment and risk management. Other important aspect since the AR4 is the improvement of climate modeling and the generation of high-resolution climate scenarios, that in countries in CA and SA resulted in the first integrated regional studies on impacts and vulnerability assessments of climate change focusing on sectors such as agriculture, energy and human health.

Research on adaptation and the scientific understanding of the various processes and determinants of adaptive capacity is also mandatory for the region, with particular emphasis on increasing adaptation capacity involving the traditional knowledge of ancestral cultures and how this knowledge is transmitted. Linking indigenous knowledge with scientific knowledge is important. Although some adaptation processes have been initiated in the recent years, there is no literature assessing their efficiency so far.

The research agenda needs to address vulnerability and foster adaptation in the region; encompassing an inclusion of the regions' researchers and focusing also on governance structures and action-oriented research that addresses resource distribution inequities.

Regional and international partnerships, and research networks and programs have allowed linking those programs with local strategies for adaptation and mitigation, also providing opportunities to address research gaps and exchange among researchers. Examples are the European Union funded projects CLARIS LPB in SESA and AMAZALERT in Amazonia. Other important initiatives come from the IAI, WHO, GEF, IDB, ECLAC (CEPAL), La Red and BirdLife International, among others. The same holds for local international networks such as ICLEI or C40, of which CA and SA cities form part. The weADAPT initiative is a good example on how CA and SA practitioners, researchers and policy makers can have access to credible, high quality information and to share experiences and lessons learnt in other regions of the world.

27.8. Conclusions

CA and SA harbor unique ecosystems and maximum biodiversity, with a variety of eco-climatic gradients rapidly changing from development initiatives. Agricultural and beef production as well as bioenergy crops are on the raise mostly by expanding agricultural frontiers. Poverty and inequality are decreasing, but at a low pace. Socioeconomic development shows a high level of heterogeneity and a very unequal income distribution, resulting in high vulnerability to climatic conditions. There is still a high and persistent level of poverty in most countries (45% for CA and 30% for SA for year 2010) in spite of the sustained economic growth observed in the last decade.

The IPCC AR4 and SREX reports contain ample evidence of increase in extreme climate events in CA and SA. During 2000-2010, 630 weather and climate extreme events lead to 16,000 fatalities, and 46.6 million people affected, with estimated losses of US$ 208 million. During 2000-2009, 39 hurricanes occurred in the CA-Caribbean basin compared to 15 and 9 in the decade of 1980 and 1990, respectively. In SESA, more frequent and intense rainfall extremes have favored an increase in the occurrence of flash floods and landslides. In Amazonia extreme droughts were reported in 2005 and 2010 and record floods were observed in 2009 and 2012. In 2012-2013 an extreme drought affected NEB.

While warming occurred in most of CA and SA, cooling was detected off the coast of Southern Peru and Chile. There is growing evidence that Andean glaciers (both tropical and extratropical) are retreating in response to warming trends. Increases in precipitation were registered in SESA, CA and the NAMS regions, while decreases were observed in Southern Chile, and a slight decrease in NEB after the middle 1970s. In CA it has been observed a gradual delay of the beginning of the rainfall season. SLR varied from 2 to 7 mm/yr between 1950 and 2008 in CA and SA, which is a reason for concern since a large proportion of the population of the region lives by the coast.

Land use and land cover change are key drivers of regional environmental change in SA and CA. Natural ecosystems are affected by climate variability/change and land use change. Deforestation, land degradation, and biodiversity loss are mainly attributed to increased extensive agriculture for traditional export activities and bioenergy crops. Agricultural expansion has affected fragile ecosystems, causing severe environmental degradation and reducing the environmental services provided by these ecosystems. Deforestation has intensified the process of land degradation, increasing the vulnerability of communities exposed floods, landslides and droughts. Plant species are rapidly declining in CA and SA, with a high percentage of rapidly declining amphibian species. However, the region has still large extensions of natural vegetation cover, with the Amazon being the main example. Ecosystem-based Adaptation practices, such as the establishment of protected areas and their effective management, conservation agreements, community management of natural areas, and payment for ecosystem services are increasingly more common across the region.

Figure 27-7 summarizes of some of the main observed trends in global environmental change drivers across different representative regions of CA and SA. Changes in climate and non-climate drivers have to be compounded with other socioeconomic related trends; such as the rapid urbanization process experienced the region

Some observed impacts on human and natural systems can be directly or indirectly attributed to human influences, and can be summarized as (Figure 27-8):

- Changes in river flow variability in the Amazon River during the last two decades, and robust positive trends in streamflow in sub-basins of the La Plata River basin, and increased dryness for most of the river basins in west coast of South America during the last 50 years.
- Reduction in tropical glaciers and icefields in tropical and extra tropical Andes over the second half of the 20th century that can be attributed to an increase in temperature
- Coastal erosion, bleaching of coral reefs in the coast of CA, and reduction in fisheries stock.
- Increase in agricultural yield in SESA, and shifting in agricultural zoning: significant expansion of agricultural areas, mainly in climatically marginal regions.
- Increase in frequency and extension of dengue fever, yellow fever and malaria.

However, for some impacts the number of concluding studies is still insufficient, leading to low levels of confidence for attribution to human influences.

[INSERT FIGURE 27-7 HERE
Figure 27-7: Summary of observed changes in climate and other environmental factors in representative regions of CA and SA. The boundaries of the regions in the map are conceptual (neither geographic nor political precision). Information and references to changes provided are presented in different sections of the chapter.]

[INSERT FIGURE 27-8 HERE
Figure 27-8: Observed impacts of climate variations and attribution of causes in CA and SA.]

By the end of the century, the CMIP5 derived projections for RCP8.5 projected: CA: mean annual warming of 2.5ºC (range: 1.5°C to 5.0 °C), mean rainfall reduction of 10% (range: -25% to +10%), and reduction in summertime precipitation; SA: mean warming of 4ºC (range: 2.0°C to 5.0 °C), with rainfall reduction up to 15% in tropical SA east of the Andes, and an increase of about 15-20% in SESA, and in other regions of the continent. Increases in warm days and nights are *very likely* to occur in most of SA. SESA: Increases in heavy precipitation. Northeastern South America: increases in dry spell. However, there is some degree of uncertainty on climate change projections for regions, particularly for rainfall in CA and tropical SA.

Current vulnerability in terms of water supply in the semi-arid zones and the tropical Andes is expected to increase even further due to climate change. This would be exacerbated by the expected glacier retreat, precipitation reduction and increase evapotranspiration demands as expected in the semi-arid regions of CA and SA. These scenarios would affect water supply for large cities, small communities, hydropower generation and food production. There is a need for re-assessing current practices to reduce the mismatch between water supply and demand in order to reduce future vulnerability, and to implement constitutional and legal reforms towards more efficient and effective water resources management.

SLR due to climate change and human activities on coastal and marine ecosystems pose threats to fish stocks, corals, mangroves, recreation and tourism, and diseases control in CA and SA. Coral reefs, mangroves, fisheries, and other benthic marine invertebrates that provide key ecosystem services, such as nutrient cycling, water quality regulation, and herbivory, are also threatened by climate change. It is possible that the Mesoamerican coral reef will collapse by mid-century (between 2050 and 2070), causing major economic and environmental losses. In the southwestern Atlantic coast, eastern Brazilian reefs might suffer a massive coral cover decline in the next 50 years. In the Rio de La Plata area extreme-flooding events may become more frequent since return periods are decreasing, and urban coastal areas in the eastern coast will be particularly affected. Beach erosion is expected to increase in southern Brazil and in scattered areas at the Pacific coast.

Urban populations in CA and SA face diverse social, political, economic and environmental risks in daily life, and climate change will add a new dimension to these risks. Since urban development remains fragile in many cases, with weak planning responses, climate change can compound existing challenges, e.g. water supply in cities from glacier, snowmelt and paramos related runoff in the Andes (Lima, La Paz/El Alto, Santiago de Chile, Bogota), flooding in several cities like São Paulo and Buenos, and health related challenges in many cities of the region.

Climate change will affect individual species and biotic interactions. Vertebrate fauna will suffer major species losses especially in high altitude areas; elevational specialists might be particularly vulnerable because of their small geographic ranges and high energetic requirements; freshwater fisheries can suffer alterations in physiology and life histories. In addition, modifications in phenology, structure of ecological networks, predator-preys interactions and non-trophic interactions among organisms will affect biotic interactions. Shifts in biotic interactions are expected to have negative consequences on biodiversity and ecosystem services in High Andean ecosystems. Although in the region biodiversity conservation is largely confined to protected areas it is expected that many species and vegetational types will lose representativeness inside such protected areas.

Changes in food production and food security are expected to have a great spatial variability, with a wide range of uncertainty mainly related to climate and crop models. In SESA average productivity could be sustained or increased until the mid-century, although interannual and decadal climate variability are likely to impose important damages. In other regions like NEB, CA, and some Andean countries agricultural productivity could decrease in the short-term, threatening the food security of the poorest population. The expansion of pastures and croplands is expected to continue in the coming years, particularly from an increasing global demand for food and biofuels. The great challenge for CA and SA will be to increase the food and bioenergy production and at the same time sustain the environmental quality in a scenario of climate change.

Renewable energy provides a great potential for adaptation and mitigation. Hydropower is currently the main source of RE in CA and SA, followed by biofuels. SESA is one of the main sources of production of the feedstocks for biofuels’ production, mainly with sugarcane and soybean, and future climate conditions may lead to an increase in productivity and production. Advances in second generation biofuels will be important as a measure of adaptation, as they have the potential to increase biofuels productivity. In spite of the large amount of arable land available, the expansion of biofuels might have some direct and indirect land use change effects, producing teleconnections that could lead to deforestation of native tropical forests and loss of employment in some countries. This might also affect food security.

Changes in weather and climatic patterns are negatively affecting human health in CA and SA, either by increasing morbidity, mortality, and disabilities, and through the emergence of diseases in previously non-endemic regions. Multiple factors increase the region’s vulnerability to climate change: precarious health systems, malnutrition, inadequate water and sanitation services, population growth, poor waste collection and treatment systems, air, soil and water pollution, food in poor regions, lack of social participation, and inadequate governance. Vulnerabilities vary with geography, age, gender, race, ethnicity, and socio-economic status, and are rising in large cities. Climate change and variability may exacerbate current and future risks to health.

Climate change will bring modifications to environmental conditions in space and time, and the frequency and intensity of weather and climate processes. In many CA and SA countries, a first step toward adaptation to climate change is to reduce the vulnerability to present climate, taking into account future potential impacts, particularly of weather and climate extremes. Long-term planning and the related human and financial resource needs may be seen as conflicting with present social deficit in the welfare of the CA and SA population. Such conditions weaken the importance of adaptation planning to climate change on the political agenda. Currently, there are few experiences on synergies between development, adaptation and mitigation planning, which can help local communities and governments to allocate available resources in the design of strategies to reduce vulnerability and to develop adaptation measures. Facing a new climate system and, in particular, the exacerbation of extreme events, will call for new ways to manage human and natural systems for achieving sustainable development.

Table 27-8: Key risks from climate change and the potential for risk reduction through mitigation and adaptation.]

Frequently Asked Questions

FAQ 27.1: What is the impact of glacier retreat on natural and human systems in the tropical Andes?
[to be inserted at end of Section 27.3.1.2]
The retreat of glaciers in the tropical Andes mountains, with some fluctuations, started after the Little Ice Age (16th to 19th centuries), but the rate of retreat (area reduction between 20-50%) has accelerated since the late 1970s. the changes in runoff from glacial retreat into the basins fed by such runoff vary depending on the size and phase of glacier retreat. In an early phase, runoff tends to increase due to accelerated melting, but after a peak, as the glacierized water reservoir gradually empties, runoff tends to decrease. This reduction in runoff is more evident during dry months when glacier melt is the major contribution to runoff (high confidence).

A reduction in runoff could endanger high Andean wetlands (bofedales) and intensify conflicts between different water users among the highly vulnerable populations in high elevation Andean tropical basins. Glacier retreat has also been associated with disasters such as glacial lake outburst floods that are a continuous threat in the region. Glacier retreat could also impact activities in high mountainous ecosystems such as alpine tourism, mountaineering and adventure tourism (high confidence).

FAQ 27.2: Can payment for ecosystem services (PES) be used as an effective way to help local communities adapt to climate change? *[to be inserted in Section 27.3.3.2]*
Ecosystems provide a wide range of basic services, like providing breathable air, drinkable water, and moderating flood risk (very high confidence). Assigning values to these services and designing conservation agreements based on these (broadly known as PES), can be an effective way to help local communities adapt to climate change. It can simultaneously help protect natural areas, and improve livelihoods and human well-being (medium confidence). However, during design and planning, a number of factors need to be taken into consideration at the local level in order to avoid potentially negative results. Problems can arise if a) the plan sets poor definitions about whether the program should focus just on actions to be taken or the end result of those actions, b) many perceive the initiative as commoditization of nature and its intangible values, c) the action is inefficient to reduce poverty, d) difficulties emerge in building trust between various stakeholders involved in agreements, and e) there are eventual gender or land tenure issues.

FAQ 27.3: Are there emerging and re emerging human diseases as a consequence of climate variability and change in the region? *[to be inserted in Section 27.3.7.2]*
Human health impacts have been exacerbated by variations and changes in climate extremes. Climate-related diseases have appeared in previously non-endemic regions (e.g. malaria in the Andes, dengue in CA and Southern SA) (*high confidence*). Climate variability and air pollution have also contributed to increase the incidence of respiratory and cardiovascular, vector- and water-borne and chronic kidney diseases, Hantaviruses and rotaviruses, pregnancy-related outcomes, and psychological trauma (*very high confidence*). Health vulnerabilities vary with geography, age, gender, ethnicity, and socio-economic status, and are rising in large cities. Without adaptation measures (e.g. extending basic public health services), climate change will exacerbate future health risks, owing to population growth rates and existing vulnerabilities in health, water, sanitation and waste collection systems, nutrition, pollution, and food production in poor regions (*medium confidence*).

Table 27-1: Regional observed changes in temperature, precipitation and climate extremes in various sectors of CA and SA. Additional information on changes in observed extremes can be found in the IPCC SREX (Seneviratne *et al.*, 2012) and Chapter 2 IPCC WGI AR5 [2.4, 2.5, 2.6]

Region	Period	Observed changes
CA and Northern SA/Variable		
Precipitation in the NAMS (Englehart and Douglas, 2006)	1943-02	+0.94 mm/day/58 years
Rainfall onset in NAMS (Grantz *et al.*, 2007)	1948-04	-10 to -20 days/57 years
Summertime Precipitation in NAMS *(Anderson et al., 2010)*	1931-00	+17.6 mm century^{-1}
Rainfall extremes (P95) in NAMS (Cavazos *et al.*, 2008)	1961-98	+1.3% decade^{-1}
Cold days and nights in CA and Northern SA (Donat *et al.*, 2013)	1951-10	Cold days: -1 day decade^{-1}, Cold nights: -2 day decade^{-1}
Warm days and nigths in Northern SA ((Donat *et al.*, 2013)	1951-10	Warm days: +2 to +4 day decade^{-1}, warm nights: +1 to +3 day decade^{-1}
Heavy precipitation (R10) in Northern SA ((Donat *et al.*, 2013)	1951-10	+1 to +2 day decade^{-1},
Consecutive dry days (CDD) in Northern SA (Donat *et al.*, 2013)	1951-10	-2 day decade^{-1},
West Coast of SA		
SST and air temperatures off coast of Peru and Chile (15S-35S) (Falvey and Garreaud, 2009; Gutiérrez *et al.*, 2011a; Gutiérrez *et al.*, 2011b; Kosaka and Xie, 2013)	1960-10	-0.25 ºC /decade, -0.7 ºC /11 years for 2002-2012
Temperature, precipitation, cloud cover, and number of rainy days since the middle 1970´s off coast of Chile (18S-30S) (Schulz *et al.*, 2012)	1920-09	-1 ºC /40 years, -1.6 mm/40 years, -2 octas/40 years, and -0.3 days/40 years
Wet days until 1970, increase after that, reduction in the precipitation rate in southern Chile (37S-43S) (Quintana and Aceituno, 2012)	1900-07	-0.34% until 1970 and +0.37 after that, -0.12 %
Cold days and nights in all South American coast (Donat *et al.*, 2013)	1951-10	Cold days: -1 days decade^{-1}; cold nights: -2 days decade^{-1}
Warm nights in all South American coast, warm days in the northern coast of South America, warm days off the coast of Chile (Donat *et al.*, 2013)	1951-10	Warm night: -1 days decade^{-1}; warm days: +3 days decade^{-1} ; warm days: -1 days decade^{-1}
Warm nights in the coast of Chile (Dufek *et al.*, 2008)	1961-90	+5 to +9%/31 years
Dryness as estimated by the Palmer Drought Severity Index (PDSI) for most of the west coast of SA (Chile, Ecuador, Northern Chile) (Dai, 2011)	1950-08	-2 to -4 / 50 years
Heavy precipitation (R95) in northern and central Chile (Dufek *et al.*, 2008)	1961-90	-45 to -105 mm/31 years
Temperature and precipitation in southern Chile (Vicuña *et al.*, 2013)	1976-08	-45 to -105 mm/31 years
SESA		
Mean annual air temperature in southern Brazil (Sansigolo and Kayano, 2010)	1913-06	+0.5 to +0.6 ºC /decade, -31.4 - -47.6 mm/decade
Frequency of cold days and nights, warm days in Argentina and Uruguay (Rusticucci and Renom, 2008)	1935-02	-1.2%/decade, -1%/decade/, +0.2%/decade
Highest annual maximum temperature, lowest annual minimum air temperature in Argentina and Uruguay (Rusticucci and Tencer, 2008)	1956-03	+0.8 C/47 years, +0.6C/47 years
Warm nights in Argentina and Uruguay and southern Brazil (Rusticucci, 2012)	1960-09	10-20%/41 years
Warm nights in most of the region (Dufek *et al.*, 2008)	1961-90	+7 to +9%/31 years
Cold nights in most of the region (Dufek *et al.*, 2008)	1961-90	-5 to -9%/31 years
Cold days and nights in most of the region (Donat *et al.*, 2013)	1951-10	warm nights: +3 days decade^{-1}; warm days: +4 days decade^{-1}
Warm days and nights in most of the region (Donat *et al.*, 2013)	1951-10	Cold nights: -3 days decade^{-1}; cold days: -3 days decade^{-1}
Consecutive dry days (CDD) in the La Plata Basin countries (Argentina, Bolivia and Paraguay) and decrease of CDD in SA South of 30 S (Dufek *et al.*, 2008)	1961-90	+15 to +21 days/31 years, -21 to -27 days/31 years
Number of dry months during the warm season October-March in the Pampas region between	1904-00	From 2-3 months in 1904-1920 to 1-2 months from 1980-2000

25S-40S (Barrucand *et al.*, 2007)		
Moister conditions as estimated by the Palmer Drought Severity Index (PDSI) in most of SESA (Dai, 2011)	1950-08	0 to 4/50 years
Rainfall trends in the Parana River Basin (Dai *et al.*, 2009)	1948-08	+1.5 mm/day/50 years
Number of days with precipitation above 10 mm (R10) in most of the region (Donat *et al.*, 2013)	1951-10	+2 days/decade^{-1}
Heavy precipitation (R95) in most of the region (Donat *et al.*, 2013)	1951-10	+1% decade^{-1} and -4 days decade $^{--1}$
Heavy precipitation (R95) in most of the region (Dufek *et al.*, 2008)	1961-90	+45 to +135 mm/31 years
Heavy precipitation (R95) in the state of Sao Paulo (Dufek and Ambrizzi, 2008)	1950-99	+50 to +75 mm/40 years
Consecutive dry days (CDD) in the state of Sao Paulo (Dufek and Ambrizzi, 2008)	1950-90	-25 to-50 days/40 years
Lightning activity significantly with change in temperature in the state of Sao (Pinto and Pinto, 2008; Pinto *et al.*, 2013)	1951-06	+40% per 1ºC for daily and monthly time scales and approximately 30% per 1 ºC for decadal timescale
Number of days with rainfall above 20 mm in the city of Sao Paulo (Marengo *et al.*, 2013; Silva Dias *et al.*, 2012)	2005-11	+5 to +8 days/11 years
Excess rainfall events duration after 1950 (Krepper and Zucarelli, 2010)	1901-03	+ 21 months/53 years
Dry events and events of extreme dryness from 1972 to 1996 (Vargas *et al.*, 2011)	1972-96	-29 days/24 years
Number of dry days in Argentina (Rivera *et al.*, 2013)	1960-05	-2 to -4 days/decade
Extreme daily rainfall in La Plata Basin (Penalba and Robledo, 2010)	1950-00	+33 to +60% increase in Spring, Summer and Autumn, -10 to -25% decrease in winter
Frequency of heavy rainfall in Argentina, Southern Brazil and Uruguay (Re and Barros, 2009)	1959-02	+50 to +150 mm/43 years
Annual precipitation in the La Plata Basin (Doyle *et al.*, 2012)(Doyle and Barros, 2011) (Doyle and Barros, 2011)	1960-05	+5 mm/year
Andes		
Mean maximum temperature along the Andes, and increase in the number of frost days *(Marengo et al., 2011b)*	1921-10	+0.10 to +0.12 ºC /decade in 1921-2010, and +0.23-0.24 ºC /decade during 1976-2010; 8 days/decade during 196-2002
Air temperature and changes in precipitation Northern Andes (Colombia, Ecuador) (Villacís, 2008)	1961-90	+0.1 C to +0.22 ºC /decade, -4 to +4 %/decade years
Temperature and precipitation in northern and central Andes of Peru (SENAMHI, 2005; 2007; 2009a; 2009c; 2009d)	1963-06	+0.2 to +0.45 ºC /decade, -20 to -30%/40 years
Temperature and precipitation in the southern Andes of Peru (Marengo *et al.*, 2011b; SENAMHI, 2007; 2009a; 2009b; 2009c; 2009d)	1964-06	+0.2 to 0.6 ºC /decade, -11 to +2 mm/decade
Air temperature and rainfall over Argentinean and Chilean Andes and Patagonia (Falvey and Garreaud, 2009; Masiokas *et al.*, 2008)	1950-90	+0.2 to 0.45 ºC /decade, -10 to -12%/decade
Number of days with rainfall above 10 mm (R10) (Donat *et al.*, 2013)	1950-10	-3 days decade^{-1}
Dryness in the Andes between 35.65 S-39.9 S using the PDSI (Christie *et al.*, 2011)	1950-03	-7 PDSI/53 years
Rainfall decrease in the Mantaro Valley, central Andes of Peru (SENAMHI, 2009c)	1970-05	-44 mm/decade
Air temperature in Colombian Andes (Poveda and Pineda, 2009)	1959-07	+1 ºC /20 years
Amazon region		
Decadal variability of rainfall in northern and southern Amazonia *(Marengo et al., 2009; Satyamurty et al., 2010)*	1920-08	-3 STD/30 years in northern Amazonia and +4 STD/30 years in southern Amazonia since the middle 1970's
Rainfall in all the region (Espinoza *et al.*, 2009a; 2009b)	1975-03	-0.32 %/28 years
Onset of the rainy season in southern Amazonia (Butt *et al.*, 2011; Marengo *et al.*, 2011b)	1950-10	-1 month since 1976 to 2010

Precipitation in the SAMS core region (Wang *et al.*, 2012)	1979-08	+ 2 mm/day decade^{-1}
Onset becomes steadily earlier from 1948 to early 1970s, demise dates have remained later, and SAMS duration was longer after 1972 (Carvalho *et al.*, 2011)	1948-08	SAMS from 170 days (1948–1972) to 195 days (1972–1982).
Spatially varying trends of heavy precipitation (R95), increase in many areas and insufficient evidence in others (Marengo *et al.*, 2009)	1961-90	+100 mm/31 years in western and extreme eastern Amazonia,
Spatially varying trends in dry spells in (CDD), increase in many areas and decrease in others (Marengo *et al.*, 2009; Marengo *et al.*, 2010)	1961-90	+15 mm/31 years in western Amazonia, -20 mm/ in southern Amazonia
Rainfall in most of Amazonia and in western Amazonia (Dai *et al.*, 2009; Dai, 2011)	1948-08	+1 mm/day/50 years, -1.5 mm/day/50 years
Dryness as estimated by the Palmer Drought Severity Index PDI in southern Amazonia and moister conditions in western Amazonia (Dai, 2011)	1950-08	-2 to -4/50 years, +2 to +4 /50 years
Seasonal mean convection and cloudiness (Arias *et al.*, 2011)	1984-07	+30 W/m2/23 years, -8 %/23 years
Onset of rainy season in southern Amazonia due to land use change (Butt *et al.*, 2011)	1970-10	-0.6 days/30 years
Precipitation in the region (Gloor *et al.*, 2013)	1990-10	-20 mm/21 years
Northeast Brazil		
Rainfall trends interior Northeast Brazil and in northern Northeast Brazil (Dai *et al.*, 2009; Dai, 2011)	1948-08	-0.3 mm/day/50 years, +1.5 mm/day/50 years
Heavy precipitation (R95) in some areas, and in southern Northeast Brazil (Silva and Azevedo, 2008)	1970-06	-2 mm/24 years to + 6 mm/24 years,
Consecutive dry days CDD in most of southern Northeast Brazil (Silva and Azevedo, 2008)	1970-06	-0.99 days/24 years
Total annual precipitation in northern Northeast Brazil (Santos and Brito, 2007)	1970-06	+1 to +4 mm/year/24 years
Spatially varying trends in heavy precipitation (R95) in northern Northeast Brazil (Santos and Brito, 2007)	1970-06	-0.1 to +5 mm/yeas/24 years
Spatially varying trends in heavy precipitation (R95) and consecutive dry days (CDD) in northern Northeast Brazil (Santos *et al.*, 2009)	1935-06	-0.4 to +2.5 mm/year/69 years, -1.5 to +1.5 days/year/69 years,
Dryness in Southern Northeast Brazil as estimated by the PDSI, and northern Northeast Brazil (Dai, 2011)	1950-08	-2 to -4/50 years, 0 to +1/50 years

Table 27-2: Regional projected changes in temperature, precipitation, and climate extremes in different sectors of CA and SA. Various studies used A2 and B2 scenarios from CMIP3 and various RCPs scenarios for CMIP5, and different time slices from 2010 to 2100. In order to make results comparable, the CMIP3 and CMIP5 at the time slice ending in 2100 are included. Additional information on changes in projected extremes can be found in the IPCC SREX (see IPCC, 2012), and Chapters 9 and 14 from IPCC WG1AR5 [9.5, 9.6 and 14.2, 14.7]

Region	Models and scenarios	Projected changes
CA and Northern SA		
Leaf Area Index (LAI), evapotranspiration by 2070-2099 in CA (Imbach *et al.*, 2012)	23 CMIP3 models, A2	Evapotranspiration: +20%; LAI:-20%+0.94 mm/day/58 years
Air temperature by 2075 and 2100 in CA (Aguilar *et al.*, 2009)	9 CMIP3 models, A2	+2.2 C by 2075; +3.3 C by 2100
Rainfall in CA and Venezuela, air temperature in the region (Hall *et al.*, 2013; Kitoh *et al.*, 2011)	20 km MRI-AGCM3.1S model, A1B	Rainfall decrease/increase of about -10%/+10%, by 2079. Temperature increases of about +2.5-+3.5 ºC by 2079
Precipitation and evaporation in most of the region. Soil moisture in most land areas in all seasons (Nakaegawa *et al.*, 2013b)	20 km MRI-AGCM3.1S model, A1B	Precipitation decrease of about -5 mm/day, evaporation increase of about +3 to +5 mm/day; soil moisture to decrease by -5 mm/day.
Rainfall in Nicaragua, Honduras, Northern Colombia and Northern Venezuela, rainfall in Costa Rica and Panama. Temperature in all region by 2071-2100 (Campbell *et al.*, 2011)	PRECIS forced by the HadAM3, A2	Rainfall: -25 to -50%, and +25 to +50%. Temperature: +3 to +6 C
Precipitation and temperature in northern SA, decrease in interior Venezuela, temperature increases by 2071-2100 (Marengo *et al.*, 2011a)	Eta forced with HadCM3, A1B	Increases by +30 to 50%, and reductions between -10 to -20%; temperature: +4 to +5 C
Precipitation and temperature by 2100 in CA (Karmalkar *et al.*, 2011)	PRECIS forced with HadAM3, A2	Precipitation: -24 to -48%; temperature: +4 to +5 C
Warm nights, consecutive dry days and heavy precipitation in Venezuela, by 2100 (Marengo *et al.*, 2009; 2010)	PRECIS forced with HadAM3, A2	Increase by +12 to +18%, +15 to +25 days and reduction of 75 to 105 days
Air temperature and precipitation in CA by 2100 (Giorgi and Diffenbaugh, 2008)	23 CMIP3 models, A1B	Increase by +3 to +5 ºC; reduction by -10 to -30%
Consecutive dry days and in heavy precipitation by 2099 (Kamiguchi *et al.*, 2006)	20 km MRI-AGCM3.1S model, A1B	Increase by +5 days, and between +2 to +8 %
Rainfall over Panama by 2099 (Fábrega *et al.*, 2013)	20 km MRI-AGCM3.1S model, A1B	Increase by +5 %
West Coast of SA		
Precipitation, runoff and temperature at the Limari river basin in semi-arid Chile by 2100 (Vicuña *et al.*, 2011)	PRECIS forced with HadAM3, A2	Precipitation: -15 % to -25%; runoff: -6 to -27%; temperature: + 3 to +4 ºC
Ai temperature and surface winds in west coast of SA (Chile) by 2100 (Garreaud and Falvey, 2009)	15 CMIP3 models, PRECIS forced with HadAM3, A2	Temperature: +1 ºC; coastal winds: +1.5 m/sec
Precipitation in the bands 5N-10S, and 25S-30S, and 10S-25S and 30S-50S; temperature increase between by 2100 (Marengo *et al.*, 2011a)	Eta model forced with HadCM3, A1B	Increases of 30-40%; increases of 3 to 5 ºC
Warm nights, consecutive dry days, and heavy precipitation in 5N-5S by 2100 (Marengo *et al.*, 2009; 2010)	PRECIS forced with HadAM3, A2	Increase of +3 to +18%, reduction of -5 to – 8 days, increase by +75 to +105 days
Air temperature, increase of precipitation between 0 and 10S, and between 20 and 40S by 2100 (Giorgi and Diffenbaugh, 2008)	23 CMIP3 models, A1B	Increase of +2 to +3 ºC; increase by 10%, reduction by -10 to -30%

Consecutive dry days between 5 N and 10 S and south of 30S, heavy precipitation between 5S-20S and south of 20S by 2099 (Kamiguchi *et al.*, 2006)	20 km MRI-AGCM3.1S model, A1B	Increase by 10 days and between +2 to +10%
Precipitation between 15 and 35 S; and south of 40S; temperature by 2100 (Nuñez *et al.*, 2009)	MM5 forced with HadAM3, A2	Precipitation: -2 mm/day; +2 mm/day; temperature: +2.5 ºC
Precipitation in Panama and Venezuela, heavy precipitation in Panama and in Venezuela, consecutive dry days over Panama and Colombia by 2099 (Sörensson *et al.*, 2010)	RCA forced with ECHAM5-MPI OM model, A1B	Precipitation:-1 to -3 mm/day,
SESA		
Precipitation and runoff, an in air temperature by 2100 (Marengo *et al.*, 2011a)	Eta forced with HadCM3, A1B	Precipitation: + 20 to +30%; Runoff: +10 to +20%; air temperature: +2.5 to +3.5 ºC
Precipitation and temperature in the La Plata basin by 2050 (Cabré *et al.*, 2010)	MM5 forced with HadAM3, A2	Precipitation: +0.5 to 1.5 mm/day; temperature: +1.5 ºC to 2.5 ºC.
Warm nights, consecutive dry days and heavy precipitation by 2100 (Menendez and Carril, 2010)	7 CMIP3 models, A1B	Warm nights: +10 to +30%; Consecutive dry days: +1 to +5 days; Heavy precipitation: +3 to +9 %.
Precipitation during summer and spring, and in fall and winter by 2100 (Seth *et al.*, 2010)	9 CMIP3 models, A2	Precipitation: + 0.4 to +0.6 mm/day, -0.02 to -0.04 mm/day
Warm nights, consecutive dry days and heavy precipitation by 2100 (Marengo *et al.*, 2009; 2010)	PRECIS forced with HadAM3, A2	Increase of +6 to +12%, +5 to +20 days, +75 to +105 days
Air temperature and rainfall by 2100 (Giorgi and Diffenbaugh, 2008)	23 CMIP3 models, A1B	Increase by +2 to +4 ºC, increase by +20 to +30 %
Consecutive dry days and in heavy precipitation by 2099 (Kamiguchi *et al.*, 2006)	20 km MRI-AGCM3.1S model, A1B	Increase by +5 to +10% and by +2 to +8 %
Precipitation in north central Argentina, decrease in southern Brazil, increase of air temperature by 2100 (Nuñez *et al.*, 2009)	MM5 forced with HadAM3, A2	Increase of +0.5 to +1 mm/day, reduction of -0.5 mm/day, increase of +3 to +4.5 ºC
Drought frequency, intensity and duration in South America South of 20 S for 2011-40 relative to 1979-2008 (Penalba and Rivera, 2013)	15 CMIP5 models, RCP 4.5 and 8.5	Frequency increase between 10-20%, increase in severity between 5-15% and reduction in duration between 10 and 30%
Precipitation, heavy precipitation, reduction of consecutive dry days in the eastern part of the region, increase in the western part of the region by 2099 (Sörensson *et al.*, 2010)	RCA forced with the ECHAM5 mode, A1B	Increase of +2 mm/day, of +5 to +15 mm, reduction of -10 days and increase of +5 days
Precipitation in SESA by 2100 (Sörensson *et al.*, 2010)	9 CMIP3 models, A1B	Increase between +0.3 to +0.5 mm/day
Andes		
Precipitation and temperature, increase by 2100 in the Altiplano (Minvielle and Garreaud, 2011)	11 CMP3 models, A2	Precipitation: -10 to -30 %; temperature:>3 ºC
Precipitation at 5N-5S, and 30S-45 S, at 5-25 S; temperature by 2100 (Marengo *et al.*, 2011a)	Eta forced with HadCM3, A1B	Increase between +10 and +30%, decrease by -20 to -30%, increase of +3.5 to +4.5 ºC
Warm nights, heavy precipitation and consecutive dry days south of 15 S by 2100 (Marengo *et al.*, 2009)	PRECIS forced with HadAM3, A2	Increase by +3 to +18%, reduction by -10 to -20 days, and -75 to -105 days
Air temperature, rainfall between 0-10S and reduction between 10-40 S (Giorgi and Diffenbaugh, 2008)	23 CMIP3 models, A1B	Increase by +3 to +4 ºC, increase by 10% and reduction by -10%
Consecutive dry days and increase of heavy precipitation by 2099 (Kamiguchi *et al.*, 2006)	20 km MRI-AGCM3.1S model, A1B	Reduction by -5 days, increase by +2 to +4 % south of 20S
Precipitation, heavy precipitation, and consecutive dry days by 2070-99 (Sörensson *et al.*, 2010)	RCA forced with ECHAM5, A1B	Increases of +1 to +3 mm/day, +5 mm and of +5 to +10 days

Summer precipitation and surface air temperature in the Altiplano region by 2099 (Minvielle and Garreaud, 2011)	9 CMIP3 models, A2	Reduction in precipitation between -10% and -30%, an temperature increase of +3 ºC
Temperature and rainfall in lowland Bolivia inn 2070-2999 (Seiler *et al.*, 2013)	5 CMIP3 models (A1B) ad 5 CMIP5 models (RCP4.5, 8.5)	Increase from 2.5 ºC to 5 ºC, reduction of 9% annual precipitation
Precipitation in the dry season, temperature and evapotranspiration 2079-98 (Guimberteau *et al.*, 2013)	CMIP3 models, A1B	-1.1 mm; +2 ºC; +7%
Amazon region		
Rainfall in central and eastern Amazonia, and in western Amazonia, air temperature in all region by 2100 (Marengo *et al.*, 2011a)	Eta forced with HadCM3, A1B	Precipitation: -20 to -30%, +20 to +30%; temperature: +5 to +7 ºC
Intensity of the South Atlantic Convergence Zone and in rainfall in the South American monsoon region, 2081-2100 (Bombardi and Carvalho, 2009)	10 CMIP3 models, A1B	Precipitation: -100 to -200 mm/20 years
Precipitation in western Amazonia during summer and in winter in Amazonia by 2100 (Mendes and Marengo, 2010)	5 CMIP3 models, A2 and ANN	+1.6% in summer and -1.5% in winter
Number of South American Low Level Jet east of the Andes events (SALLJ), and in the moisture transport from Amazonia to the La Plata basin by 2090 (Soares and Marengo, 2009)	PRECIS forced by HadAM3, A2	+50 events of SALLJ during summer, increase in moisture transport by 50%
Precipitation in the South American monsoon during summer and spring, and during fall and winter by 2100 (Seth *et al.*, 2010)	9 CMIP3 models, A2	Increase of +0.15 to +0.4 mm/, reductions of -0.10 to -0.26 mm/day
Warm nights, consecutive dry days in eastern Amazonia, heavy precipitation in western Amazonia and in eastern Amazonia by 2100 (Marengo *et al.*, 2009)	PRECIS forced with HadAM3, A2	Increase of +12 to +15%, by 25-30 days in eastern Amazonia, increase in western Amazonia by 75-105 days and reduction by -15 to 75 days in eastern Amazonia
Increase in air temperature, rainfall increase in western Amazonia and decrease in eastern Amazonia by 2100 (Giorgi and Diffenbaugh, 2008)	CMIP3 models, A1B	Increase of +4 to +6 ºC, increase of +10% and decrease between -10 to -30%
Reduction of consecutive dry days and increase in heavy precipitation by 2099 (Kamiguchi *et al.*, 2006)	20 km MRI-AGCM3.1S model, A1B	Reduction of -5 to -10 days, increase by +2 to +8 %
Onset and late demise of the rainy season in SAMS by 2040-2050 relative to 1951-80 (Jones and Carvalho, 2013)	10 CMIP5 models, RCP8.5	Onset 14 days earlier than present, demise 17 days later than present
Precipitation in SAMS during the monsoon wet season in 2071-2100 relative to 1951-80 (Jones and Carvalho, 2013)	10 CMIP5 models, RCP8.5	Increase of 300 mm during the wet season
Precipitation in western Amazonia, heavy precipitation in northern Amazonia and in southern Amazonia, consecutive dry days in western Amazonia and increase by 2099 (Sörensson *et al.*, 2010)	RCA forced with the ECHAM5 model, A1B	Increase of +1 to +3 mm/day, reduction of -1 to -3 mm, increase of +5 to +10 mm, decrease of -5 to -10 days, increase by +20 to +30 days
Northeast Brazil		
Rainfall and temperature in the entire region by 2100 (Marengo *et al.*, 2011a)	Eta forced with HadCM3, A1B	Precipitation: -20 to -20%; temperature: +3 to +4 ºC
Warm nights, consecutive dry days, heavy precipitation by 2100 (Marengo *et al.*, 2009)	PRECIS forced with HadAM3, A2	Increase by +18 to +24%, by +25 to +30 days and -15 to –75 days
Air temperature and precipitation by 2100 (Giorgi and Diffenbaugh, 2008)	23 CMIP3 models, A1B	Increase of +2 to +4 ºC, reduction -10 to -30%
Consecutive dry days and heavy precipitation by 2099 (Kamiguchi *et al.*, 2006)	20 km MRI-AGCM3.1S model, A1B	Reduction of -5 to -10% and increase of +2 to +6 %
Precipitation, heavy precipitation and consecutive dry days by 2099 (Sörensson *et al.*, 2010)	RCA forced with ECHAM5 model, A1B	Increase of +1 to +2 mm/day, increase by +5 to +10 mm, and increase by +10 to +30 days

Table 27-3: Observed trends related to Andean cryosphere.
a) Andean tropical glacier trends

Country *Documented massifs (latitude)*	**Significant changes recorded** **(Variable code number[a]) Value of trend (period of observed trend)**	**References**
Venezuela *Cordillera de Merida (10°N)*	(1) +300/+500m between Little Ice Age (LIA) maximum and today. (5) Accelerated melting since 1972. Risk of disappearing completely as ELA close to the highest peak (Pico Bolívar, 4979 m)	Polissar *et al.* (2006); Morris *et al.* (2006)
Colombia *Parque Los Nevados (4°50N)* *Sierra Nevada del Cocuy (6°30N)* *Sierra Nevada de Santa Marta (10°40N)*	(3) LIA maximum between AD 1600 and 1850 (3) Many small/low elevation (<5000 m a.s.l.) glaciers have disappeared (3) -60/-84% (1850-2000); -50% (last 50 yrs); -10/-50% (past 15yrs); Retreat 3.0km²/yr (since 2000)	Ruiz *et al.* (2008); Ceballos *et al.* (2006); Poveda and Pineda (2009); IDEAM (2012); Rabatel *et al.* (2013)
Ecuador *Antisana (0°28S)* *Chimborazo and Carihuayrazo (1°S)*	(1) +300 between the middle 18th (maximum LIA) and the last decades of the 20th C; ~+200m (20th C) (3) ~-45% (1976-2006). Glaciers below 5300m in process of extinction	Francou *et al.* (2007); Vuille *et al.* (2008); Jomelli *et al.* (2009); Cáceres (2010); Rabatel *et al.* (2013)
Peru *Cordillera Blanca (9°S)*	(1) ~+100m (between LIA maximum and beginning 20th C); +150m (20th C) (3) -12/-17% (18th C); -17/-20% (19th C); -20/-35% (1960s-2000s); -26% (1962 and 2000) (4) -8 m decade^{-1} since 1970 (Yanamarey glacier) (8) +1.6% (± 1.1) (glaciers with >20 percent glacier area); (7) Seven out of nine watersheds decreasing dry-season discharge	Raup *et al.* (2007); Jomelli *et al.* (2009); UGHR (2010); Bury *et al.* (2011); Mark *et al.* (2010); Baraer *et al.* (2012); Rabatel *et al.* (2013)
Coropuna volcano (15°33S)	(3) -26% (1962-2000)	Racoviteanu *et al.* (2007)
Cordillera Vilcanota (13°55S)	(3) 10 times faster in 1991-2005 compared to 1963-2005 (2-4) about -30% of area and about -45% of volume since 1985	Thompson *et al.* (2006; 2011) Salzmann *et al.* (2013)
Bolivia *Cordillera Real and Cordillera Quimza Cruz (16°S)*	(1) +300 m (between LIA maximum and late 20th C); +180/+200m (20th C) (3) -48% (1976-2006) in the Cordillera Real; Chacaltaya vanished in 2010. (5) Zongo glacier have lost a mean of 0.4m w.e./yr in the 1991-2011 period; glaciers in the Cordillera Real lost -43% of their volume from 1963 to 2006 (maximum from 1976 to 2006). (2) +1.1±0.2°C over the 20th century at ~6340 m a.s.l.	Rabatel *et al.* (2006; 2008); Francou *et al.* (2007); Vuille *et al.* (2008); Jomelli *et al.* (2011); Soruco *et al.* (2009); Gilbert *et al.* (2010); Rabatel *et al.* (2013)
Sur Lipez, Caquella, 21°30S	(7) Evidence of recent degradation of Caquella rock glacier (South Bolivian Altiplano)	Francou *et al.* (1999)

b) Extra tropical Andean cryosphere (glaciers, snowpack, runoff effects) trends.

Region *Documented massifs/latitude*	**Significant changes recorded and reference** **(Variable code number[a]) Value of trend (period of observed trend)**	**References**
Chile, Argentina and Bolivia and Argentinean Patagonia	(6) No significant trend.	Foster *et al.* (2009)
Dessert Andes (17°S-31°S)		

Huasco basin glaciers (29°S)	(5) –0.84 m w.e./yr (2003/2004–2007/2008)	Nicholson *et al.* (2009); Rabatel *et al.* (2011); Gascoin *et al.* (2011)
Central Andes (31°S-36°S)		
Piloto/Las Cuevas (32°S)	(5) - 10.50 m w.e. (last 24 yrs)	Leiva *et al.* (2007)
Aconcagua basin glaciers (33°S)	(3) -20% (last 48 years); (2) -14% (1955-2006). (8) Significant decrease in Aconcagua basin streamflow	Nicholson *et al.* (2009); Bown *et al.* (2008); Pellicciotti *et al.* (2007)
Central Andes glaciers (33–36 °S)	(3) -3% (since 1955); (4) –50/–9my^{-1} (during 20th C); (5) -0.76/-0.56 m/y (during 20th C)	Le Quesne *et al.* (2009)
ELA across central Andes	(1) +122 ± 8 m (winter) and 200 ± 6 m (summer) (1975 and 2001)	Carrasco *et al.* (2005)
Snowpack (30 °S -37°S)	(6) Positive, though nonsignificant, linear trend (1951–2005); (8) Mendoza river streamflow. Possible link to rising temperatures and snowpack/glacier effects. Not conclusive; (8) Increase in high and low flows possibly associated with increase in temperature and effects on snowpack	Masiokas *et al.* (2006) Vich *et al.* (2007) Vicuña *et al.* (2013)
Morenas coloradas rock glacier (32-33°S)	(7) Significant change in active layer possibly associated with warming processes.	Trombotto and Borzotta (2009)
Cryosphere in the Andes of Santiago (33.5°S.)	(5) Expansion of thermokarst depressions	Bodin *et al.* (2010)
Basins (28-47 °S)	(8) Not significant increase in February runoff possible increase of glacier melt (1950–2007).	Casassa *et al.* (2009)
Basins (30-40 °S)	(8) Significant negative timing trend (CT date shifting towards earlier in the year) for 23 out of the 40 analyzed series.	Cortés *et al.* (2011)
Patagonian Andes (36°S-55°S)		
Streamflow from basins (28-47 °S)	(8) Not significant increase in February run-off trends that might suggest an increase of glacier melt in the Andes (1950–2007).	Casassa *et al.* (2009)
NW Patagonia (38°-45°S)	(4) Recession of 6 glaciers based on areal photograph analysis.	Masiokas *et al.* (2008)
Casa Pangue glacier (41°S)	(5) –2.3±0.6 m/y (1961-1998); (4) –3.6±0.6 m/y (1981-1998)	Bown and Rivera (2007)
Manso Glacier (41°S)	(8) Reduction in discharge associated with reduction in melt and precipitation	Pasquini *et al.* (2013)
North Patagonian Icefield (NPI)	(8) Glacial lake outburst flood (GLOF) possible response to retreat of Calafate glacier (20th C)	Harrison *et al.* (2006)
Southern Patagonia Icefield (SPI)	(4) Larger retreating rates observed on the west side coinciding with lower elevations of the ELAs	Barcaza *et al.* (2009)
NPI, SPI, Cordillera Darwin Icefield	(4) 5.7-12.2 km (1945-2005)	Lopez *et al.* (2010)
Gran Campo Nevado (GCN) (53 °S)	(5) Slow retreat from Late LIA. Acceleration started 60 years ago	Strelin and Iturraspe (2007)
	(5) -2.8% of glacier length per decade (1942-2002); (3) -2.4% per decade (1942-2002)	Schneider *et al.* (2007)
Cordón Martial glaciers (54 °S)	(5) -1.6 m/year or -27.9 ± 11 km3/year (2002-2006)	Chen *et al.* (2007)
Proglacial lakes (40-50°S)	(8) Summertime negative trend on lakes indicating that melt water is decreasing	Pasquini *et al.* (2008)

Notes: [a] Variable coding: (1) Increase in Equilibrium line altitude (ELA); (2) Atmospheric warming revealed by englacial temperature measured at high elevation; (3) Area reduction; (4) Frontal retreat; (5) Volume (water equivalent) reduction; (6) Snow cover; (7) Rock glaciers; (8) Runoff change;

Table 27-4: Synthesis of projected climate change impacts on hydrologic related variables in CA and SA basins and major glaciers.

Notes: [a] Variable coding: (1) Runoff/Discharge; (2) Demand; (3) Recharge; (4) Glaciar change; (5) Unmet demand/water availability

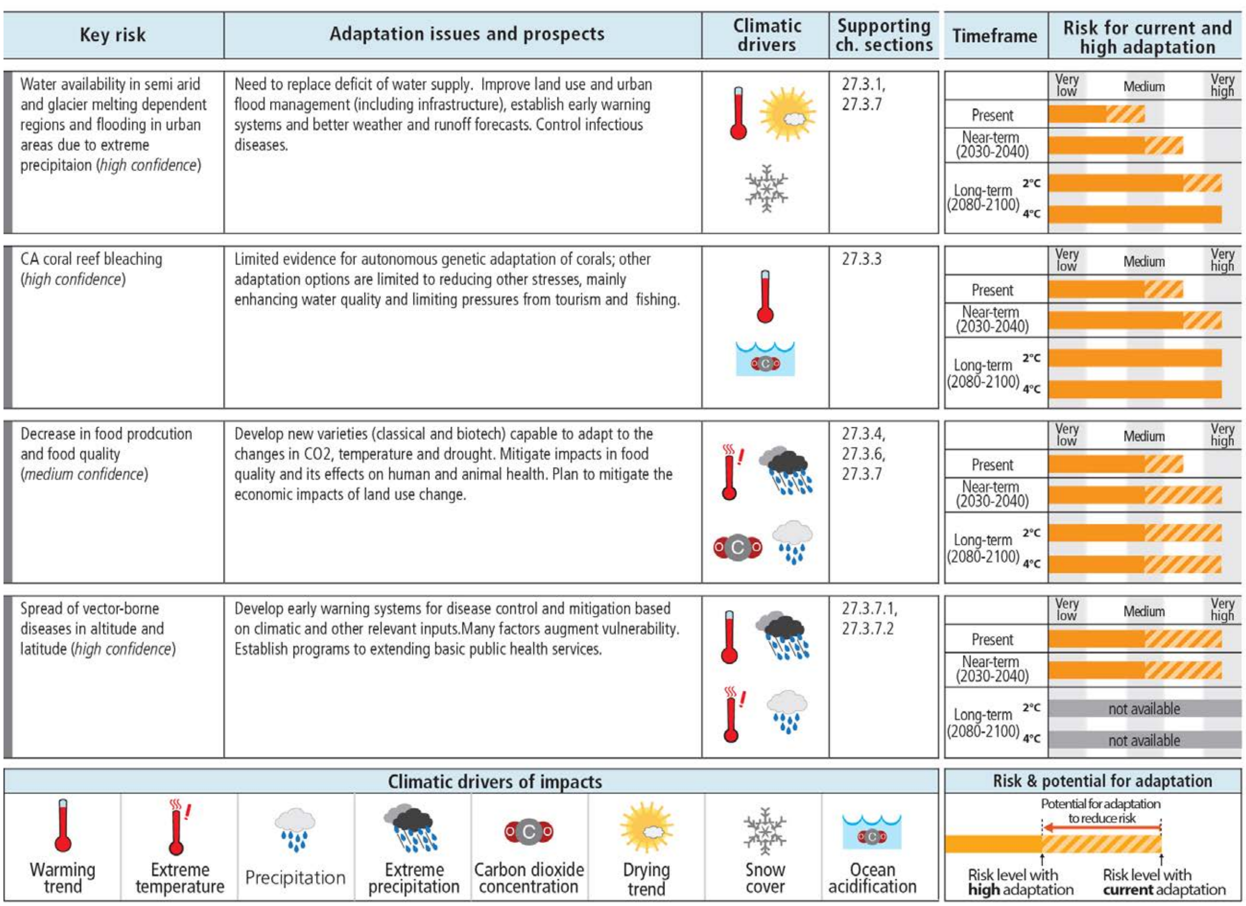
Table 27-7: Cases of government-funded PES schemes in CA and SA.

Countries	Level	Start	Name	Benefits	References
Brazil	Sub-national (Amazonas state)	2007	*Bolsa Floresta*	By 2008, 2700 traditional and indigenous families already benefitted: financial compensation and health assistance in exchange for zero deforestation in primary forests.	Viana (2008)
Costa Rica	National	1997	FONAFIFO fund	PES is a strong incentive for reforestation and, for agroforestry ecosystems alone, over 7,000 contracts have been set since 2003, and nearly 2 million trees were planted.	Montagnini and Finney (2011)
Ecuador	National	2008	*Socio-Bosque*	By 2010, the program already included more than half a million hectares of natural ecosystems protected and has over 60,000 beneficiaries.	De Koning *et al.* (2011)
Guatemala	National	1997	Programa de Incentivos Forestales, PINFOR	By 2009, the program included 4,174 beneficiaries who planted 94,151 hectares of forest. In addition, 155,790 hectares of natural forest were under protection with monetary incentives.	Instituto Nacional de Estadística (2011)

Table 27-8: Key risks from climate change and the potential for risk reduction through mitigation and adaptation.



Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
Water availability in semi arid and glacier melting dependent regions and flooding in urban areas due to extreme precipitaion (*high confidence*)	Need to replace deficit of water supply. Improve land use and urban flood management (including infrastructure), establish early warning systems and better weather and runoff forecasts. Control infectious diseases.		27.3.1, 27.3.7	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high
CA coral reef bleaching (*high confidence*)	Limited evidence for autonomous genetic adaptation of corals; other adaptation options are limited to reducing other stresses, mainly enhancing water quality and limiting pressures from tourism and fishing.		27.3.3	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high
Decrease in food prodcution and food quality (*medium confidence*)	Develop new varieties (classical and biotech) capable to adapt to the changes in CO2, temperature and drought. Mitigate impacts in food quality and its effects on human and animal health. Plan to mitigate the economic impacts of land use change.		27.3.4, 27.3.6, 27.3.7	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high
Spread of vector-borne diseases in altitude and latitude (*high confidence*)	Develop early warning systems for disease control and mitigation based on climatic and other relevant inputs.Many factors augment vulnerability. Establish programs to extending basic public health services.		27.3.7.1, 27.3.7.2	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high; Long-term 2°C: not available; 4°C: not available

Climatic drivers of impacts: Warming trend; Extreme temperature; Precipitation; Extreme precipitation; Carbon dioxide concentration; Drying trend; Snow cover; Ocean acidification

Risk & potential for adaptation: Potential for adaptation to reduce risk; Risk level with **high** adaptation; Risk level with **current** adaptation

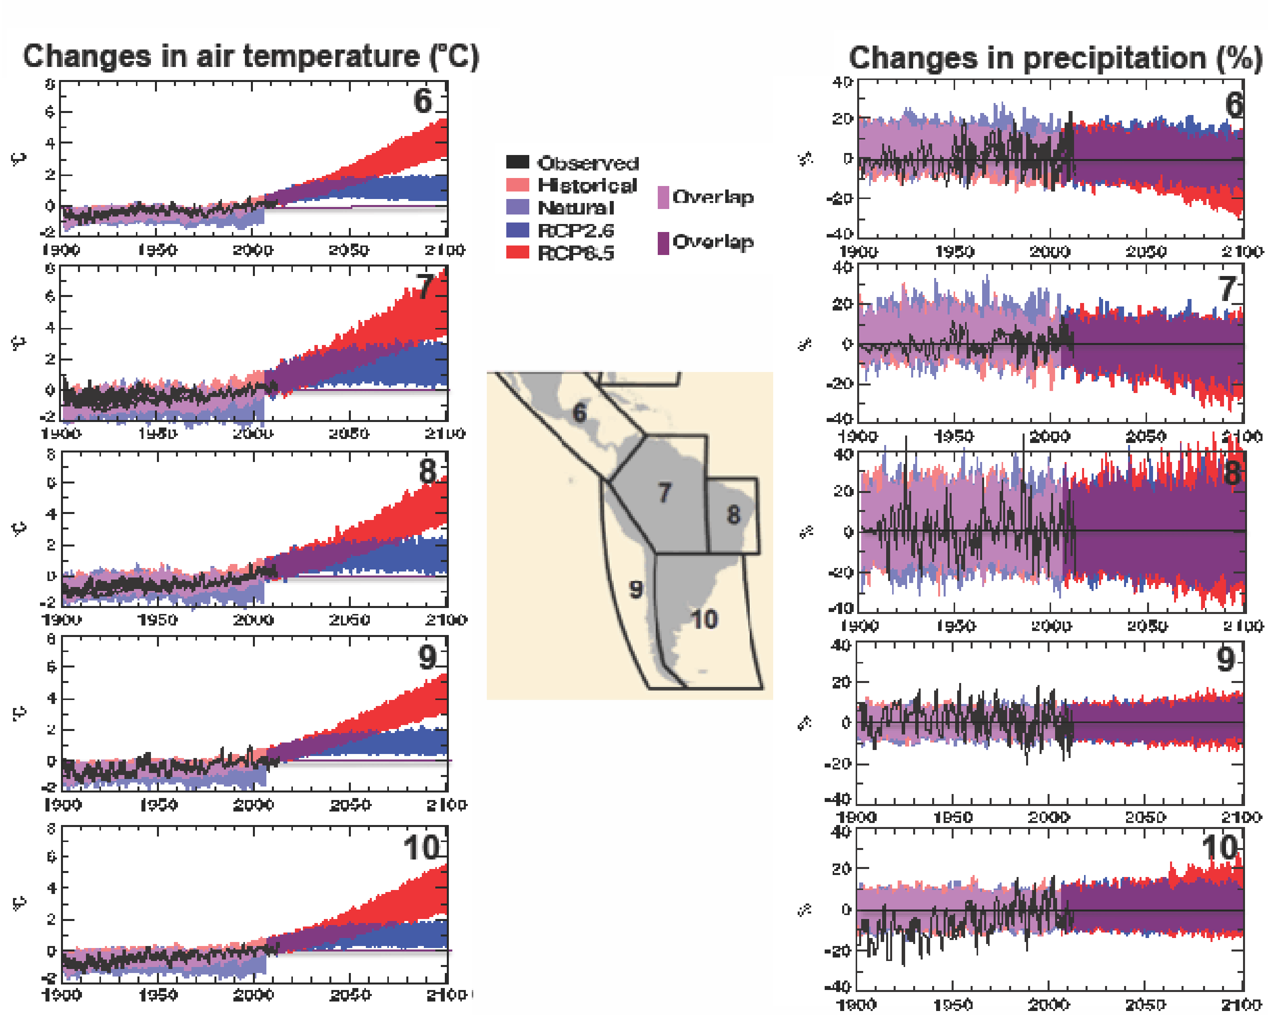


Figure 27-1: Observed and simulated variations in past and projected future annual average temperature over the Central and South American regions defined in IPCC (2012). Black lines show various estimates from observational measurements. Shading denotes the 5-95 percentile range of climate model simulations driven with "historical" changes in anthropogenic and natural drivers (63 simulations), historical changes in "natural" drivers only (34), the "RCP2.6" emissions scenario (63), and the "RCP8.5" (63). Data are anomalies from the 1986-2006 average of the individual observational data (for the observational time series) or of the corresponding historical all-forcing simulations. Further details are given in Box 21-3.
[Illustration to be redrawn to conform to IPCC publication specifications.]

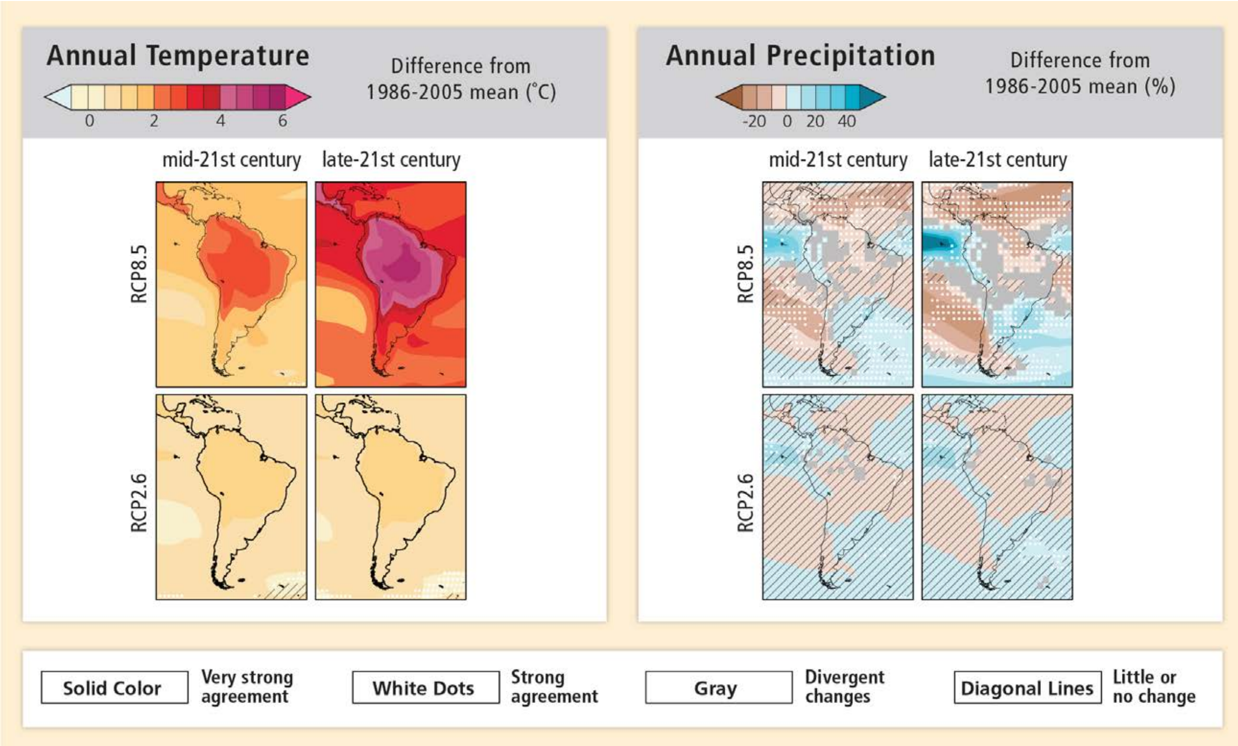

Figure 27-2: Projected changes in annual average temperature and precipitation. CMIP5 multi-model mean projections of annual average temperature changes (left panel) and average percent change in annual mean precipitation (right panel) for 2046-2065 and 2081-2100 under RCP2.6 and 8.5. Solid colors indicate areas with very strong agreement, where the multi-model mean change is greater than twice the baseline variability, and>90% of models agree on sign of change. Colors with white dots indicate areas with strong agreement, where>66% of models show change greater than the baseline variability and>66% of models agree on sign of change. Gray indicates areas with divergent changes, where>66% of models show change greater than the baseline variability, but<66% agree on sign of change. Colors with diagonal lines indicate areas with little or no change, less than the baseline variability in>66% of models. (There may be significant change at shorter timescales such as seasons, months, or days.). Analysis uses model data and methods building from WGI AR5 Figure SPM.8. See also Annex I of WGI AR5. [Boxes 21-3 and CC-RC]

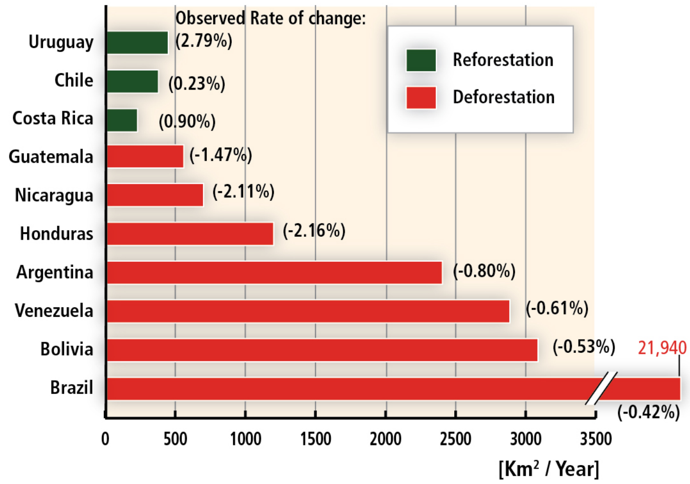

Figure 27-3: Area deforested per year for selected countries in CA and SA (2005-2010). Notice three countries listed with a positive change in forest cover (based on data from FAO, 2010).

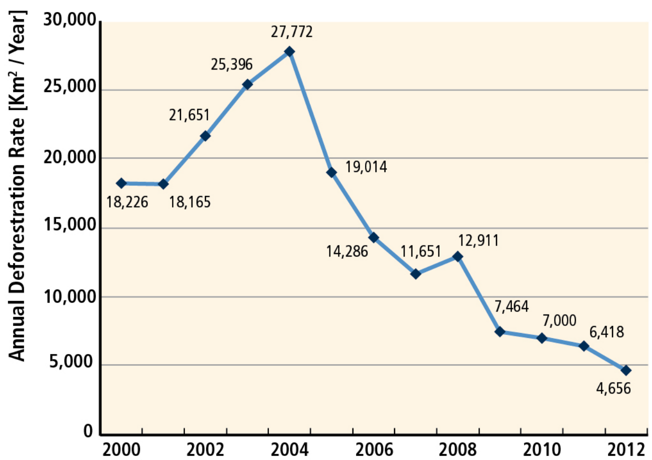

Figure 27-4: Deforestation rates in the Brazilian Amazonia (km²/year) based on measurements by the PRODES project (INPE, 2011).

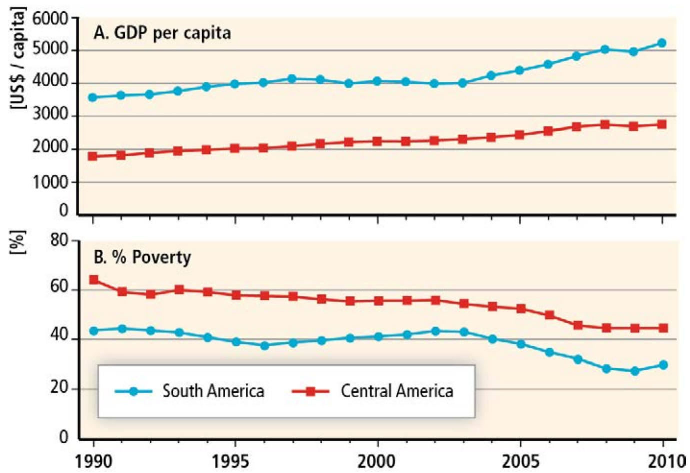

Figure 27-5: Evolution of GDP per capita and poverty (income below US$ 2 per day) from 1990-2010: CA and SA (US-Dollars per inhabitant at 2005 prices and percentages) (ECLAC on the basis of CEPALSTAT (2012) and ECLAC (2011b)).

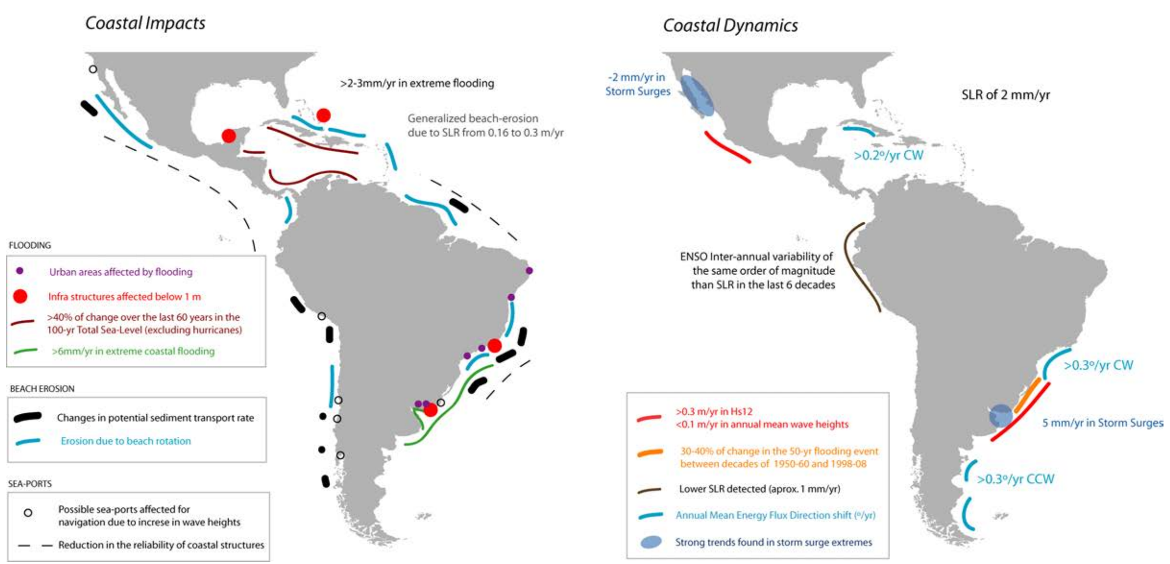

Figure 27-6: Current and predicted coastal impacts and coastal dynamics in response to climate change.

Coastal impacts - based on trends observed and projections, the figure shows how potential impacts may be distributed in the region. Three cases: a) flooding: since flooding probability increases with increasing sea-level, one may expect a higher probability of flooding in locations showing >40% of change over the last 60 years in the 100-years total sea-level (excluding hurricanes). The figure also identifies urban areas where the highest increase in flooding level has been obtained.; b) beach erosion: it increases with potential sediment transport, thus locations where changes in potential sediment transport have increased over a certain threshold have a higher probability to be eroded; c) sea-ports and reliability of coastal structures: the figure shows locations where, in the case of having a protection structure in place, there is a reduction in the reliability of the structures due to the increase in the design wave height estimates (ECLAC, 2011a).

Coastal dynamics - information based on historical time series that have been obtained by a combination of data reanalysis, available instrumental information and satellite information. Advanced statistical techniques have been used for obtaining trends including uncertainties (Izaguirre *et al.*, 2013; Losada *et al.*, 2013).

Executive Summary

Additional and stronger scientific evidence has accumulated since the AR4 that reinforces key findings made in the Fourth Assessment Report (AR4).

The impacts of climate change, and the adaptations to it, exhibit strong spatial heterogeneity in the Polar Regions because of the high diversity of social systems, bio-physical regions and associated drivers of change (*high confidence*). [28.2.2] For example, the tree line has moved northward and upward in many, but not all, Arctic areas (*high confidence*) and significant increases in tall shrubs and grasses have been observed in many places (*very high confidence*). [28.2.3.2]

Some marine species will shift their ranges in response to changing ocean and sea ice conditions in the Polar Regions (*medium confidence*)**.** The response rate and the spatial extent of the shifts will differ by species based on their vulnerability to change and their life history. [28.2.2; 28.3.2] Loss of sea ice in summer and increased ocean temperature is expected to enhance secondary pelagic production in some but not all regions of the Arctic Ocean with associated changes in the energy pathways within the marine ecosystem (*medium confidence*). These changes are expected to alter the species composition and carrying capacity with associated impacts on marine fish and shellfish populations (*medium confidence*). [28.2.2.1] Also, changes in sea ice and the physical environment to the west of the Antarctic Peninsula are altering phytoplankton stocks and productivity, and krill (*high confidence*). [28.2.2.2]

Climate change is impacting terrestrial and freshwater ecosystems in some areas of Antarctica and the Arctic. This is due to ecological effects resulting from reductions in the duration and extent of ice and snow cover and enhanced permafrost thaw (*very high confidence*), and through changes in the precipitation-evaporation balance (*medium confidence*). [28.2]

The primary concern for polar bears over the foreseeable future is the recent and projected loss of annual ice over continental shelves, decreased ice duration, and decreased ice thickness (*high confidence*). Of the two subpopulations where data are adequate for assessing abundance effects, it is *very likely* that the recorded population declines are caused by reductions in sea ice extent. [28.2.2.1.2; 28.3.2.2.2]

Rising temperatures, leading to the further thawing of permafrost and changing precipitation patterns have the potential to affect infrastructure and related services in the Arctic (*high confidence*). Particular concerns are associated with the damage of residential buildings due to thawing permafrost, including, Arctic cities; small, rural settlements; and storage facilities for hazardous materials. [28.2.4; 28.2.4.2; 28.2.5]

In addition, there is new scientific evidence that has emerged since the AR4.

The physical, biological and socio-economic impacts of climate change in the Arctic have to be seen in the context of often interconnected factors that include not only environmental changes caused by drivers other than climate change but also demography, culture and economic development. Climate change has compounded some of the existing vulnerabilities caused by these other factors (*high confidence*). [28.2.4; 28.2.5; 28.4] For example, food security for many indigenous and rural residents in the Arctic is being impacted by climate change and in combination with globalization and resource development projected to increase significantly in the future (*high confidence*). [28.2.4]

The rapid rate at which climate is changing in the Polar Regions will impact natural and social systems (*high confidence)* **and may exceed the rate at which some of their components can successfully adapt** (*low to medium confidence*). [28.2.4; 28.4] The decline of Arctic sea-ice in summer is occurring at a rate that exceeds most model projections (*high confidence*) and evidence of similarly rapid rates of change is emerging in some regions of Antarctica. [IPCC WGI Chapter 14] In the future, trends in Polar Regions of populations of marine mammals, fish and birds will be a complex response to multiple stressors and indirect effects (*high confidence*). [28.3.2] Already, accelerated rates of change in permafrost thaw, loss of coastal sea ice, sea level rise and increased weather intensity are forcing relocation of some indigenous communities in Alaska (high confidence). [28.2.4.2; 28.2.5; 28.3.4]

Shifts in the timing and magnitude of seasonal biomass production could disrupt matched phenologies in the food webs, leading to decreased survival of dependent species (*medium confidence*). If the timing of primary and secondary production is no longer matched to the timing of spawning or egg release, survival could be impacted with cascading implications to higher trophic levels. This impact would be exacerbated if shifts in timing occur rapidly (*medium confidence*). [28.2.2; 28.3.2] Climate change will increase the vulnerability of terrestrial ecosystems to invasions by non-indigenous species, the majority likely to arrive through direct human assistance (*high confidence*).

Ocean acidification has the potential to inhibit embryo development and shell formation of some zooplankton and krill in the Polar Regions with potentially far-reaching consequences to food webs in these regions (*medium confidence*). Embryos of Antarctic krill have been shown to be vulnerable to increased concentrations of CO_2 in the water (*high confidence*). As well, there is increasing evidence that pelagic mollusks (pteropods) are vulnerable to ocean acidification (*medium confidence*). [28.2.2; 28.3.2]

There is increased evidence that climate change will have large effects on Arctic communities, especially where narrowly based economies leave a smaller range of adaptive choices. [28.2.6.1; 28.4] Some commercial activities will become more profitable while others will face decline. Increased economic opportunities are expected with increased navigability in the Arctic Ocean and the expansion of some land- and freshwater-based transportation networks. [28.2.6.1.3; 28.3.4.3] The informal, subsistence-based economy will be impacted (*high confidence*). There *is high confidence* that changing sea-ice conditions will result in more difficult access for hunting marine mammals. [28.2.6.1.6] Although Arctic residents have a history of adapting to change, the complex inter-linkages between societal, economic, and political factors and climatic stresses represent unprecedented challenges for northern communities, particularly as the rate of change will be faster than the social systems can adapt (*high confidence*). [28.4; 28.4.1; 28.2.5]

Impacts on the health and well-being of Arctic residents from climate change are significant and projected to increase – especially for many indigenous peoples (*high confidence*). [28.2.4] These are expected to vary among the diverse settlements, which range from small, remote predominantly indigenous communities to large cities and industrial settlements (*high confidence*), especially those located in highly vulnerable locations along ocean and river shorelines. [28.2.4]

28.1. Introduction

Several recent climate impact assessments on Polar Regions have been undertaken, including the synthesis report on Snow, Water, Ice and Permafrost in the Arctic (AMAP, 2011), the State of the Arctic Coast 2010 (2011) reports, the Antarctic Climate and the Environment (Turner *et al.*, 2009, 2013), Arctic Resilience Interim Report 2013 (2013), and the findings of the International Polar Year (IPY) (Krupnick *et al*., 2011). These reports draw a consistent pattern of climate-driven environmental, societal and economic changes in the Polar Regions in recent decades. In this chapter, we use the scientific literature, including these reports, to consolidate the assessment of the impacts of climate change on Polar Regions from 2007, advance new scientific evidence of impacts and identify key gaps in knowledge on current and future impacts.

Previous IPCC reports define the Arctic as the area within the Arctic Circle (66ºN), and the Antarctic as the continent with surrounding Southern Ocean south of the polar front, which is generally close to 58ºS (IPCC, 2007). For the purpose of this report we use the conventional IPCC definitions as a basis, while incorporating a degree of flexibility when describing the Polar Regions in relation to particular subjects.

[INSERT FIGURE 28-1 HERE

Changes in the physical and chemical environments of the Polar Regions are detailed in IPCC WG-1 report. The Arctic has been warming since the 1980s at approximately twice the global rate demonstrating the strongest temperature changes (~ 1 °C per decade) in winter and spring, and smallest in autumn. Sea ice declined at an average rate of 13% per decade; the Arctic Ocean is projected to become nearly ice-free in summer within this century. The duration of snow cover extent and snow depth are decreasing in North-America while increasing in Eurasia. Since late 1970s permafrost temperatures have increased between 0.5 to 2 °C. In the Southern Hemisphere, the strongest rates of atmospheric warming are occurring in the western Antarctic Peninsula (WAP, between 0.2 and 0.3 °C per decade) and the islands of the Scotia Arc, where there have also been increases in oceanic temperatures and large regional decreases in winter sea ice extent and duration. Warming, although less than WAP, has also occurred in the continental margins near to Bellingshausen Sea, Prydz Bay and the Ross Sea, with areas of cooling in between. Land regions have experienced glacial recession and changes in the ice and permafrost habitats in the coastal margins. The Southern Ocean continues to warm, with increased freshening at the surface due to precipitation leading to increased stratification. In both Polar Regions, surface waters will become seasonally corrosive to aragonite within decades, with some regions being affected sooner than others (Box CC-OA, WGI AR5 Chapter 6). Observations and models indicate that the carbon cycle of the Arctic and Southern Oceans will be impacted by climate change and increased CO_2.

28.2. Observed Changes and Vulnerability under Multiple Stressors

28.2.1. Hydrology and Freshwater Ecosystems

28.2.1.1. Arctic

Arctic rivers and lakes continue to show pronounced changes to their hydrology and ecology. Previously noted increases in Eurasian Arctic river flow (1936-1999; Peterson *et al.*, 2002) could not, for a similar period (1951-2000), be attributed with certainty to precipitation changes (Milliman *et al.*, 2008) but has been, including more recent extreme increases (2007), to enhanced poleward atmospheric moisture transport (Zhang *et al.*, 2013). By contrast, decreased flow in high-latitude Canadian rivers (1964-2000; average -10%) does match that for precipitation (Déry and Wood, 2005). Recent data (1977-2007) for 19 circumpolar rivers also indicates an area-weighted average increase of +9.8% (–17.1 to 47.0%; Overeem and Syvitski, 2010) accompanied by shifts in flow timing, with May snowmelt increasing (avg. 66%) but flow in the subsequent month of peak discharge decreasing (~7%). Across the Russian Arctic, dates of spring maximum discharge have also become earlier, particularly in the most recent [1960-2001] period analyzed (average -5d; range for 4 regions +0.2 to -7.1 d), but no consistent trend exists for magnitude (average -1%; range +21 to -24%; Shiklomanov *et al.*, 2007). Earlier timing was most pronounced in eastern, colder continental climates where increases in air temperature have been identified as the dominant control (Tan *et al.*, 2011).

Increases have also occurred in winter low flows for many Eurasian and North American rivers (primarily late 20th century; Smith *et al.*, 2007; St. Jacques and Sauchyn, 2009*;* Walvoord and Striegl, 2007; Ye *et al.*, 2009), the key exceptions being decreases in eastern North America and unchanged flow in small basins of eastern Eurasia (Rennermalm *et al.*, 2010). Most of such studies suggest permafrost thaw (WGI, Ch.4) has increased winter flow, while others suggest increases in net winter precipitation minus evapotranspiration (Landerer *et al.*, 2010; Rawlins *et al.*, 2009a, b). Insufficient precipitation stations preclude deciphering the relative importance of these factors (WGI, Ch. 2.5.1).

The surface-water temperatures of large water bodies has warmed (1985-2009; Schneider and Hook, 2010), particularly for mid- and high latitudes of the northern hemisphere with spatial patterns generally matching those for air temperature. Where water bodies warmed more rapidly than air temperature, decreasing ice cover was suggested as enhancing radiative warming. Paleolimnological evidence indicates that highest primary productivity was associated with warm, ice-free summer conditions and the lowest with periods of perennial ice (Melles *et al.*, 2007). Increasing water temperatures affect planktonic and benthic biomass and lead to changes in species composition (Christoffersen *et al.* 2008; Heino *et al.* 2009, Jansson *et al.* 2010). Reduced ice cover with higher air temperatures and evaporation are responsible for the late 20th c – early 21st c desiccation of some Arctic ponds (Smol and Douglas, 2007).

Changes have occurred in the size and number of permafrost lakes over the last half-century (Hinkel *et al.*, 2007; Marsh *et al.*, 2009), but their patterns and rates of change are not consistent because of differing thawing states, variations in warming and effects of human activities (Hinket *et al.* 2007; Prowse and Brown, 2010a). Thawing permafrost affects the biogeochemistry of water entering lakes and rivers (Frey and McClelland, 2009; Kokelj et al., 2009) and their ecological structure and function (Lantz and Kokelj, 2008; Mesquita *et al.*, 2010; Thompson *et al.*, 2008), such as enhancing eutrophication by a shift from pelagic to benthic-dominated production (Thompson *et al.*, 2012).

The aquatic ecosystem health and biodiversity of northern deltas is dependent on combined changes in the elevation of spring river ice-jam floods and sea level (Lesack and marsh, 2007, 2010). Diminishing ice shelves (last half-century) have also caused a decline in the number of freshwater epishelf lakes that develop behind them (Veillette *et al.*, 2008; Vincent *et al.*, 2009). While such biophysical dependencies have been established, temporal trends in such river-delta and epishelf lake impacts and their linkages to changing climate remain to be quantified precisely.

An interplay of freshwater-marine conditions also affect the timing, growth, run size and distribution of several Arctic freshwater and anadromous fish. Key examples include: the timing of marine exit of Yukon River Chinook salmon (*Oncorhynchus tshawytscha;* 1961-2009) varied with air and sea temperatures and sea ice cover (Mundy and Evenson, 2011); the growth of young-of-year Arctic cisco (*Coregonus autumnalis;* 1978 – 2004) varied in response to lagged sea-ice concentration and Mackenzie River discharge, also indicating that decreased sea-ice concentration and increased river discharge enhanced marine primary production leading to more favorable foraging conditions (Von Biela *et al.* (2011); and factors that influence the water level and freshening of rivers, as well as the strength, duration and directions of prevailing coastal winds, affect survival of anadromous fishes during coastal migration and their subsequent run size (Fechhelm *et al.*, 2007).

28.2.1.2. Antarctic

Biota of Antarctic freshwater systems (lakes, ponds, short streams and seasonally wetted areas) are dominated by benthic microbial communities of cyanobacteria and green algae in a simple food web. Mosses occur in some continental lakes with higher plants absent. Planktonic ecosystems are typically depauperate and include small algae, bacteria and colourless flagellates, with few metazoans and no fish (Quesada and Velázquez, 2012). Recent compilations of single-year datasets have reinforced previous conclusions on the changing freshwater habitats in Antarctica (Verleyen *et al.*, 2012). In regions where the climate has warmed the physical impacts on aquatic ecosystems include loss of ice and perennial snow cover, increasing periods of seasonal open water, increased water column temperatures and changes in water column stratification. In some areas a negative water balance has occured due to increased temperature and changes in wind strength driving enhanced evaporation and sublimation and leading to increased salinity in lakes in recent decades (Hodgson *et al.*, 2006a). In other areas, especially glacial forelands, increased temperatures have led to greater volumes of seasonal meltwater in streams and lakes together with increased nutrient fluxes (*high confidence*). In both cases the balance between precipitation and evaporation can have detectable effects on lake ecosystems (*medium confidence*) through changes in water body volume and lake chemistry (Lyons *et al.*, 2006; Quesada *et al.*, 2006). Non-dilute lakes with a low lake depth to surface area ratio are most susceptible to inter-annual and inter-decadal variability in the water balance, as measured by changes in specific conductance (*high confidence*) (Verleyen *et al.*, 2012). Warming in the northwestern Antarctic Peninsula region has resulted in permafrost degradation in the last c. 50 yr impacting surface geomorphology and hydrology (Bockheim *et al.*, 2013) with the potential to increase soil biomass.

28.2.2. Oceanography and Marine Ecosystems

28.2.2.1. Arctic

28.2.2.1.1. Marine plankton, fish, and other invertebrates

Working Group I documents the expected physical and chemical changes that will occur in Arctic marine ecosystems (WGI AR5 Chapters 4, 6, and 11). In addition to climate change, naturally occurring interannual, decadal, and multi-decadal variations in climate will influence the Arctic Ocean and its neighboring high latitude seas (WGII Chapter 5). In recent years (2007-2012) ocean conditions in the Bering Sea have been cold (Stabeno *et al.*, 2012a), while the Barents Sea has been warm (Lind and Ingvaldsen, 2012).

In this section we build on previous reviews of observed species responses to climate (Wassman *et al*. 2011) to summarize the current evidence of the impact of physical and chemical changes in marine systems on the phenology, spatial distribution and production of Arctic marine species. For each type of response, the implications for phytoplankton, zooplankton, fish and shellfish are discussed. The implications of these changes on marine ecosystem structure and function will be the result of the synergistic effects of all three types of biological responses.

Phenological response

The timing of spring phytoplankton blooms is a function of seasonal light, hydrographic conditions, and the timing of sea ice breakup (Wassman, 2011). In addition to the open water phytoplankton bloom, potentially large ice algal blooms can form under the sea ice (Arrigo, 2012). During the period 1997-2009, a trend towards earlier phytoplankton blooms was detected in approximately 11% of the area of the Arctic Ocean (Kahru *et al.*, 2011). This advanced timing of annual phytoplankton blooms coincided with decreased sea ice concentration in early summer. Brown and Arrigo (2013) studied the timing and intensity of spring blooms in the Bering Sea from 1997-2010 and found that in northern regions, sea ice consistently retreated in late spring and was associated with ice-edge blooms, whereas, in the southern regions the timing of sea ice retreat varied, with ice-edge blooms associated with late ice retreat, and open water blooms associated with early ice retreat. Given the short time series and limited studies, there is *medium confidence* that climate variability and change has altered the timing and the duration of phytoplankton production.

The life cycles of calanoid copepods in the Arctic Ocean and Barents Sea are timed to utilize ice algal and phytoplankton blooms (Falk-Petersen *et al*. 2009; Søreide *et al.*, 2010; Darnis *et al.* 2012). Based on a synthesis of existing data, Hunt *et al.* (2011) hypothesized that in the southeastern Bering Sea, ocean conditions and the timing of sea ice retreat influences the species composition of dominant zooplankton, with lipid rich copepods being more abundant in cold years.

There is ample evidence that the timing of spawning and hatching of some fish and shellfish is aligned to match larval emergence with seasonal increases availability of prey (Gjosaeter *et al.*, 2009; Vikebø *et al*., 2010; Bouchard and Fortier, 2011; Drinkwater *et al*., 2011). These regional phenological adjustments to local conditions occurred over many generations (Ormseth and Norcross, 2009; Geffen *et al.*, 2011; Kristiansen *et al.*, 2011). There is *medium* to *high confidence* that climate induced disruptions in this synchrony can result in increased larval or juvenile mortality or changes in the condition factor of fish and shellfish species in the Arctic marine ecosystems.

Observed spatial shifts

Spatial heterogeneity in primary production has been observed (Lee *et al.*, 2010; Grebmeier, 2012). Simulation modeling studies show that spatial differences in the abundance of four species of copepod can be explained by regional differences in the duration of the growing season and temperature (Ji *et al*., 2012). Retrospective studies based on surveys from 1952-2005 in the Barents Sea revealed that changes in the species composition, abundance and distribution of euphausiids were related to climate-related changes in oceanographic conditions (Zhukova *et al.*, 2009).

Retrospective analysis of observed shifts in the spatial distribution of fish and shellfish species along latitudinal and depth gradients showed observed spatial shifts were consistent with expected responses of species to climate change (Simpson *et al.*, 2011; Poloczanska *et al*. 2013; Box CC-MB, Chapter 30). Retrospective studies from the Bering Sea, Barents Sea, and the northeast Atlantic Ocean and Icelandic waters, showed that fish shift their spatial distribution in response to climate variability (i.e. interannual, decadal or multi-decadal changes in ocean temperature; Mueter and Litzow, 2008; Sundby and Nakken, 2008; Hátún *et al.*, 2009; Valdimarsson *et al.*, 2012; Kotwicki and Lauth, 2013). There are limits to the movement potential of some species. Vulnerability assessments indicate that the movement of some sub-arctic fish and shellfish species into the Arctic Ocean may be impeded by the presence of water temperatures on the shelves that fall below their thermal tolerances (Hunt *et al.*, 2013; Hollowed *et al.*, 2013). Coupled bio-physical models have reproduced the observed spatial dynamics of some the species in the Bering and Barents Seas, and are being used to explain the role of climate variability and change on the distribution and abundance of some species (Huse and Ellingsen, 2008; Parada *et al.*, 2010). In summary, there is *medium* to *high confidence* based on observations and modeling that some fish and shellfish have shifted their distribution in response to climate impacts on the spatial distribution and volume of suitable habitat.

Observed variations in production

Seasonal patterns in light, sea ice cover, freshwater input, stratification and nutrient exchange act in concert to produce temporal cycles of ice algal and phytoplankton production in Arctic marine ecosystems (Wassmann, 2011; Perrette *et al.*, 2011; Tremblay *et al*., 2012). Satellite observations and model estimates for the period 1988–2007 showed that phytoplankton productivity increased in the Arctic Ocean in response to a downward trend in the extent of summer sea ice (Zhang *et al.*, 2010). Satellite data provided evidence of a 20% increase in annual net primary production in the Arctic Ocean between 1998 and 2009 in response to extended ice free periods (Arrigo and van Dijken, 2011). Regional trends in primary production will differ in response to the amount of open water area in summer (Arrigo and van Dijken, 2011). Other studies showed gross primary production increased with increasing air temperature in the Arctic Basin and Eurasian shelves (Slagstad *et al.*, 2011). A recent 5 year study (2004-2008) in the Canadian Basin showed that smaller phytoplankton densities were higher than larger phytoplankton densities in years when sea surface temperatures were warmer, the water column was more stratified, and nutrients were more depleted during the Arctic summer (Li *et al.*, 2009; Morán *et al.*, 2010). Additional observations will help to resolve observed differences between in-situ and satellite derived estimates of primary production (Matrai *et al.*, 2013). In conclusion, based on recent observations and modeling, there is *medium to high confidence* that primary production has increased in the Arctic Ocean in response to changes in climate and its impact on the duration and areal extent of ice free periods in summer.

Regional differences in zooplankton production have been observed. During a period of ocean warming (1984-2010), Dalpadado *et al*. (2012) observed an increase in the biomass of lipid rich euphausiids in the Barents Sea and relatively stable levels of biomass and production of *Calanus finmarchicus*. In the Bering Sea, observations over the most recent decade in the southeast Bering Sea showed *C. marshallae* were more abundant in cold years than warm years (Coyle *et al.*, 2011).

There is strong evidence that climate variability impacts the year-class strength of Arctic marine fish and shellfish through its influence on: predation risk; the quality, quantity and availability of prey; and reproductive success (Mueter *et al.*, 2007; Bakun 2010; Drinkwater *et al.*, 2010). Regional differences in the species responses to climate change will be a function of the exposure of the species to changing environmental conditions, the sensitivity of the species to these changes (Beaugrand and Kirby, 2010) and the abilities of species to adapt to changing conditions (Pörtner and Peck, 2010; Donelson *et al.*, 2011). There is *high confidence* that shifts in ocean conditions have impacted the abundance of fish and shellfish in Arctic regions. Observed trends in the abundance of commercial fish and shellfish may also be influenced by historical patterns of exploitation (Vert-pre *et al*., 2013).

28.2.2.1.2. Marine mammals, polar bear, and sea birds

Studies on responses of Arctic and subarctic marine mammals to climate change are limited and vary according to insight into their habitat requirements and trophic relationships (Laidre *et al.*, 2008). Many Arctic and subarctic marine mammals are highly specialized, have long-life spans, and are poorly adapted to rapid environmental change (Moore and Huntington, 2008), and changes may be delayed until significant sea ice loss has occurred (Freitas *et al.*, 2008; Laidre *et al.*, 2008).

Climate change effects on Arctic and subarctic marine mammal species will vary by life history, distribution, and habitat specificity (*high confidence*). Climate change will improve conditions for a few species, have minor negative effects for others, and some will suffer major negative effects (Ragen *et al.*, 2008; Laidre *et al.*, 2008). Climate change resilience will vary and some ice-obligate species should survive in regions with sufficient ice and some may adapt to ice-free conditions (Moore and Huntington, 2008). Less ice-dependent species may be more adaptable but an increase in seasonally migrant species could increase competition (Moore and Huntington, 2008).

Climate change vulnerability was associated with feeding specialization, ice dependence, and ice reliance for prey access and predator avoidance (Laidre *et al.*, 2008). There is *medium agreement* on which species' life histories are most vulnerable. Hooded seals (*Cystophora cristata)* and narwhal (*Monodon monoceros)* were identified as most at risk and ringed seals (*Pusa hispida)* and bearded seals (*Erignathus barbatus)* as least sensitive (Laidre *et al.*, 2008). Kovacs *et al.* (2010) shared concern for hooded seals and narwhal but had concerns for ringed seals and bearded seals. Narwhal may have limited ability to respond to habitat alteration (Williams *et al.* 2011). Species that spend only part of the year in the Arctic (e.g., gray whale (*Eschrichtius robustus*), killer whale (*Orcinus orca*)) may benefit from reduced ice (Moore, 2008; Laidre *et al.*, 2008; Higdon and Ferguson, 2009; Matthews *et al.*, 2011; Ferguson *et al.*, 2012). Killer whale expansion into the Arctic could cause a trophic cascade (Higdon and Ferguson, 2009) although there is *limited evidence* at this time.

There is *limited evidence* although *medium agreement* that generalists and pelagic feeding species may benefit from increased marine productivity from reduced ice while benthic feeding species near continental shelf habitats may do poorly (Bluhm and Gradinger, 2008). There is *limited evidence* but *high agreement* that dietary or habitat specialists will do poorly with reduced ice. Reduction of summer/autumn ice was the primary extrinsic factor affecting Pacific walrus (*Odobenus rosmarus)* with predictions of distribution changes, reduced calf recruitment, and longer-term predictions of high extinction probability (Cooper *et al.*, 2006; MacCracken, 2012). Summer ice retreat may make migration to such habitats energetically unprofitable for ringed seals (Freitas *et al.*, 2008). Ice loss threatens Baltic ringed seals (Kovacs and Lydersen, 2008). In Hudson Bay, earlier spring break-up and changes in snow cover over lairs have reduced ringed seal recruitment (Ferguson *et al.*, 2005). Changes in snowfall over the 21st century were projected to reduce ringed seal habitat for lairs by 70% (Hezel *et al.*, 2012). Similarly, harp seal (*Pagophilus groenlandicus)* breeding habitat was affected by changing ice conditions that could reduce pup survival (Bajzak *et al.*, 2011). While there is *limited evidence*, there are concerns that climate change may cause indirect effects on Arctic marine mammals' health (e.g., pathogen transmission, food web changes, toxic chemical exposure, shipping, and development) (Burek *et al.*, 2008).

Empirical studies provide direct insight into the mechanisms of climate change impact on polar bears (*Ursus maritimus*) but modelling allows predictive capacity (Hunter *et al.*, 2010; Amstrup *et al.*, 2010; Durner *et al.*, 2011; Castro de la Guardia *et al.*, 2013).

Polar bears are highly specialized and use annual ice over the continental shelves as their preferred habitat (Durner *et al.*, 2009; Miller *et al.*, 2012). The recent and projected loss of annual ice over continental shelves, decreased ice duration, decreased ice thickness, and habitat fragmentation is causing reduced food intake, increased energy expenditure, and increased fasting in polar bears (*high confidence*) (Stirling and Parkinson, 2006; Regehr *et al.*, 2007; Durner *et al.*, 2009; Amstrup *et al.*, 2010; Hunter *et al.*, 2010; Derocher *et al.*, 2011; Rode *et al.*, 2012; Sahanatien and Derocher, 2012; Castro de la Guardia *et al.*, 2013).

Subpopulation response varies geographically. Only 2 of the 19 subpopulations, Western Hudson Bay (Regehr *et al.*, 2007) and the Southern Beaufort Sea (Regehr *et al.*, 2010; Rode *et al.*, 2010a) have data series adequate for clear identification of abundance effects related to climate change. Many other subpopulations show characteristics associated with decline but some remain stable. Declining ice is causing lower body condition, reduced individual growth rates, lower fasting endurance, lower reproductive rates, and lower survival (*high confidence*) (Regehr *et al.*, 2007; Regehr *et al.*, 2010; Rode *et al.*, 2010a; Molnar *et al.*, 2011; Rode *et al.*, 2012). Condition is a precursor to demographic change (*very high confidence*) (Regehr *et al.*, 2010; Hunter *et al.*, 2010; Rode *et al.*, 2010a; Robinson *et al.*, 2011). The decline in the subpopulation in Western Hudson Bay by 21% between 1987 and 2004 was related to climate change (*medium confidence*) (Regehr *et al.*, 2007).

Replacement of multiyear ice by annual ice could increase polar bear habitat (*low confidence*) (Derocher *et al.*, 2004). Increasing the distance to multiyear ice and terrestrial refugia at maximal melt may result in drowning, cub mortality, and increased energetic costs (Monnett and Gleason, 2006; Durner *et al.*, 2011; Pagano *et al.*, 2012).

There is *robust evidence* of changes in sea ice conditions changing polar bear distribution including den areas (*high confidence*) (Fischbach *et al.*, 2007; Schliebe *et al.*, 2008; Gleason and Rode, 2009; Towns *et al.*, 2010; Derocher *et al.*, 2011). The number of human-bear interactions are projected to increase with warming (*high confidence*) (Stirling and Parkinson, 2006; Towns *et al.*, 2009).

Use of terrestrial resources by polar bears was suggested as adaptive (Dyck *et al.*, 2007; Dyck and Romberg, 2007; Armstrong *et al.*, 2008; Dyck *et al.*, 2008; Dyck and Kebreab, 2009; Rockwell and Gormezano, 2009; Smith *et al.*, 2010). Polar bears cannot adapt to terrestrial foods (Stirling *et al.*, 2008b; Amstrup *et al.*, 2009; Slater *et al.*, 2010; Rode *et al.*, 2010b), and will *most likely* not be able to adapt to climate change and reduced sea ice extent (*very high confidence*). Changing ice conditions are linked to cannibalism (Amstrup *et al.*, 2006), altered feeding (Cherry *et al.*, 2009), unusual hunting behaviour (Stirling *et al.*, 2008a), and diet change (Iverson *et al.*, 2006; Thiemann *et al.*, 2008) (*medium confidence*).

Upwelling or subsurface convergence areas found in frontal zones and eddies, and the marginal ice zone, are associated with high marine productivity important to Arctic seabirds (e.g. (Irons *et al.*, 2008). Long-term or permanent shifts in convergence areas and the marginal ice-edge zone induced by climate change may cause mismatch between the timing of breeding and the peak in food availability and, thus, potentially have strong negative impacts on seabird populations (Gaston *et al*., 2005; Moline *et al*., 2008; Gaston *et al*., 2009; Gremillet and Boulinier, 2009) (m*edium confidence*).

The contrasting results from the relatively few studies of impacts of climate change on Arctic seabirds, demonstrate that future impacts will be highly variable between species and between populations of the same species (*medium confidence*). Retreating sea ice and increasing SSTs have favored some species and disadvantaged others (Gaston et al. 2005; Byrd *et al*. 2008; Irons *et al*. 2008; Karnovsky *et al*. 2010; Fredriksen et al. 2013). Some species of sea birds respond to a wide range of sea surface temperatures via plasticity of their foraging behaviour, allowing them to maintain their fitness levels (Grémillet *et al*. 2012). Phenological changes and changes in productivity of some breeding colonies have been observed (Byrd *et al*. 2008; Gaston and Woo 2008; Moe *et al*. 2009). Negative trends in population size, observed over the last few decades for several species of widespread Arctic seabirds, may be related to over-harvesting and pollution as well as climate change effects (Gaston, 2011). For those species whose distribution is limited by sea ice and cold water, polar warming could be beneficial (Mehlum 2012).

A major ecosystem shift in the Northern Bering Sea starting in the mid 1990s caused by increased temperatures and reduced sea ice cover had a negative impact on benthic prey for diving birds and these populations have declined in the area (Grebmeier *et al.*, 2006). More recently, the Bering Sea has turned colder again.

28.2.2.2. Antarctica

Productivity and food web dynamics in the Southern Ocean are dominated by the extreme seasonal fluctuations of irradiance and the dynamics of sea ice, along with temperature, carbonate chemistry and vertical mixing (Massom and Stammerjohn, 2010; Boyd *et al.*, 2012; Murphy *et al*., 2012a). Moreover, there is large-scale regional variability in habitats (Grant *et al*., 2006) and their responses to climate change (WGI). Antarctic krill, *Euphausia superba* (hereafter, 'krill') is the dominant consumer, eating diatoms, and, in turn, is the main prey of fish, squid, marine mammals and seabirds. Krill is dominant from the Bellingshausen Sea east through to the Weddell Sea and the Atlantic sector of the Southern Ocean (Rogers *et al.*, 2012). In the East Indian and southwest Pacific sectors of the Southern Ocean, the krill-dominated system lies to the south of the Southern Boundary of the Antarctic Circumpolar Current (Nicol *et al.*, 2000a,b) while to the north copepods and myctophid fish are most important (Rogers *et al.*, 2012). Further west, where the Weddell Sea exerts an influence, krill are found as far north as the Subantarctic Circumpolar Current Front (Jarvis *et al.*, 2010). Where sea ice dominates for most of the year, ice-obligate species (e.g. *Euphausia crystallorophias* and *Peluragramma antarcticum*) are most important (Smith *et al.*, 2007).

Few studies were available in AR4 to document and validate the changes in these systems resulting from climate change. Those studies reported increasing abundance of benthic sponges and their predators, declining populations of krill, Adélie and emperor penguins, and Weddell seals, and a possible increase in salps, noting some regional differences in these trends. The importance of climate processes in generating these changes could not be distinguished from the indirect consequences of the recovery of whale and seal populations from past over-exploitation (Trathan and Reid, 2009; Murphy *et al*., 2012a,b).

28.2.2.2.1. Marine plankton, krill, fish, and other invertebrates

Distributions of phytoplankton and zooplankton have moved south with the frontal systems (Hinz *et al.*, 2012; Mackey *et al.*, 2012), including range expansion into the Southern Ocean from the north by the coccolithophorid, *Emiliania huxleyi* (Cubillos *et al.*, 2007), and the red-tide dinoflagellate *Noctiluca scintillans* (McLeod *et al.*, 2012) (*medium confidence*). There is *insufficient evidence* to determine whether other range shifts are occurring.

Collapsing ice shelves are altering the dynamics of benthic assemblages by exposing areas previously covered by ice shelves, allowing increased primary production and establishment of new assemblages (e.g. collapse of the Larson A/B ice shelves) (Peck *et al.*, 2009; Gutt *et al.*, 2011) (*medium confidence*). More icebergs are grounding, causing changes in local oceanography and declining productivity that consequently affects productivity of benthic assemblages (Thrush and Cummings 2011) (*low confidence)*. Iceberg scour on shallow banks is also increasing, disrupting resident benthic assemblages (Barnes and Souster 2011; Gutt *et al.*, 2011) (*medium confidence*).

Primary production is changing regionally in response to changes in sea ice, glacial melt and oceanographic features (Arrigo *et al.*, 2008; Boyd *et al.*, 2012) (*medium confidence*). Off the west Antarctic Peninsula, phytoplankton stocks and productivity have decreased north of 63°S, but increased south of 63°S (Montes-Hugo *et al.*, 2009) (WGII Chapter 6) (*high confidence*). This study (based on time-series of satellite-derived and measured chlorophyll concentrations) also indicated a change from diatom-dominated assemblages to ones dominated by smaller phytoplankton (Montes-Hugo *et al.*, 2009). The reduced productivity in the north may be tempered by increased inputs of iron through changes to ocean processes in the region (Dinniman *et al.*, 2012) (*low confidence*).

Since the 1980s, Antarctic krill densities have declined in the Scotia Sea (Atkinson *et al*., 2004), in parallel with regional declines in the extent and duration of winter sea ice (Flores *et al.*, 2012). Uncertainty remains over changes in the krill population because this decline was observed using net samples and is not reflected in acoustic abundance time series (Nicol and Brierley 2010); the observed changes in krill density may have been partly a result of changes in distribution (Murphy *et al*. 2007). Nevertheless, given its dependence on sea ice (Nicol *et al.*, 2008) the krill population may already have changed and will be subject to further alterations (*high confidence*).

The response of krill populations is probably a complex response to multiple stressors. Decreases in recruitment of post-larval krill across the Scotia Sea have been linked to declines in sea-ice extent in the Antarctic Peninsula region (Wiedenmann *et al.,* 2009) (*medium confidence*) but these declines may have been offset by increased growth arising from increased water temperature in that area (Wiedenmann *et al.*, 2008). However, near South Georgia krill productivity may have declined as a result of the increased metabolic costs of increasing temperatures (Hill *et al.,* 2013) (*low confidence*). The combined effects of changing sea ice, temperature and food have not been investigated.

28.2.2.2.2. Marine mammals and sea birds

In general, many Southern Ocean seals and seabirds exhibit strong relationships to a variety of climate indices, and many of these relationships are negative to warmer conditions (Trathan *et al.*, 2007; Barbraud *et al.*, 2012; Forcada *et al.*, 2012) (*low confidence*). Regional variations in climate change impacts on habitats and food will result in a mix of direct and indirect effects on these species. For example, Adélie penguin colonies are declining in recent decades throughout the Antarctic Peninsula while the reduction in chinstrap penguins is more regional (Lynch *et al.,* 2012) and related to reductions in krill availability (Lima and Estay, 2013). In contrast gentoo penguins are increasing in that region and expanding south (Lynch *et al.*, 2012) (*high confidence*). This may be explained by the reduced sea ice habitats and krill availability in the north resulting in a southward shift of krill predators, particularly those dependent on sea ice (Forcada *et al.,* 2012) and the replacement of these predators in the north by species that do not depend on sea ice, such as gentoo penguins and elephant seals (Costa *et al.*, 2010; Trivelpiece *et al.*, 2011; Ducklow *et al.,* 2012; Murphy *et al.,* 2013) (*low confidence*). A contrasting situation is in the Ross Sea where Adélie penguin populations have increased (Smith *et al.*, 2012). The mechanisms driving these changes are currently under review and may be more than simply sea ice (Lynch *et al.*, 2012; Melbourne-Thomas et al., 2013). For example, too much or too little sea ice may have negative effects on the demography of Adélie and emperor penguins (see Barbraud *et al.,* 2012 for review). Also, increased snow precipitation which accumulates in breeding colonies can decrease survival of chicks of Adélie penguins when accompanied by reduced food supply (Chapman *et al.,* 2011).

Changes elsewhere are less well known. Some emperor penguin colonies have decreased in recent decades (Barbraud *et al.,* 2008; Jenouvrier *et al.,* 2009) (*low confidence*) and one breeding site has been recorded as having been vacated (Trathan *et al.,* 2011). However, there is *insufficient evidence* to make a global assessment of their current trend. In the subantarctic of the Indian sector, reductions in seal and seabird populations may indicate a region-wide shift to a system with lower productivity (Weimerskirch *et al.,* 2003; Jenouvrier *et al.,* 2005a, b) (*low confidence*) but commercial fishing activities may also play a role.

Where frontal systems are shifting south, productive foraging areas also move to higher latitudes. In the Indian sector, this is thought to be causing declines in king penguin colonies on subantarctic islands (Péron *et al.,* 2010) (*low confidence*), while the shift in wind patterns may be causing changes to the demography of albatross (Weimerskirch *et al.,* 2012) (*low confidence*).

As identified in the last assessment, some species' populations may suffer as a result of fisheries while others are recoverying from past over-exploitation, either of which may confound interpretation of the response of these species and their food webs to climate change. The recovery of Antarctic fur seals on some subantarctic islands has been well documented and their populations may now be competing with krill-eating macaroni penguins (Trathan *et al.,* 2012). More recently, there has been confirmation that populations of some Antarctic whales are recovering, such as humpbacks (Nicol *et al.*, 2008; Zerbini *et al.*, 2010), suggesting that food is currently not limiting. In contrast, a number of albatross and petrel populations are declining as a result of incidental mortality in longline fisheries in southern and temperate waters where these birds forage (Croxall *et al.*, 2012).

28.2.3. Terrestrial Ecosystems

28.2.3.1. Arctic

Arctic terrestrial ecosystems have undergone dramatic changes throughout the late Pleistocene and Holocene (last 130 000 years) mainly driven by natural climate change. Significant altitudinal and latitudinal advances and retreats in tree line have been common, animal species have gone extinct, and animal populations have fluctuated significantly throughout this period e.g. (Lorenzen *et al.*, 2011; Salonen *et al.*, 2011; Mamet and Kershaw, 2012).

28.2.3.1.1. Phenology

Phenological responses attributable to warming are apparent in most Arctic terrestrial ecosystems (*medium confidence*). They vary from earlier onset and later end of season in western Arctic Russia (Zeng *et al.*, 2013), to little overall trend in plant phenology in the Swedish sub Arctic (Callaghan *et al.*, 2010), to dramatic earlier onset of phenophases in Greenland (Høye *et al*., 2007; Post *et al.*, 2009a; Callaghan *et al.*, 2011a) (Figure 28-2).

[INSERT FIGURE 28-2 HERE
Figure 28-2: Temporal change in onset of flowering (plants), median date of emergence (arthropods) and clutch initiation dates (birds) in high-Arctic Greenland. Red dots are statistically significant, blue dots are not. Source: Høye *et al.*, 2007.]

28.2.3.1.2. Vegetation

The latest assessment of changes in NDVI (Normalized Difference Vegetation Index, a proxy for plant productivity) from satellite observations between 1982 and 2012 shows that about a third of the Pan-Arctic has substantially greened, <4% browned and > 57% did not change significantly (Xu et al., 2013) (Figure 28-3). The greatest increases reported in recent years were in the North American high Arctic, along the Beaufort Sea and the east European Arctic (Zhang *et al.*, 2008; Pouliot *et al.*, 2009; Bhatt *et al.*, 2010; Forbes *et al.*, 2010; Walker *et al.*, 2011; Epstein *et al.*, 2012; Macias-Fauria *et al.*, 2012; Xu *et al.*, 2013).

[INSERT FIGURE 28-3 HERE
Figure 28-3: Significant changes ($p< 0.01$) in photosynthetically active period NDVI between 1982 and 2012. Source: Xu et al., 2013.]

The positive trends in NDVI are associated with increases in the summer warmth index (sum of the monthly-mean temperatures above freezing expressed as ^{o}C per month) that have increased on average by 5^{o}C per month for the Arctic as a whole (Xu *et al.*, 2013). However, the even greater 10 to 12^{o}C per month increase for the land adjacent to the Chukchi and Bering Seas (Figure 28-3) was associated with decreases in NDVI. On the Yamal Peninsula in Russia the pattern of NDVI is partly due to surface disturbance, such as landslide activity (Walker *et al.*, 2009). Small rodent cycles reduce NDVI in sub Arctic Sweden, by decreasing biomass and changing plant species composition (Olofsson *et al.*, 2012). The changing NDVI signal should therefore generally be interpreted with care.

In common with treeline trees and herbs, the abundance and biomass of deciduous shrubs and graminoids (grasses and grass-like plants) have increased substantially in certain parts of the Arctic tundra in recent years, but remained stable or decreased in others (*very high confidence*). Attribution for the increases and decreases in deciduous shrubs and graminoids is heterogeneous with drivers varying among different regions (*very likely*), including Arctic warming, differences in herbivory, industrial development, legacies from past land use, and changes in moisture (Post and Pedersen 2008; Olofsson *et al.*, 2009; Forbes *et al.*, 2009 and 2010; Kitti *et al.*, 2009; Kumpula *et al.*, 2011 and 2012; Myers-Smith *et al.*, 2011; Elmendorf *et al.*, 2012b;Callaghan *et al.*, 2011b and 2013: Gamon *et al.*, 2013).

Shrubs have generally expanded their ranges and/or growth over the last 20 years (Danby and Hik, 2007; Hudson and Henry, 2009; Forbes *et al.*, 2010; Hallinger *et al.*, 2010; Rundqvist *et al.*, 2011; Hedenås *et al.*, 2011; Hill and Henry, 2011; Myers-Smith *et al.*, 2011a,b; Callaghan *et al.*, 2011b; Elmendorf *et al.*, 2012a,b; Macias-Fauria *et al.*, 2012), and have varied from dramatic, i.e. 200% area increase in study plots (Rundqvist *et al.*, 2011) in sub arctic Sweden to early invasion of a fell field community on west Greenland by low shrubs (Callaghan *et al.*, 2011a).

A synthesis (61 sites: (Elmendorf *et al.*, 2012a) of experimental warming studies of up to 20 years duration in tundra sites worldwide, showed, overall, increased growth of deciduous shrubs and graminoids, decreased cover of mosses and lichens, and decreased species diversity and evenness. Elmendorf et al., (2012a) point out that the groups that increased most in abundance under simulated warming were graminoids in cold regions and primarily shrubs in warm regions of the tundra. However, strong heterogeneity in responses to the experimental warming suggested that other factors could moderate the effects of climate warming significantly like herbivory, differences in soil nutrients and pH, precipitation, winter temperatures and snow cover, and species composition and density.

Snow bed habitats have decreased in sub arctic Sweden (Björk and Molau, 2007; Hedenås *et al.*, 2011). In other plant communities, changes have been less dramatic, ranging from small increases in species richness in the south west Yukon of the Canadian sub Arctic (Danby *et al.*, 2011), through subtle changes in plant community composition in west and southeast Greenland (Daniëls and De Molenaar, 2011; Callaghan *et al.*, 2011a) to 70 year stability of a plant community on Svalbard (Prach *et al.*, 2010).

The responses to Arctic warming of lichen and bryophyte (mosses) diversity have been heterogenous, varying from consistent negative effects to significant increases in recent years (Hudson and Henry, 2009; Tømmervik *et al.*, 2009; Tømmervik *et al.*, 2012). Forbes and Kumpula (2009) recorded long-term and widespread lichen degradation in northern Finland attributed more to trampling of dry lichens by reindeer in summer than winter consumption as forage.

Palaeorecords of vegetation change indicate that the northern tree line should extend upwards and northwards during current climate warming (Callaghan *et al.*, 2005) because tree line is related to summer warmth (e.g. Harsch *et al.*, 2009). Although the tree line has moved northwards and upwards in many Arctic areas, it has not shown a general circumpolar expansion in recent decades (*high confidence*).

Model projections that suggest a displacement of between 11 and 50% of tundra by forest by 2100 (see references in Callaghan *et al.*, 2005) and shifts upslope by 2 to 6 m per year (Moen *et al.*, 2004) and northwards by 7.4–20 km per year (Kaplan and New, 2006) might be overestimating rate of tree line advance by a factor of up to 2000 (Van Bogaert *et al.*, 2011). The fastest upslope shifts of tree lines recorded during 20th century warming are 1 to 2 m per year (Shiyatov *et al.*, 2007; Kullman and Öberg, 2009) whereas the fastest so-far recorded northward-migrating tree line replaces tundra by taiga at a rate of 3–10 m per year (Kharuk *et al.*, 2006). In some areas, the location of the tree line has not changed or has changed very slowly (Payette, 2007; MacDonald *et al.*, 2008a). A global study by Harsch *et al.* (2009) showed that only 52% of 166 global tree line sites studied had advanced over the past 100 years. In many cases the tree line has even retreated (Cherosov *et al.*, 2010). At the small scale, the tree line has shown increase, decrease and stability in neighboring locations (Van Bogaert *et al.*, 2011; Lloyd *et al.*, 2011).

Evidence for densification of the forest at the sub Arctic tree line is robust and consistent within Fennoscandia (Tømmervik *et al.*, 2009; Rundqvist *et al.*, 2011; Hedenås *et al.*, 2011) and Canada (Danby and Hik, 2007). Dendroecological studies indicate enhanced conifer recruitment during the twentieth century in the northern Siberian taiga (Briffa *et al.*, 2008). Some of the changes are dramatic, such as an increase in area of mountain birch in study plots in northern Sweden by 600% between 1977/8 and 2009/10 (Rundqvist *et al.*, 2011) and a doubling of tree biomass in Finnmarksvidda in northern Norway since 1957 (Tømmervik *et al.*, 2009). However, model projections of displacement of deciduous forest by evergreen forest (Wolf *et al.*, 2008; Wramneby *et al.*, 2010) have not so far been validated.

Where the mountain birch tree line has increased in elevation and shrub (e.g. willow, dwarf birch) abundance has increased, the response can be an interaction between climate warming, herbivory pressure and earlier land use

(Olofsson *et al.*, 2009; Hofgaard *et al.*, 2010; Van Bogaert *et al.*, 2011). In Fennoscandia and Greenland, heavy grazing by large herbivores may significantly check deciduous low erect shrub (e.g. dwarf shrub and willow) growth (Post *et al.*, 2008; Kitti *et al.*, 2009; Olofsson *et al.*, 2009).

Less moisture from snow and more rain now favors broadleaf trees over conifers and mosses in some areas (Juday, 2009) while moisture deficits are reducing the growth of some northern forests (Goetz *et al.*, 2005; Verbyla, 2008; Yarie, 2008) and making them more susceptible to insect pest outbreaks (see references in (Callaghan *et al.*, 2011c). Death of trees through drought stress or insect pest activity will increase the probability of fire that will have positive feedbacks (increase warming) on the climate (Mack *et al.*, 2011).

28.2.3.1.3. Changes in animal populations

The documented collapse or dampening of population cycles of voles and lemmings over the last 20-30 years in parts of Fennoscandia and Greenland (Schmidt *et al.*, 2012), can be attributed with *high confidence* to climate change (Ims *et al.*, 2007; Gilg *et al.*, 2009; Ims *et al.*, 2011; Kausrud *et al.*, 2009). A shortening of the snow season and more thaw and/or rain events during the winter will influence on the subnivean space which provide thermal insulation, access to food, and protection from predators (Berg *et al.*, 2008; Johansson *et al.*, 2011; Kausrud et al., 2009). However, the causes of the changes in the lemming and vole cycles are still being debated as factors other than climate change may also be of importance (Brommer *et al.*, 2010; Krebs, 2011).

Climate-mediated range expansion both in altitude and latitude of insect pests, and increased survival due to higher winter temperatures, has been documented for bark beetles in North America (Robertson *et al.*, 2009) and for geometrid moths in Fennoscandia (Jepsen *et al.*, 2008; Callaghan *et al.*, 2010; Jepsen *et al.*, 2011), causing more extensive forest damage than before. Outbreaks of insect pests like geometrid moths can even reduce the strengths of CO_2 sinks in some areas (Heliasz *et al.*, 2011).

The decline in wild reindeer and caribou (both *Rangifer tarandus*) populations in some regions of about 30 percent over the last 10-15 years has been linked both to climate warming and anthropogenic landscape changes (Post et al., 2009a; Vors and Boyce 2009; Russell and Gunn 2010). Even though most of the Arctic has warmed, the decline in the populations has not been uniform. Some of the North American large, wild herds have for example declined by 75-90 percent, while other wild herds and semi-domestic herds in Fennoscandia and Russia have been stable or even increased (Gunn *et al.*, 2009; Vors and Boyce, 2009; Joly *et al.*, 2011; Forbes *et al.*, 2009; Forbes 2010; Kumpula *et al.*, 2012).

The expected and partially observed increased primary productivity of Arctic tundra may potentially increase the supply of food for Arctic ungulates. However, the overall quality of forage may decline during warming, for example if the nitrogen content of key fodder species for ungulates were to drop during warming (Turunen *et al.*, 2009; Heggberget *et al.*, 2010), while lichen biomass, an important winter fodder for reindeer, is decreasing over parts of the Arctic region. Herbivory also changes the vegetation itself in concert with the warming, further complicating the prediction of vegetation changes and their impacts on ungulate populations (van Der Wal *et al.*, 2007; Turunen *et al.*, 2009).

More frequent rain-on-snow icing events and thicker snow-packs caused by warmer winters and increased precipitation may restrict access to vegetation and may have profound negative influences on the population dynamics of Arctic ungulates (Berg *et al.*, 2008; Forchhammer *et al.*, 2008; Miller and Barry, 2009; Stien *et al.*, 2010; Hansen *et al.*, 2011; Stien *et al.*, 2012). Such events have caused heavy mortality in some semi-domestic reindeer herds and musk oxen in recent years (Grenfell and Putkonen, 2008; Forbes, 2009; Bartsch *et al.*, 2010), and have also been shown to synchronize the dynamics of a resident vertebrate community (small mammals, reindeer and Arctic fox) in Svalbard (Hansen *et al.*, 2013). In contrast, Tyler *et al.* (2008) and Tyler (2010) suggested that generally warmer winters enhance the abundance of reindeer populations.

It has been suggested that warming-induced trophic mismatches between forage availability and quality and timing of calving have a role in the decline of circumpolar reindeer and caribou populations (Post and Forchhammer, 2008; Post *et al.*, 2009a,b), although such trophic mismatch has been disputed (Griffith *et al.*, 2010).

Adjustment via phenotypic plasticity instead of adaptation by natural selection is expected to dominate vertebrate responses to rapid Arctic climate change, and many such adjustments have already been documented (Gilg *et al.*, 2012).

28.2.3.1.4. Long-term trends and event-driven changes

Long-term climate change impacts on vegetation and animal populations are accelerated when tipping points are triggered by events such as extreme weather, fire, insect pest and disease outbreaks. The impacts of winter thaw events on ecosystems are now well-documented e.g. (Bokhorst *et al.*, 2011) but studies of the severe impacts of tundra fires on vegetation and biospheric feedbacks are recent (Mack *et al.*, 2011). Results from experimental winter thaws were validated by a natural event in northern Norway and Sweden in 2007 that reduced NDVI by almost 30% over at least 1400 km^2 (Bokhorst *et al.*, 2009). Studies on relationships between climate change and plant disease are rare but Olofsson *et al.*, (2011) showed that increased snow accumulation led to a higher incidence of fungal growth on sub Arctic vegetation.

28.2.3.2. Antarctica

Antarctic terrestrial ecosystems occur in 15 biologically-distinct areas (Terauds *et al.*, 2012) with those in the maritime and sub-Antarctic islands experiencing the warmest temperatures, reduced extreme seasonality and greatest biodiversity (Convey, 2006). In the cooler conditions on the continent, species must be capable of exploiting the short periods where temperature and moisture availability are above physiological and biochemical thresholds. In many areas there is no visible vegetation, with life being limited, at the extreme, to endolithic (within rock) communities of algae, cyanobacteria, fungi, bacteria and lichens (Convey, 2006).

Few robust studies are available of biological responses to observed climatic changes in natural Antarctic terrestrial ecosystems. The rapid population expansion and local-scale colonisation by two native flowering plants (*Deschampsia antarctica* and *Colobanthus quitensis*) in maritime Antarctica (Parnikoza *et al.*, 2009) remains the only published repeat long-term monitoring study of any terrestrial vegetation or location in Antarctica. Radiocarbon dating of moss peat deposits has shown that growth rates and microbial productivity have risen rapidly on the Antarctic Peninsula since the 1960s, consistent with temperature changes, and are unprecedented in the last 150 years (Royles *et al*., 2013). In east Antarctica moss growth rates over the last 50 yrs have been linked to changes in wind speed and temperature and their influence on water availability (Clarke *et al.*, 2012). A contributing factor is that air temperatures have increased past the critical temperature at which successful sexual reproduction (seed set) can now take place, changing the dominant mode of reproduction, and increasing the potential distance for dispersal (Convey, 2011) (*low confidence*). Similar changes in the local distribution and development of typical cryptogamic vegetation of this region have been reported (Convey, 2011), including the rapid colonisation of ice free ground made available through glacial retreat and reduction in extent of previously permanent snow cover (Olech and Chwedorzewska, 2011). As these vegetation changes create new habitat, there are concurrent changes in the local distribution and abundance of the invertebrate fauna that then colonise them (*low confidence*).

28.2.4. Health and Well-Being of Arctic Residents

The warming Arctic and major changes in the cryosphere are significantly impacting the health and well-being of Arctic residents and projected to increase – especially, for many indigenous peoples. While impacts are expected to vary among the diverse settlements that range from small, remote predominantly indigenous to large cities and industrial settlements, this section focuses more on health impacts of climate change on indigenous, isolated, and rural populations because they are especially vulnerable to climate change due to a strong dependence on the environment for food, culture and way of life; their political and economic marginalization; existing social, health, poverty disparities; as well as their frequent close proximity to exposed locations along ocean, lake or river shorelines (Ford and Furgal, 2009; Galloway-McLean, 2010; Larsen *et al.*, 2010; Cochran *et al.*, 2013).

28.2.4.1. Direct Impacts of a Changing Climate on the Health of Arctic Residents

Direct impacts of climate changes on the health of Arctic residents include extreme weather events, rapidly changing weather conditions, and increasingly unsafe hunting conditions (physical/mental injuries, death, disease), temperature-related stress (limits of human survival in thermal environment, cold injuries, cold-related diseases), and UV-B radiation (immunosuppression, skin cancer, non-Hodgkin's lymphoma, cataracts) (Revich, 2008; AMAP, 2009 ; IPCC, 2012). Intense precipitation events and rapid snowmelt are expected to impact the magnitude and frequency of slumping and active layer detachment resulting in rock falls, debris flow, and avalanches (Kokelj *et al.*, 2009; Ford *et al.*, 2010). Other impacts from weather, extreme events, and natural disasters are the possibility of increasingly unpredictable, long duration and/or rapid onset of extreme weather events, storms, inundation by large storm surges, which, in turn, may create risks to safe travel or subsistence activities, loss of access to critical supplies and services to rural or isolated communities (e.g. food, fuel, telecommunications), and risk of being trapped outside one's own community (Laidre *et al.*, 2008; Parkinson, 2009; Brubaker *et al.*, 2011b). Changing river and sea ice conditions affect the safety of travel for indigenous populations especially, and inhibit access to critical hunting, herding and fishing areas (Andrachuk and Pearce, 2010; Derksen *et al.*, 2012; Huntington and Watson, 2012).

Cold exposure has been shown to increase the frequency of certain injuries (e.g. hypothermia, frostbite) or accidents, and diseases (respiratory, circulatory, cardiovascular, musculoskeletal skin) (Revich and Shaposhmikov, 2010). Studies in Northern Russia have indicated an association between low temperatures and social stress and cases of cardiomyopathy (Revich and Shaposhnikov, 2010). It is expected that winter warming in the Arctic will reduce winter mortality rates, primarily through a reduction in respiratory and cardiovascular deaths (Shaposhnikov *et al.*, 2010). Researchers project that a reduction in cold-related injuries may occur, assuming that the standard for protection against the cold is not reduced (including individual behavior-related factors) (Nayha, 2005). Conversely, studies are showing respiratory and cardio stress associated with extreme warm summer days and that rising temperatures are accompanied by increased air pollution and mortality, especially in Russian cities with large pollution sources (Revich, 2008; Revich and Shaposhnikov, 2012).

28.2.4.2. Indirect Impacts of Climate Change on the Health of Arctic Residents

Indirect effects of climate change on the health of Arctic residents include a complex set of impacts such as changes in animal and plant populations (species responses, infectious diseases), changes in the physical environment (ice and snow, permafrost), diet (food yields, availability of country food), the built environment (sanitation infrastructure, water supply system, waste systems, building structures), drinking water access, contaminants (local, long-range transported), and coastal issues (harmful algal blooms, erosion) (Maynard and Conway, 2007; Brubaker *et al.*, 2011a; Parkinson and Evengard, 2009; Chapter 11).

In addition to the climate change impacts and processes, are the complicated impacts from contaminants such as POPs (persistent organic pollutants), radioactivity, and heavy metals (e.g., mercury) which create additional and/or synergistic impacts on the overall health and well-being of all Arctic communities (Armitage *et al*., 2011; UNEP/AMAP, 2011; Teran *et al*., 2012). Ambient temperature variability and temperature gradients directly affect the volatilization, remobilization, and transport pathways of mercury and POPs in the atmosphere, ocean currents, sea ice and rivers. Transport pathways, intercompartmental distribution, bioaccumulation and transformation of environmental contaminants such as persistent organic pollutants (POPs), mercury (Hg) and radionuclides in the Arctic may consequently be affected by climate change (AMAP 2011;UNEP/AMAP 2011; Ma *et al.*, 2011; Teng *et al.*, 2012) (*high confidence*). Ma *et al.* (2011) and Hung *et al*. (2010) demonstrated that POPs are already being remobilized into the air from sinks in the Arctic region as a result of decreasing sea ice and increasing temperatures.

Contaminants and human health in the Arctic are tightly linked to the climate and Arctic ecosystems by factors such as contaminant cycling and climate (increased transport to and from the Arctic), and the related increased risks of transmission to residents through subsistence life ways (Maynard, 2006; AMAP, 2010; Armitage *et al*., 2011; UNEP/AMAP 2011; Teran *et al*., 2012). The consumption of traditional foods by indigenous peoples places these populations at the top of the Arctic food chain and through biomagnification, therefore, they may receive some of the highest exposures in the world to certain contaminants (Armitage *et al.*, 2011; UNEP/AMAP, 2011). Contaminants such as POPs are known for their adverse neurological and medical effects on humans, particularly, the developing fetus, children, women of reproductive age and the elderly, thus it is important to include contaminants as a significant part of any climate impact assessment (UNEP/AMAP, 2011).

Radioactivity in the Arctic is also a concern because there are many potential and existing radionuclide sources in some parts of the Arctic and contamination can remain for long periods of time in soils and some vegetation, creating potentially high exposures for people (AMAP, 2010). Climate changes can mobilize radionuclides throughout the Arctic environment, and also potentially impact infrastructure associated with nuclear activities by changes in permafrost, precipitation, erosion, and extreme weather events (AMAP, 2010).

Warming temperatures are enabling increased overwintering survival and distribution of new insects that sting and bite as well as many bird, animal, and insect species that can serve as disease vectors and, in turn, causing an increase in human exposure to new and emerging infectious diseases (Parkinson *et al.*, 2008; Epstein and Ferber, 2011). Examples of new and emerging diseases are tick-borne encephalitis (brain infection) in Russia and Canada (Ogden *et al.*, 2010; Tokarevich *et al.*, 2011) and Sweden (Lindgren and Gustafson, 2001), *Giardia* spp. and *Cryptosporidium* spp. infection of ringed seals (*Phoca hispida*) and bowhead whales (*Balaena mysticetus*) in the Arctic Ocean (Hughes-Hanks *et al.*, 2005). It is also expected that temperature increases will increase the incidence of zoonotic diseases as relocations of animal populations occur (Revich et al., 2012; Hueffler *et al.*, 2013).

Harmful algal blooms (HABs), whose biotoxins can be a serious health hazard to humans or animals (paralysis, death), are increasing globally and expected to increase in the Arctic, and HABS are influenced directly by climate change related factors such as temperature, winds, currents, nutrients and runoff (Portier *et al.*, 2010; Epstein and Ferber, 2011; Walsh *et al.*, 2011; Chapters 6; 11). Increasing ocean temperatures have caused an outbreak of a cholera-like disease, Vibrio parahaemolyticusin, in Alaskan oysters (McLaughlin *et al.*, 2005). In addition, warmer temperatures raise the possibility of anthrax exposure in Siberia from permafrost thawing of historic cattle burial grounds (Revich and Podolnaya, 2011).

The impacts of climate change on food security and basic nutrition are critical to human health because subsistence foods from the local environment provide Arctic residents, especially, indigenous peoples, with unique cultural and economic benefits necessary to well-being and contribute a significant proportion of daily requirements of nutrition, vitamins and essential elements to the diet (Ford and Berrang-Ford, 2009; Ford, 2009). However, climate change is already an important threat due to the decrease in predictability of weather patterns, low water levels and streams, timing of snow, ice extent and stability, impacting the opportunities for successful hunting, gathering, fishing and access to food sources and increasing the probability of accidents (Ford and Furgal, 2009; Ford et al., 2010). Populations of marine and land mammals, fish and water fowl are also being reduced or displaced, thus, reducing the traditional food supply (Gearheard *et al.*, 2006; West and Hovelsrud, 2010; Lynn *et al.*, 2013).

Traditional food preservation methods such as drying of fish and meat, fermentation, and ice cellar storage are being compromised by warming temperatures, thus further reducing food available to the community (Brubaker *et al.*, 2011b). For example, food contamination caused by thawing of permafrost "ice cellars" is occurring and increasingly wet conditions make it harder to dry food for storage (Hovelsrud *et al.*, 2011). Indigenous people increasingly have to abandon their semi-nomadic lifestyles, limiting their overall flexibility to access traditional foods from more distant locations (www.arctichealthyukon.ca). These reductions in the availability of traditional foods plus general globalization pressures are forcing indigenous communities to increasingly depend upon expensive, non-traditional and often less healthy western foods, increasing the rates of modern diseases associated with processed food and its packaging, such as cardiovascular diseases, diabetes, dental cavities, and obesity (Armitage *et al.*, 2011; Berrang-Ford *et al.*, 2011; Brubaker *et al.*, 2011b).

Climate change is beginning to threaten community and public health infrastructure, often in communities with no central water supply and treatment sources. This is especially serious in low-lying coastal Arctic communities (e.g., Shishmaref, Alaska, USA; Tuktoyaktuk, Northwest Territories, Canada) through increased river and coastal flooding and erosion, increased drought and thawing of permafrost, resulting in loss of reservoirs, damage to landfill sites, or sewage contamination (GAO, 2009; Bronen, 2011). Salt-water intrusion and bacterial contamination may also be threatening community water supplies (Parkinson *et al.*, 2008; Virginia and Yalowitz, 2012). Quantities of water available for drinking, basic hygiene and cooking are becoming limited due to damaged infrastructure, drought, and changes in hydrology (Virginia and Yalowitz, 2012). Disease incidence caused by contact with human waste may increase when flooding and damaged infrastructure spreads sewage in villages with no municipal water supply. This can result in higher rates of hospitalization for pneumonia, influenza, skin infections, and respiratory viral infections (Parkinson and Evengard, 2009; Virginia and Yalowitz, 2012). Compounding these impacts in rural areas as well as cities are respiratory and other illnesses caused by airborne pollutants (e.g., contaminants, microbes, dust, mold, pollen, smoke) (Revich, 2008; Rylander and Schilling, 2011; Revich and Shaposhnikov, 2012).

It is now well-documented that the many climate-related impacts on Arctic communities are causing significant psychological and mental distress and anxiety among residents (Portier *et al.*, 2010; Coyle and Susteren, 2012; AR5 Chapter 11; Levintova, 2010). For example, changes in the physical environment (e.g., through thawing permafrost and erosion) which may lead to forced or voluntary relocation of residents out of their villages or loss of traditional subsistence species are causing mental health impacts among indigenous and other vulnerable, isolated populations (Curtis *et al.*, 2005; Albrecht *et al.*, 2007; Coyle and Susteren, 2012; Maldonado et al, 2013). Special concern has been expressed by many communities about the unusually high and increasing numbers of suicides in the Arctic especially among indigenous youth, and efforts are under way to try to develop a thorough assessment as well as establish effective intervention efforts (Albrecht *et al.*, 2007; Portier *et al.*, 2010; USARC, 2010).

28.2.5. Indigenous Peoples and Traditional Knowledge

Indigenous populations in the Arctic – the original Native inhabitants of the region – are considered especially vulnerable to climate change, due to their close relationship with the environment and its natural resources for physical, social, and cultural well-being (Nuttall *et al.*, 2005; Parkinson, 2009; Cochran *et al.*, 2013). Arctic indigenous peoples are estimated to number between 400,000 and 1.3 million (Bogoyavlensky and Siggner, 2004; Galloway-McLean, 2010). According to the 2010 census data, there are 68,3 thousand indigenous people living in the Russian Arctic. These Arctic residents depend heavily on the region's terrestrial, marine and freshwater renewable resources, including fish, mammals, birds, and plants; however, the ability of indigenous peoples to maintain traditional livelihoods such as hunting, harvesting, and herding is increasingly being threatened by the unprecedented rate of climate change (Nakashima *et al.*, 2012; Cochran *et al.*, 2013). In habitats across the Arctic, climate changes are affecting these livelihoods through decreased sea ice thickness and extent, less predictable weather, severe storms, sea level rise, changing seasonal melt/freeze-up of rivers and lakes, changes in snow type and timing, increasing shrub growth, permafrost thaw, and storm-related erosion which, in turn, are causing such severe loss of land in some regions that a number of Alaskan coastal villages are having to relocate entire communities (Oskal, 2008; Mahoney *et al.*, 2009; Forbes and Stammler, 2009; Bartsch *et al.*, 2010; Weatherhead *et al.*, 2010; Brubaker *et al.*, 2011b; Bronen, 2011; Bongo *et al.*, 2012; Eira *et al.*, 2012; McNeeley, 2012; Huntington and Watson, 2012; Maldonado *et al.*, 2013). In addressing these climate impacts, indigenous communities must at the same time consider multiple other stressors such as resource development (oil and gas, mining), pollution, changes in land use policies, changing forms of governance, and the prevalence in many indigenous communities of poverty, marginalization, and resulting health disparities (Abryutina, 2009; Reinert et al., 2009; Magga et al., 2011; Nakashima *et al.*, 2012 Vuojala-Magga *et al.*, 2011).

Traditional knowledge is the historical knowledge of indigenous peoples accumulated over many generations and it is increasingly emerging as an important knowledge base for more comprehensively addressing the impacts of environmental and other changes as well as development of appropriate adaptation strategies for indigenous communities (IPCC AR4; IPCC AR5, chp 15; Oskal, 2008; Reinert *et al.*, 2008; Wildcat, 2009; Nakashima *et al.*, 2012; Magga *et al.*, 2011; Vuojala-Magga *et al.*, 2011; Vogesser et al, 2013) For example, Saami reindeer herders have specialized knowledge of dynamic snow conditions, which mediate access to forage on autumn, winter and spring reindeer rangelands (Roturier and Roue, 2009; Eira *et al.*, 2012; Vikhamar-Schuler *et al.*, 2013) and traditional governance systems for relating to natural environments (Sara, 2013). Increasingly, traditional knowledge is being combined with western scientific knowledge to develop more sustainable adaptation strategies for all communities in the changing climate.

For example, at Clyde River, Nunavut, Canada, Inuit experts and scientists both note that wind speed has increased in recent years and that wind direction changes more often over shorter periods (within a day) than it did during the past few decades (Gearheard *et al.*, 2010; Overland et al., 2012). In Norway, Sámi reindeer herders and scientists are both observing direct and indirect impacts to reindeer husbandry such as changes in snow and ice cover, forage availability and timing of river freeze-thaw patterns from increasing temperatures. (Eira *et al.*,2012). On the Yamal Peninsula in western Siberia, detailed Nenets observations and recollections of iced-over autumn and winter pastures due to rain-on-snow events have proven suitable for calibrating the satellite-based microwave sensor SeaWinds (Bartsch *et al.*, 2010) and NASA's AMSR-E sensor (Bongo *et al.*, 2012).

28.2.6. Economic Sectors

28.2.6.1. Arctic

28.2.6.1.1. Agriculture and forestry

Climate change presents benefits and costs for forestry and agriculture (Aaheim *et al.*, 2009; Hovelsrud *et al.*, 2011). In Iceland for example tree limits are found at higher altitudes than before, and productivity of many plants has increased (Björnsson *et al.*, 2011). Grain production in Iceland, has increased in the last two decades, and work on soil conservation and forestry has benefited from warming (Sigurdsson *et al.*, 2007; Björnsson *et al.*, 2011), but also the number of new insect pests on trees and shrubs has increased in the past 20 years. A strong relationship between rate of new insect pest colonisation and outbrake intensity in forests exists with changes in annual temperature during the past century (Halldórsson *et al.*, 2013). Climate change impacts on species change and fire frequency have potential impact on commercial forest harvesting activity. Vulnerability of forestry to changes that affect road conditions and thus accessibility during thawing periods has been found in Sweden (Keskitalo, 2008). A case study on Greenland found challenges for plant diseases in potatoes and grass fields, with pathogens and pests present in agricultural cropping systems, e.g. black scurf (Rhizoctonia) and common scab (Streptomyces scabies) (Neergaard *et al.*, 2009).

28.2.6.1.2. Open and freshwater fisheries

Current commercial fisheries are sharply divided between regions of high-yield and value commercial fisheries in the southern Bering Sea, Baffin Bay, the east and west Greenland Seas, the Iceland Shelf Sea, the deep Norwegian/Greenland Sea, and the Barents Seas and subsistence fisheries in the coastal regions of the Arctic Ocean. The relative absence of commercial fishing activity in the Arctic Ocean results from a combination of fisheries policy, the abundance of the resource, the lack of infrastructure for capturing and processing fish, and the difficulties in accessing fishing grounds especially during winter. In most regions, fisheries management strategies have been developed to build sustainable fisheries and rebuild overfished stocks (Froese and Proelß, 2010; Livingston *et al.*, 2011). Recently observed changes in the spatial distribution and abundance of mackerel (*Scomber scombrus*) has challenged existing international agreements for shared resources in the North Atlantic (Arnason, 2012; Astthorsson *et al.*, 2012). Although loss of sea ice in summer is allowing greater access to fisheries resources in the Arctic Ocean, some nations have prohibited commercial fishing within their EEZ until there is sufficient understanding of stock status to ensure that proposed fisheries would be managed sustainably (Wilson and Ormseth, 2009; Stram and Evans, 2009).

Several Arctic coastal sea-run fishes are targeted for subsistence and commercial use in the Arctic. Commercial transactions from fishing are typically for local markets, however, the socioeconomic and cultural importance of these fishes to Indigenous Peoples far outweighs their monetary value. Reist *et al.* (2006) and Fechhelm *et al.* (2007)

found that climate related factors that influenced the water level and freshening of rivers were related to run size of arctic cisco (*Coregonus autumnalis*). Similarly, a recent study based on Chinook salmon (*Oncorhynchus tshawytscha*) run timing for the period (1961-2009) showed that success in the fishery was dependent on the timing of the marine exit, which was tightly coupled to environmental conditions that were linked to climate (Mundy and Evenson, 2011).

28.2.6.1.3. Marine transportation

Observations and climate models indicate that in the period between 1979-1988 and 1998-2007 the number of days with ice free conditions (less than 15% ice concentration) increased by 22 days along the Northern Sea Route (NSR) in the Russian Arctic, and by 19 days in the Northwest Passage (NWP) in the Canadian Arctic, while the average duration of the navigation season in the period 1980-1999 was 45 and 35 days, respectively (Mokhow and Khon, 2008). Increased shipping associated with the opening of the NSR will lead to increased resource extraction on land and in the sea, and with two-way commodity flows between the Atlantic and Pacific. The future status of marine, terrestrial and freshwater biota may be negatively affected due to substantial coastal infrastructure to facilitate offshore developments (Meschtyb *et al.*, 2010). Also, the frequency of marine transportation along the NSR is at its highest during the most productive and vulnerable season for fish and marine mammals, which is the late spring/summer, when these resources can be found throughout the NSR area (Østreng, 2006).

28.2.6.1.4. Infrastructure

Much of the physical infrastructure in the Arctic rely on and are adapted to local sea-ice conditions, permafrost, and snow (Huntington *et al.*, 2007; Sundby and Nakken, 2008; West and Hovelsrud, 2010; Forbes, 2011; Sherman *et al.*, 2009). Damage from ice action and flooding to installations such as bridges, pipelines, drilling platforms, and hydropower poses major economic costs and risks, which are more closely linked to the design of the structure than with thawing permafrost. Current engineering practices are designed to help minimize the impacts (Prowse *et al.*, 2009). Much of the infrastructure has been built with weather conditions in mind, but remains vulnerable and inadequate to respond to environmental emergencies, natural disasters, and non-environmental accidents (NRTEE, 2009). Northern safety, security, and environmental integrity are much dependent upon transportation infrastructure. Ice as a provisioning system provides a transportation corridor and a platform for a range of activities and access to food sources in the Arctic (Eicken *et al.*, 2009).

In Northern Canada climate warming presents an additional challenge for northern development and infrastructure design. While the impacts of climate change become increasingly significant over the longer time scales, in the short term of greater significance will be the impacts associated with ground disturbance and construction (Smith and Risebrough, 2010).

Climate change impacts have increased the demand for improved communication infrastructure and related services and community infrastructure for the safety and confidence in drinking water (NRTEE, 2009). The access, treatment and distribution of drinking water is generally dependent upon a stable platform of permafrost for pond or lake retention. Several communities have reported the need for more frequent water-quality testing both municipal systems and untreated water sources to ensure its suitability for drinking (Furgal, 2008).

28.2.6.1.5. Resource exploration

The Arctic has large reserves of minerals (Lindholt, 2006; Peters *et al.*, 2011; Harsem *et al.*, 2011) and potentially large reserves of undiscovered sources of raw minerals, and oil and gas. Predicted new access to offshore energy resources is hypothesized to be a significant share of the global supply of oil and gas (Gautier *et al.*, 2009; Berkman *et al.*, 2010).The socio-economic impacts of oil and gas exploration activity may be positive or negative (Duhaime *et al.*, 2004; Huntington *et al.*, 2007; Forbes, 2008; Kumpula *et al.*, 2011; Forbes *et al.*, 2009; Harsem *et al.*, 2011).

Climatic warming is accelerating access to northern lands for development (Forbes *et al.*, 2009). Yamal in Western Siberia has approximately 90 % of Russia's gas reserves, but at the same time represents the largest area of reindeer herding in the world (Jernsletten and Klokov, 2002; Stammler, 2005; Forbes and Kumpula, 2009). Development activities to obtain these resources would shrink the grazing lands, and have been characterized as one of the major human activities in the Arctic contributing to loss of "available room for adaptation" for reindeer husbandry (Oskal, 2008; Forbes *et al.*, 2009; Nuttall *et al.*, 2005). Sharp increases in future oil and gas and other resource development in the Russian North and other Arctic regions is anticipated - along with associated infrastructure, pollution, and other by products of development – which will reduce the availability of pasturelands for reindeer and indigenous communities (Derome and Lukina, 2011; Degteva and Nellermann, 2013).

28.2.6.1.6. Informal, subsistence-based economy

Hunting, gathering, herding, and fishing for subsistence, as well as commercial fishing, all play an important role in the mixed cash-subsistence economies (Nuttall *et al.*, 2005; Poppel and Kruse, 2009; Larsen and Huskey, 2010; Crate *et al.*, 2010). In the early 1990s – initially in western Canada, and later elsewhere - indigenous communities started reporting climate change impacts (Berkes and Armitage, 2010). According to some herders, whalers and walrus hunters non-predictable conditions resulting from more frequent occurrence of unusual weather events are the main effect of recent warming (Forbes and Stammler, 2009; Ignatowski and Rosales, 2013; Forbes *et al.*, 2009).

The Inuit and Saami have expressed strong concern about the effects of climate warming on their livelihoods (Forbes and Stammler, 2009; Magga *et al.*, 2011). For the Inuit, the issues revolve around sea ice conditions, such as later freeze-up in autumn, earlier melt-out and faster sea ice retreat in spring, and thinner, less predictable ice in general (Krupnik and Jolly, 2002; Cochran *et al.*, 2013). Diminished sea ice translates into more difficult access for hunting marine mammals, and greater risk for the long-term viability of subsistence species such as polar bear populations (Laidre *et al.*, 2008). Most Inuit communities depend to some extent on marine mammals for nutritional and cultural reasons, and many benefit economically from polar bear and narwhal hunting. A reduction in these resources represents a potentially significant economic loss (Hovelsrud *et al.*, 2008). Among Fennoscandian Saami, the economic viability of reindeer herding is threatened by competition with other land users coupled with strict agricultural norms (Forbes, 2006; Magga *et al.*, 2011). Reindeer herders are concerned that more extreme weather may exacerbate this situation (Oskal, 2008).

Climate change is affecting reindeer herding communities through greater variability in snow melt/freeze, ice, weather, winds, temperatures and precipitation, which, in turn are affecting snow quality and quantity – the most critical environmental variables for reindeer sustainability (Magga *et al.*, 2011; Eira *et al.*, 2012). Increasing temperature variations in wintertime, with temperatures rising above freezing with rain, followed by refreezing ("rain-on-snow" conditions), are becoming more frequent, forming ice layers in the snow which then block the animals' access to their forage and subsequent starvation (Maynard *et al.*, 2011; Eira *et al.*, 2012; Bongo *et al.*, 2012).

28.2.6.2. Antarctica and the Southern Ocean

Economic activities in the Antarctic have been limited to fishing and tourism (IPCC WG2, 2007). Ship-based tourism is a significant industry in Antarctica but does not involve permanent shore-based infrastructure. Over recent decades, the number of tourists landing in Antarctica has risen from 7322 in 1996/1997 to 32,637 in 2007/2008 (IAATO, 2012). Visits generally coincide with the times when wildlife are breeding and are often restricted because of the presence of fast ice, sea ice or icebergs. They are expected to continue to increase, with an increasing chance of terrestrial alien species being introduced from tourism and other vectors as ice-free areas increase from climate change (Chown *et al.*, 2012). Scientific activity by a number of nations is also taking place and has the potential to impact upon local ecologies. Mineral resource activity is prohibited south of 60°S under the Protocol on Environmental Protection to the Antarctic Treaty.

Fisheries in Antarctica, primarily through fisheries for Antarctic krill, could amount to approximately 6% of existing global marine capture fisheries (Nicol *et al.*, 2011). The pattern of the krill fishery has been affected by changes in the sea ice extent around the Antarctic Peninsula where the fishery has been taking advantage of the ice-free conditions and taking more of its catch during winter in that region (*high confidence*) (Kawaguchi *et al.*, 2009). Ecosystem-based management of krill fisheries by the Commission for the Conservation of Antarctic Marine Living Resources (CCAMLR) is yet to include procedures to account for climate change impacts, although the need to do so has been identified (Trathan and Agnew, 2010; Constable, 2011).

28.3. Key Projected Impacts and Vulnerabilities

28.3.1. Hydrology and Freshwater Ecosystems

28.3.1.1. Arctic

Accompanying projected increases in high-latitude river flow (WGI Ch.12.4.5.4. and WGII Ch. 3.4.5.) are earlier spring runoff (Dankers and Middelkoop, 2008; Hay and McCabe, 2010; Pohl *et al.*, 2007), greater spring snowmelt (Adam *et al.*, 2009) and increases in spring sediment fluxes (Lewis and Lamoureux, 2010). Enhanced permafrost thaw (WGI Ch. 12.4.6.2) will continue to affect the dynamics of thermokarst lakes and related ecological effects (Section 28.2.1.1). Thawing permafrost and changes in the hydrological regime of the Arctic rivers, particularly those traversing regions affected by industrial developments, will increase the contaminant flow (Nikanorov *et al.*, 2007). Loss of glacier ice masses will alter runoff hydrographs, sediment loads, water chemistry, thermal regimes, and related channel stability, habitat and biodiversity (Milner et al., 2009; Moore et al. 2009).

Although snow, freshwater ice and permafrost affect the morphology of arctic alluvial channels, their future combined effects remain unclear (McNamara and Kane, 2009). For small permafrost streams, however, longer projected periods of flowing water will modify nutrient and organic matter processing (Greenwald *et al.*, 2008; Zarnetske *et al.*, 2008) but long-term negative impacts of increased sediment load on biological productivity could outweigh any positive effects from increased nutrient loading (Bowden *et al.*, 2008).

Changes to river-ice flooding are also projected to occur due to changes in i) hydraulic gradients for near-coastal locations because of sea-level rise, ii) streamwise air-temperature gradients, and iii) the timing and magnitude of spring snowmelt (Prowse et al. 2011). Synergistic/antagonistic effects among these factors, however, require detailed site-specific analyses for accurate projections of future conditions (Beltaos and Prowse, 2009). Reduced (increased) ice-jam flooding will have positive (negative) benefits for river-side northern communities/infrastructure but could also alter delta-riparian (Lesack and Marsh, 2010) and coastal-marine (Emmerton *et al.*, 2008) ecosystems. The quality of river water entering the marine environment will also be affected by the reduction or loss of stamukhi lakes that process river inputs (Dumas *et al.*, 2006; Galand *et al.*, 2008).

Future changes to lake-ice regimes will include: delayed freeze-up, advanced break-up, thinner ice and changes in cover composition (especially white ice in areas of enhanced winter precipitation), increased water temperature, and earlier and longer-lasting summer stratification (Dibike et al. 2011), all of which will affect a range of aquatic processes, including secondary productivity (Prowse and Brown, 2010b; Borgstrøm and Museth, 2005; Prowse *et al.*, 2007). Patterns of species richness and diversity are also projected to change with alterations to ice duration - increased open-water periods favouring the development of new trophic levels, colonization of new aquatic species assemblages (Vincent *et al.*, 2009), greater atmosphere-water gas exchange and a decrease in winter kill of resident fish with cascading effects on lower trophic levels (Balayla *et al.*, 2010). The loss of ice, however, can also decrease key habitat availability and quality (Vincent *et al.*, 2008).

Geochemical responses of Arctic lakes will also be altered. As observed for thermokarst lakes, the loss of ice cover and associated warming can greatly increase methane production (Laurion *et al.*, 2010; Metje and Frenzel, 2007). Because temperature sensitivity has a stronger control over methane production than oxidation (Duc *et al.*, 2010), elevated water temperatures will enhance methanogenesis, causing increased methane release from sediments. The net balance of these two processes operating under a broad range of future changing environmental factors, however, remains to be quantified (Laurion *et al.*, 2010; Walter *et al.*, 2007a, b; 2008).

As well as methane, increased water temperatures are projected to lead to reduced organic carbon (OC) burial. Projections, based on a range of six climate warming scenarios (Solomon *et al.*, 2007), indicates that there will be a 4-27% decrease (0.9-6.4 TgC yr-1) in OC burial across lakes of the northern boreal zone by the end of the 21st Century as compared to rates for the approximately last half-century (Gudasz *et al.*, 2010). Although these estimates assume that future organic carbon delivery will be similar to present-day conditions, even with enhanced supply from thawing permafrost, higher water temperatures will increase organic carbon mineralization and thereby lower burial efficiency. The amount of burial also depends on lake depth and mixing regimes. For non-thermally stratified shallow lakes, there will be a greater opportunity for water-sediment mixing and hence, greater carbon recycling back into the water column. By contrast, for lakes that become increasingly thermally stratified, carbon sinking below the thermocline will tend not to return to the surface until an increasing later fall turnover, thereby decreasing the probability of sediment-stored carbon being returned to the water column (Flanagan *et al.*, 2006).

Changes in ice cover, thermal regimes and stratification patterns will also affect the fate of contaminants in northern lakes. Higher water temperatures can enhance the methylation of mercury and modify food-web and energy pathways, such as through enhanced algal scavenging (a major foodweb entry pathway for mercury) resulting in increased mercury bio-availability to higher trophic levels (Carrie *et al.*, 2010; Outridge *et al.*, 2007).

28.3.1.2. Antarctica

This assessment reinforces conclusions of AR4. Increased temperatures will impact aquatic ecosystems in Antarctica (*high confidence*) but the exact nature of these impacts will vary regionally. The most vulnerable freshwater systems are in the northern Antarctic Peninsula and maritime Antarctic islands, where a small increase in temperature can have widespread ecosystem impacts because the average temperature is within a few degrees of the melting point (Quesada and Velázquez 2012) (*high confidence*). Potential impacts are expected to range from immediate catastrophic impacts such as loss of bounding ice masses causing drainage of freshwater and epishelf lakes (Smith *et al.*, 2006; Hodgson, 2011), to more gradual impacts on changes in the amount and duration of catchment ice and snow cover, accelerated glacier melting, declining volumes of precipitation falling as snow, permafrost, active layer and hydrological changes, such as water retention times (e.g. Vieira *et al.*, 2010, Quesada and Velázquez 2012, Bockheim *et al.*, 2013) (*medium confidence*).

Changes in the thickness and duration of seasonal ice cover, longer melt seasons and larger volumes of water flowing into the lakes are expected in the future (Lyons *et al.*, 2006) (*medium confidence*) but the ecological effects will vary between lakes, depending on their depth to surface area ratio, with *insufficient evidence* to fully assess future changes in these systems. Longer ice free seasons may cause physical conditions to be more favorable for primary production (Hodgson and Smol 2008) but very high irradiances experienced during summer in some systems can substantially inhibit algal blooms under ice free conditions (Tanabe *et al.*, 2007), which would favor the growth of benthic cyanobacteria species (Hodgson *et al.*, 2005). In other lakes, increases in meltwater supply may increase suspended solids and reduce light penetration and may offset the increases in the underwater light regime predicted as a result of extended ice free periods (Quesada *et al.*, 2006).

Under a warming climate an increase in microbial biomass is likely because of the increased water supply from glacial melt and warmer temperatures, and could result in further development of soils and elevated nutrient and dissolved organic carbon delivery to lakes (Velázquez *et al.*, 2013). This organic supply will promote growth and reproduction in the benthos and plankton and imbalances in population dynamics (Quesada and Velázquez, 2013). Nutrient enrichment of some freshwater habitats in the vicinity of fur seal colonies will increase because of expanding fur seal populations (Quayle *et al*. 2013) (*high confidence*).

Away from glacial forelands, increasing aridity will occur in the long-term in some areas of the continent (Hodgson *et al.*, 2006b) and on subantarctic islands (Smith Jr *et al.*, 2012) (*medium confidence*). Closed basin lakes can dry up completely causing local extinctions or retreat into cryptic or resistant life-cycle stages, as experienced in Arctic lakes (Smol and Douglas, 2007b). Other effects include dessication of moss banks due to increased evaporation and sublimation rates (Wasley *et al.*, 2006) (*medium confidence*). Studies have also shown that warming of once cold freshwater habitats in Antarctica will allow the sub- and maritime Antarctic species to re-invade and establish self-maintaining populations on the Antarctic continent, particularly where human vectors are involved (Barnes *et al.*, 2006, Hodgson *et al.*, 2006b) (*medium confidence*). For other organisms with lower dispersal capabilities there is increasing evidence of endemism, particularly in microbial groups (Vyverman *et al.*, 2010), with a possibility that surface Antarctic lakes contain endemic species that are relicts of Gondwana (cf. Convey and Stevens 2007) and that would become extinct should they be lost from these lakes as a result of climate change..

28.3.2. Oceanography and Marine Ecosystems

28.3.2.1. Ocean Acidification in the Arctic and Antarctic

Ocean acidificaiton on polar marine food webs can have considerable implications (*medium certainty*). For example, if some regions in the Arctic become understaturated with respect to aragonite (the primary structural component of the shells of some marine calcifiers such as mollusks and urchins) the growth and survial of these organisms will be impacted (WG I, Chapter 6 Figure 6.28; Chierici and Fransson, 2009; Fabry *et al.*, 2009; Yamamoto-Kawai *et al.*, 2009). In laboratory experiments, Arctic pteropods (*Limacina helicina*, a small planktonic mollusk) held under conditions consistent with projected ocean warming and acidification in the Arctic Ocean in early spring were able to extend their shells in corosive waters but dissolution marks were observed (Comeau *et al.*, 2010; Comeau *et al.*, 2012). Additional studies are needed to scale up regional impacts to assess the population level impact of ocean acidification on *Limacina helicina* and other vulnerable species (Orr *et al.*, 2009). At the current time there is insufficient data to fully assess the ecosystem consequences of acidification on pteropods because it is unclear whether other species, with a similar nutritive value, will replace pteropods.

In the Southern Ocean, foraminifera have thinner shells than in the Holocene and there is evidence for shell thickness to be related to atmospheric CO_2, supporting the hypothesis that ocean acidification will affect this abundant protozoan in this region (Moy *et al.*, 2009). Similarly, shells are thinner from sediment traps in aragonite under-saturated water (below the aragonite saturation horizon - ASH) compared to those captured above the ASH in Subantarctic waters, but there is no time series of data related to change in the ASH (Roberts *et al.*, 2011). Shell dissolution has been observed in surface waters in the Atlantic sector as a result of both upwelling and atmosperhic changes in CO_2 (Bednarsek *et al.*, 2012) (*medium confidence*). Other impacts of acidification on Southern Ocean organisms are currently uncertain, but short term negative impacts need to be considered together with an organism’s capacity to adapt in the longer term (Watson *et al.*, 2012).

Only a few studies have been conducted on commercially exploited polar species on ocean acidification. Antarctic krill embryonic development (Kawaguchi *et al.*, 2011) and post-larval krill metabolic physiology (Saba *et al.*, 2012) may be impeded by elevated CO_2 concentrations, which may negatively impact the reproductive success of krill more generally under emission scenarios used in CMIP5 (Kawaguchi *et al.*, 2013) (*medium confidence*). Long et al. (2013) examined the effects of acidification on red king crab (*Paralithodes camtschaticus*) and found animals exposed to reduced pH exhibited increased hatch duration, decreased egg yolk, increased larval size, and decreased larval survival. In contrast, Hurst *et al.*, (2012) conducted laboratory experiments at levels of elevated CO_2 predicted to be present in the Gulf of Alaska and Bering Sea in the next century and found that juvenile walleye pollock exhibited a general resiliency of growth energetics to the direct effects of CO_2 changes.

28.3.2.2. Arctic

28.3.2.2.1. Marine plankton, fish, and other invertebrates

Phenological response

Projected changes in the timing, spatial distribution and intensity of spring blooms may result in mis-matches with the timing of the emergence of Arctic grazers (Søreide *et al.*, 2010). Based on past experience, some species will adapt to local conditions by shifting key life cycle events (hatch-date, maturity schedule and reproductive timing) or diet to accommodate differences in the regional timing and availability of prey and environmental conditions (Ormseth and Norcross, 2007; Sundby and Nakken, 2008; Vikebø *et al*., 2010, Darnis *et al.*,2012). For example, loss of sea ice cover in spring is expected to change fish behavior in ice bound areas (Mundy and Evenson, *2011*). It is uncertain whether endemic animals will be able to alter key phenologies fast enough to keep pace with the projected rates of change in the Arctic Ocean.

Projected spatial shifts

Simulation studies revealed that a 2 week longer growing season and a 2 degree C increase in temperature would not be sufficient to allow expatriate species (*Calanus finmarchicus* or *C. marshallae*) to invade the Arctic Ocean (Ji *et al.,* 2012). Ellingsen *et al.,* (2008) projected future zooplankton distribution and abundance in the Barents Sea for the period 1995-2059 using a regional climate model which was forced with climate model output based on the IPCC-SRES B2 scenario. They projected that by 2059, Atlantic origin zooplankton will increase and Arctic origin zooplankton will decrease in the Barents Sea.

The literature is mixed with respect to the potential for future movement of fish and shellfish into the Arctic Ocean. Modeling studies project that marine fish stocks potentially will shift their distributions into the Arctic Ocean resulting in an increase in biodiversity in the region (Cheung *et al.,* 2009; Cheung *et al.,* 2011; Box CC-MB). However, other studies show the persistence of cold sea water temperatures on the shelf regions of the Arctic Ocean and Northern Bering Sea will restrict or retard the movement of several sub-arctic fish and shellfish species into the Arctic Ocean (Sigler *et al.,* 2011; Stabeno *et al.,* 2012b; Hunt *et al.,* 2013). In waters off the coasts of Europe there is a potential for increased fish production because of the combined effects of intrusion of Atlantic water over the relatively broader shelf regions and advective corridors for larval drift and range expansion of spawners. Huse and Ellingsen (2008) forced a spatially explicit coupled bio-physical model for the Barents Sea with future climate scenarios to project the implications of climate change on the spawning distribution of capelin (*Mallotus villosus*). Projections show that the spawning distribution of capelin will shift to the east and new spawning grounds will be colonized. A key factor governing this expansion will be the availability of pelagic prey. In the Bering Sea, there is evidence that planktivorous species like walleye pollock (*Theragra chalcogramma*) in the eastern Bering Sea will shift their distribution in response to shifts in ocean temperature (Kotwicki and Lauth, 2013). In summary, the spatial distribution of fish and shellfish in the Barents and Bering Seas will shift in response to climate change (*high confidence*)

Projected impacts on production

In the deep basins of the Arctic Ocean the number of ice free days in summer are expected to result longer productive seasons (Slagstad *et al.,* 2011, *high confidence*). Ellingsen *et al.* (2008) projected that annual primary production would increase by 2059 in the Barents Sea. Tremblay *et al.* (2012) hypothesized that longer ice free periods in summer in the Arctic Ocean could provide for more opportunities for episodic nutrient pulses that would enhance secondary production through the growing season. However, in the Arctic Ocean, these changes in primary production may be offset later in the year by increased zooplankton grazing (Olli *et al.,* 2007) or nutrient depletion due to stronger stratification and shifts in the mixed layer depth (Tremblay *et al.,* 2012; Wassmann, 2011). Therefore, there is *medium confidence* that annual phytoplankton production will increase the central Arctic Ocean.

In the few cases where future abundance of fish has been projected using climate change scenarios, species exhibited different trends related to their vulnerability. Forward extrapolation of observed responses suggests that increased summer sea surface temperatures in the Bering Sea and Barents Sea will cause a decrease in the abundance of energy rich copepods and euphausiids (Coyle *et al.*, 2011; Slagstad *et al.*, 2011). This change in prey quality is expected to lower survival of walleye pollock in the eastern Bering Sea by 2050 (Mueter *et al.*, 2011). Climate enhanced stock projection models showed time trends in cross-shelf transport of juvenile northern rock sole (*Lepidopsetta polyxystra*) to nursery areas will not be substantially altered by climate change (Wilderbuer *et al.*, 2012).

28.3.2.2.2. Marine mammals, polar bear, and seabirds

The effects of the projected reduction is sea ice extent in this century (Wang and Overland, 2011) on Arctic marine mammals and sea birds will vary spatially and temporally (Laidre *et al.*, 2008). Many ice-associated marine mammals and sea birds will be affected by ice loss with altered species distributions, migration patterns, behaviour, interspecific interactions, demography, population changes, and vulnerability to extinction but there is limited evidence of changes for most species (*high confidence*).

The polar bear population of the Southern Beaufort Sea is projected to decline by 99% by 2100 with a probability estimated at 0.80-0.94 under A1B (Hunter *et al.*, 2010). The Northern Beaufort Sea population is stable although decline is predicted with warming (Stirling *et al.*, 2011). Projected extirpation of approximately two-thirds of the world’s polar bears was predicted for mid-century under A1B (Amstrup *et al.*, 2008). Aspects of this study were criticized (Armstrong *et al.*, 2008) but refuted (Amstrup *et al.*, 2009). The two-thirds decline is consistent with other studies and has robust evidence with *medium agreement*. Projected extinction of polar bears is *unlikely*. There is *very high confidence* of subpopulation extirpation.

Several factors other than climate influence sea bird population dynamics (Regular *et al.*, 2010), and projections of changes with a continued Arctic warming are therefore highly uncertain. Pattern of change will be non-uniform and highly complex (ACIA, 2005). At present, the resolution of AOGCMs are not detailed enough to project spatial changes in mesoscale oceanographic features like frontal zones and eddies of importance to Arctic sea birds.

It is likely that the high Arctic seabird species partly or completely dependent on the sympagic ecosystem or the cold Arctic waters close to the ice-edge will be negatively impacted if the projected changes in these physical parameters occur (medium *confidence*). A general increase in SSTs, retreat of the ice cover, and earlier break up of fast ice may improve the environmental conditions and food abundance for sea bird species that have their range in the southern part of the Arctic or south of the Arctic (medium *confidence*). A poleward expansion of the range of these species is expected during a continued warming (*medium confidence*).

Several factors other than climate influence sea bird population dynamics (Regular *et al.*, 2010), and projections of changes with a continued Arctic warming are therefore highly uncertain. Pattern of change will be non-uniform and highly complex (ACIA 2005). At present, the resolution of AOGCMs are not detailed enough to project spatial changes in mesoscale oceanographic features like frontal zones and eddies of importance to Arctic sea birds.

28.3.2.3. Antarctica and the Southern Ocean

Continued rising temperatures in the Southern Ocean will result in increased metabolic costs in many ectothermic pelagic species, southward movement of temperate species and contraction of the range of polar species (*medium confidence*). Southward movement of ocean fronts and associated biota that are prey of subantarctic island-based predators, will result in energetic inefficiencies for some of those predators (Péron *et al.*, 2012; Weimerskirch *et al.*, 2012) (*low confidence*).

For Antarctic krill, *insufficient evidence* is available to predict what will happen to the circumpolar productivity of krill because of regional variability of the effects of climate change on the different factors (positive and negative) that affect krill, directly and indirectly. For example, increased metabolic and growth rates from warming may be countered by a reduced food supply and the effects of ocean acidification (28.2.2.2, 28.3.2.1). Also, areas that are already warm may result in slower growth with further warming, such as could happen in the northern Scotia Arc (Wiedenmann *et al.,* 2008; Hill *et al.,* 2013). Models of recruitment and population dynamics indicate that the biomass of krill will decline if surface warming continues, but preliminary projections incorporating a range of factors are uncertain (*low confidence*) (Murphy *et al.,* 2007, 2012b). Physiological and behavioural responses might also ameliorate impacts. For example, krill are now known to exploit the full depth of the ocean, which could provide escapes from further warming (Schmidt *et al.,* 2011) as well as refuge from air-breathing predators.

The strong dependence of species in more southern regions (e.g. southern west Antarctic Peninsula, WAP, and Ross Sea region) on sea-ice means that changes in sea-ice distribution will cause spatial shifts in the structure of ice-obligate food webs (Murphy *et al.,* 2012b) (*low confidence*). Projections show that the loss of summer sea ice from the west Antarctic Peninsula is expected to result in ice-dependent seals declining and being replaced by other seal species that are not dependent on sea ice (Siniff *et al.,* 2008, Costa *et al.,* 2010) (*low confidence*). There is *insufficient evidence* to determine whether there will be a mismatch in phenologies of different species as a result of changes in the winter sea ice season (timing and winter extent), such as might occur if the timing of sea ice melt was not at a time of optimal growing conditions for phytoplankton (Trathan and Agnew, 2010).

Reductions in krill abundance in the marine food webs around the South Atlantic islands may result in a shift in their structure towards a more fish-centred ecosystem as observed in the Indian Sector (Trathan, et al., 2007; Shreeve *et al.,* 2009; Waluda *et al.,* 2010; Trathan *et al.,* 2012; Murphy *et al.,* 2012a; Murphy *et al.,* 2012b) (*low confidence*). Also, salps have been postulated to be competitors with krill for phytoplankton around the Antarctic Peninsula when oceanic conditions displace shelf and near-shelf waters during times of low sea ice (Ducklow *et al.,* 2012). In the absence of krill, longer food chains have lower trophic efficiency (Murphy *et al.,* 2012; Muprhy *et al.,* 2013) and the long-term implications of this for higher trophic levels are unknown.

Coastal environments will be impacted by the dynamics of fast ice, ice shelves and glacier tongues. These factors will positively affect local primary production and food web dynamics (Peck *et al.,* 2009) but negatively affect benthic communities (Barnes and Souster, 2011) (*low confidence*). Projections of the response of emperor penguins and Southern Ocean seabirds based on AR4 model outputs for sea ice and temperature in east Antarctica indicate that general declines in these populations are to be expected if sea ice habitats decline in the future (Barbraud *et al.,* 2011; Jenouvrier *et al.,* 2012) (*low confidence*). However, these responses are also expected to be regionally specific because of the regional differences in expectations of change in the ice habitats (*high confidence*). Additional studies at other sites are needed to improve confidence levels of predictions.

28.3.3. Terrestrial Environment and Related Ecosystems

28.3.3.1. Arctic

The boreal forest is generally projected by models to move northward under a warming climate, that will displace between 11% and 50% of the tundra within 100 years (Callaghan *et al.,* 2005; Wolf *et al.,* 2008; Tchebakova *et al.,* 2009; Wramneby *et al.,* 2010 in a pattern similar to that which occurred during the early Holocene climatic warming (*high confidence*). Pearson *et al.* (2013) projected that at least half of vegetated Arctic areas will shift to a different physiognomic class, and woody cover will increase by as much as 52%, in line with what has been occurring in northwest Eurasia (Macias-Fauria et al. 2012).

Dynamic vegetation models applied to Europe and the Barents Region project a general increase in net annual primary production by climate warming and CO_2 fertilization (Wolf *et al.,* 2008; Wramneby *et al.,* 2010; Anisimov *et al.,* 2011). Boreal needle-leaved evergreen coniferous forest replaces tundra and expands into the mountain areas of Fennoscandia, but this advance may be delayed or prevented in regions already occupied by clonal deciduous shrubs whose *in situ* growth has increased significantly in recent decades (Macias-Fauria et al. 2012).

In contrast to these expected results, shrubs, currently expanding in area in many Arctic locations, were modelled to decrease in extent over the next 100 years after an initial increase (Wolf *et al.,* 2008). Also counter-intuitively, tundra areas increased in the projections. This was a result of changes at the highest latitudes that opened land for colonisation at a rate exceeding displacement of tundra by shrubs in the south.

Several studies have calculated the magnitude of the effects of vegetation change in the Arctic on negative feedbacks of CO_2 sequestration and increased evapo-transpiration and the positive feedback of decreased albedo (Swann *et al.,*2010; Wramneby *et al.,* 2010; Wolf et al., 2010; Pearson *et al.,* 2013). It is *likely* that vegetation changes will result in an overall positive feedback on the climate.

Recent changes and results of climate change simulation experiments in the field have shown that there are considerable uncertainties in the projected rates of change e.g. (Van Bogaert *et al.* 2010). Furthermore, the models do not yet include vertebrate and invertebrate herbivory, extreme events such as tundra fire and extreme winter warming damage or changes in land use that either reduce the rate of vegetation change or open up niches for rapid change. Projections suggest increases in the ranges of the autumn and winter moths that have outbreaks in populations resulting in the defoliation of birch forest (Jepsen *et al.,* 2008 and 2011), and a general increase in the "background" (non-outbreak) invertebrate herbivores (Wolf *et al.,* 2008).

Animal terrestrial biodiversity is generally projected to increase in the Arctic during warming by immigration of new species from the south, vegetation changes, and indirectly by introduction of invasive species caused by increased human activities and increased survival of such species (*high confidence*) (Post *et al.,* 2009; Gilg *et al.,* 2012; CAFF 2013). Many native Arctic species will *most likely* be increasingly threatened during this century.

28.3.3.2. Antarctica

Projected effects of climate change on Antarctic terrestrial species are limited to knowledge of their ecophysiological tolerances to changes in air temperature, wind speed, precipitation (rain and snowfall), permafrost thaw and exposure of new habitat through glacial/ice retreat. The climate is expected to become more tolerable to a number of species, leading to increases in biomass and extent of existing ecological communities.

The frequency with which new potential colonising plant and animal species arrive in Antarctica (particularly the Antarctic Peninsula region) from lower latitudes, and the subsequent probability of their successful establishment will increase with regional climate warming and associated environmental changes (Chown *et al.,* 2012) (*high confidence*). Human-assisted transfers of biota may be more important by two orders of magnitude than natural introductions (Frenot *et al.,* 2005) as the transfer is faster and avoids extreme environments such as altitude or oceans (Barnes *et al.,* 2006). The potential for anthropogenic introduction of non-indigenous species to Antarctic terrestrial areas, which could have devastating consequences to the local biodiversity, will increase (Convey *et al.,* 2009; Convey, 2011, Hughes and Convey, 2010; Braun *et al.,* 2012) (*high confidence*). At present, established non-indigenous species in the sub- and maritime Antarctic are very restricted in their distributions (Frenot *et al.,* 2005). Climate change could result in a greater rate of spread of invasive species through colonisation of areas exposed by glacial retreat, as has occurred at South Georgia (Cook *et al.,* 2010) and in the maritime Antarctic (Olech and Chwedorzewska 2011). Biosecurity measures may be needed to help control dispersal of established non-indigenous species to new locations, particularly given the expected increase in human activities in terrestrial areas (Hughes and Convey, 2010; Convey *et al.,* 2011). An important gap in understanding is the degree to which climate change may facilitate some established but localised alien species to become invasive and widespread (Frenot *et al.,* 2005; Convey 2010; Hughes and Convey 2010; Cowan *et al.,* 2011), which has been shown for the sub-Antarctic (Chown *et al.,* 2012).

Overall, the likely impacts of existing and new non-indigenous species on the native terrestrial ecosystems of Antarctica and the sub-Antarctic islands, along with the continued increased presence of Antarctic fur seals are likely to have far greater importance over the timescale under consideration than are those attributable to climate change itself (Turner *et al.,* 2009; Convey and Lebouvier, 2009; Convey, 2010).

28.3.4. Economic Sectors

Projections of economic costs of climate change impacts for different economic sectors in the Arctic are limited, but current assessments suggest that there will be both benefits and costs (Forbes, 2011; AMAP, 2011). Non-Arctic actors are likely to receive most of the benefits from increased shipping and commercial development of renewable and non-renewable resources, while indigenous peoples and local Arctic communities will have a harder time maintaining their way of life (Hovelsrud *et al.,* 2011).

Contributing to the complexity of measuring the future economic effects of climate change is the uncertainty in future predictions and the rapid speed of change, which are linked with the uncertainty of the technological and ecological effects of such change (NorAcia, 2010). Communities within the same eco-zone may experience different effects from identical climate-related events because of marked local variations in site, situation, culture and economy (Clark *et al.,* 2008).

Economic cost estimates have been made for the case of the Alaskan economy, for example, which suggest that a heavy reliance on climate-sensitive businesses such as tourism, forestry, and fisheries, renders the economy vulnerable to climate change, and that Alaska Native peoples, reliant on the biodiversity of the Alaskan ecosystem, are being affected disproportionately (Epstein and Ferber, 2011). Some Alaskan villages such as Shishmaref, Kivalina, and Newtok have already lost critical infrastructure and services and are becoming unlivable due to storm damage and coastal erosion but the high costs and limitations of government mechanisms are significant barriers to the actual relocation of these communities (Bronen, 2011; Cochran *et al.*, 2013; Maldonado *et al.*, 2013).

28.3.4.1. Fisheries

Climate change will impact the spatial distribution and catch of some open ocean fisheries in the Barents and Bering Seas (*high certainty*). The future of commercial fisheries in Arctic Ocean is uncertain. There is strong evidence and considerable data showing links between climate driven shifts in ocean conditions and shifts in the spatial distribution and abundance of commercial species in the Bering and Barents Seas (Section 28.3.2.2.1). In limited cases, coupled bio-physical models or climate enhanced stock projection models have been used to predict future commercial yield or shifts in fishing locations. However, these predictions are uncertain (Huse and Ellingsen, 2008; Ianelli *et al.,* 2011; Wilderbuer *et al.* 2012). Cheung *et al.* (2011) used projections from an earth system model to estimate shifts in bio-climatic windows that included climate change effects on biogeochemistry (oxygen and acidity) and primary production to project future catch potential of 120 demersal fish and invertebrates. Results from their model suggested that the catch potential will increase in the Barents and Greenland Seas and regions > 70^o north latitude (Cheung *et al.,* 2011). In contrast, vulnerability analysis suggests that only a few species are expected to be abundant enough to support viable fisheries in the Arctic Ocean (Hollowed *et al.*, 2013). Potential fisheries for snow crab on shelf areas of the Arctic Ocean may be limited by the associated impacts of ocean acidification. If fisheries develop in the Arctic Ocean, adoption of sustainable strategies for management will be a high priority (Molenaar, 2009). The moratorium on fishing in the U.S. portion of the Chukchi and Beaufort Seas would prevent fishing until sufficient data become available to manage the stock sustainably (Wilson and Ormseth, 2009).

Predicting of how harvesters will respond to changing economic, institutional and environmental conditions under climate change is difficult. Current techniques, track fishers choices based on revenues and costs associated with targeting a species in a given time and area with a particular gear given projected changes in the abundance and spatial distribution of target species (Haynie and Pfeiffer, 2012). However, estimates of future revenues and costs will depend, in part, on future demand for fish, global fish markets and trends in aquaculture practices (Merino *et al.,* 2012; Rice and Garcia, 2011).

28.3.4.2. Forestry and Farming

Climate change is likely to have positive impacts for agriculture, including extended growing season (Grønlund, 2009; Falloon and Betts, 2009; Tholstrup and Rasmussen, 2009), although variations across regions are expected (Hovelsrud *et al.*, 2011), and the importance of impacts to the Arctic economy will likely remain minor (Eskeland and Flottorp, 2006). Potential positive effects of climatic warming for forestry include decreased risk of snow damage. Kilpelainen *et al.* (2010) estimate a 50% decrease in snow damage in Finland towards the end of the century. A warmer climate is likely to impact access conditions and plant diseases for forestry and farming. Grønlund (2009) found in the case of Northern Norway – where about half of the arable land area is covered by forest and 40% by marshland – that the potential harnessing of arable land for farming will be at the cost of forestry production, or dried-up marshlands, which may contribute to more greenhouse emissions. Larger field areas may contribute to land erosion through rainfall and predicted unstable winters, and may increase conditions for plant diseases and fungal infections (Grønlund, 2009). If the winter season continues to shorten due to climate change (Xu *et al.*, 2013), accessibility to logging sites will be negatively affected. Accessibility is higher when frozen ground makes transportation possible in sensitive locations or areas that lack road. If weather changes occur when logging has taken place, sanding of roads may be necessary which carries significant economic costs. Impact on carrying capacity of ground or road accessibility will thus affect forestry economically. Challenges may include limited storage space for wood (Keskitalo, 2008).

28.3.4.3. Infrastructure, Transportation, and Terrestrial Resources

Rising temperatures and changing precipitation patterns have the potential to affect all infrastructure types and related services, as much of the infrastructure in the North is dependent upon the cryosphere to, for example, provide stable surfaces for buildings and pipelines, contain waste, stabilize shorelines and provide access to remote communities in the winter (Furgal and Prowse, 2008; Huntington *et al.*, 2007; Sherman *et al.*, 2009; Sundby and Nakken, 2008; West and Hovelsrud, 2010; Forbes, 2011). In the long term marine and freshwater transportation will need to shift its reliance from ice routes to open-water or land-based transportation systems. Of appropriate community adaptations to the predicted changes relocation is one option to deal with persistent flooding and bank erosion (Furgal, 2008; NRTEE, 2009). Changing sea-ice (multiyear) conditions are suspected i.e. to have a regulating impact on marine shipping and coastal infrastructure through possible hazards on them (Eicken *et. al.*, 2009).

By adapting transportation models to integrate monthly climate model (CCSM3) predictions of air temperature, combined with datasets on land cover, topography, hydrography, built infrastructure, and locations of human settlements, estimates have been made of changes to inland accessibility for northern landscapes northward of 40ºN by mid-21st Century (Stephenson *et al.*, 2011). Milder air temperatures and/or increased snowfall reduce the possibilities for constructing inland winter-road networks, including ice roads, with the major seasonal reductions in road potential (based on a 2000 kg vehicle) being in the winter shoulder-season months of November and April. The average decline (compared to a baseline of 2000-2014) for eight circumpolar countries was projected to be -14%, varying from -11 to -82%. In absolute terms, Canada and Russia (both at -13%) account for the majority of declining winter-road potential with ~$1x10^6$ km^2 being lost (See Table 28.1). The winter road season has decreased since the 1970s on the Alaska´s North Slope, from as much as 200 to 100 days in some areas (Hinzman, *et al.*, 2005).

Climate change is expected to lead to a nearly ice free Arctic Ocean in late summer and increased navigability of Arctic marine waters. New possibilities for shipping routes and extended use of existing routes may result from increased melting of sea ice (Paxian *et al.*, 2010; Corbett *et al.*, 2010; Khon *et al.*, 2010; Peters *et al.*, 2011; Stephenson *et al.*, 2011).

Projections made by Stephenson *et al.* (2011) suggest that all five Arctic littoral states will gain increased maritime access to their current exclusive economic zones, especially Greenland (+28% relative to baseline), Canada (+19%), Russia (+16%) and United States (+15%). In contrast, Iceland, Norway, Sweden, and Finland display little or no increase in maritime accessibility,(Table 28.1) (Stephenson *et al.*, 2011).

GCMs generally underestimate the duration of the ice-free period in the Arctic Ocean and simulate slower changes than those observed in the past decades (Stroeve *et al.*, 2007). Mokhow and Khon (2008) used a sub-set of climate models that better than other GCMs reproduce the observed sea ice dynamics to project the duration of the navigation season along the NSR and through the NWP under the moderate SRES-A1B emission scenario. According to their results, by the end of the 21st century the NSR may be open for navigation 4.5±1.3 months per year, while the NWP may be open 2-4 months per year (Figure 28-4). The models did not predict any significant changes of the ice conditions in the NWP until the early 2030s.

[INSERT FIGURE 28-4 HERE
Figure 28-4: Projected duration of the navigation period (days) over the Northwest Passage and Northern Sea Route. Source: Mokhow and Khon, 2008.]

[INSERT TABLE 28-1 HERE
Table 28-1: Annually averaged changes in inland and maritime transportation accessibility by mid-century (2045–2059) versus baseline (2000–2014). Source: Stephenson et al., 2011.]

An increase in the length of the summer shipping season, with sea-ice duration expected to be 10 days shorter by 2020 and 20-30 days shorter by 2080, is likely to be the most obvious impact of changing climate on Arctic marine transportation (Prowse *et al.*, 2009). Reduction in sea ice and increased marine traffic could offer opportunities for economic diversification in new service sectors supporting marine shipping. Loss of sea ice may open up waterways and opportunities for increased cruise traffic (e.g. Glomsrød and Aslaksen, 2009), and add to an already rapid increase in cruise tourism (Stewart *et al.*, 2010; Stewart *et al.*, 2007; Howell *et al.*, 2007). Climate change has increased the prevalence of cruise tourism throughout Greenland, Norway, Alaska and Canada because of decreasing sea ice extent.

Projected declines in sea-ice covers leading to development of integrated land and marine transportation networks in Northern Canada may stimulate further mine exploration and development (Prowse *et al.*, 2009). These possibilities however also come with challenges including their predicted contribution to the largest change in contaminant movement into or within the Arctic, as well as their significant negative impacts on the traditional ways of life of northern residents (Furgal and Prowse, 2008). Added shipping and economic activity will increase the amount of black carbon and reinforce warming trends in the region (Lack and Corbett, 2012), leading to additional economic activity.

Longer shipping season and improved access to ports may lead to increased petroleum activities, although possible increased wave activity and coastal erosion may increase costs related to infrastructure and technology. Peters *et al*. (2011) find by using a bottom-up shipping model and a detailed global energy market model to construct emission inventories of Arctic shipping and petroleum activities in 2030 and 2050 – and based on estimated sea-ice extent – that there will be rapid growth in transit shipping; oil and gas production will be moving into locations requiring more ship transport; and this will lead to rapid growth in emissions from oil and gas transport by ship.

The Arctic contains vast resources of oil, which is hard to replace as transportation fuel, and vast resources of gas, a more climate benign fuel than coal. Petroleum resources are unevenly distributed among Arctic regions and states. Arctic resources will play a growing role in the world economy, but increased accessibility is expected to create challenges for extraction, transport, engineering, search-and-rescue needs and responses to accidents (Hovelsrud *et al.*, 2011), and climatic change presents the oil and gas industry with challenges in terms of planning and predictions (Harsem *et al.*, 2011). Increased emissions due to rapid growth in Arctic Ocean transportation of oil and gas are projected (Peters *et al.*, 2011). Due to high costs and difficult access conditions the impact on future oil and gas production in the Arctic remains unclear (Peters *et al.*, 2011; Lindholdt and Glomsrød, 2012).

28.4. Human Adaptation

There is general agreement that both indigenous and non-indigenous people in the Arctic have a history of adapting to natural variability in the climate and natural resource base, as well as recent socio-economic, cultural and technological changes (Forbes and Stammler, 2009; Wenzel, 2009; West and Hovelsrud, 2010; Ford and Pearce, 2010; Bolton *et al.*, 2011Cochran et al., 2013). Climate change exacerbates the existing stresses faced by Arctic communities (Rybråten and Hovelsrud, 2010; Crate and Nuttall, 2009) and is only one of many important factors influencing adaptation (Berrang-Ford *et al.*, 2011). Climate adaptation needs to be seen in the context of these inter-connected and mutually reinforcing factors (Tyler *et al.*, 2007; Hovelsrud and Smit, 2010). The challenges faced today by communities in the Arctic are complex and interlinked and are testing their traditional adaptive capacity.

Climatic and other large-scale changes have potentially large effects on Arctic communities, in particular where simple economies leave a narrower range of adaptive choices (Anisimov and Vaughan, 2007; Ford and Furgal, 2009; Andrachuk and Pearce, 2010; Ford *et al.*, 2010; Forbes, 2011; Berkes *et al.*, 2003). There is considerable evidence that changing weather patterns, declining sea-ice and river as well as lake ice, thawing permafrost, and plant and animal species' abundance and composition have consequences for communities in the Arctic (see 28.2.4, 28.2.5.2 and 28.3.4). Sea-ice is particularly important for coastal communities which rely upon it for transportation between communities and hunting areas (Krupnik et al., 2010). Changes in the duration and condition of sea ice and the consequent changes to country food availability significantly impact the wellbeing of communities (Furgal and Seguin, 2006; Ford and Berrang-Ford, 2009; Ford *et al.*, 2010), outdoor tourism (Dawson *et al.*, 2010) and hunting and fishing (Wiig *et al.*, 2008; Brander, 2010).

Adaptation to climate change is taking place at the local and regional levels where impacts are often felt most acutely and the resources most readily available (Oskal, 2008; Hovelsrud and Smit, 2010). Current experiences and projections of future conditions often lead to technological adaptation responses such as flood and water management and snow avalanche protection (West and Hovelsrud, 2010; Hovelsrud and Smit, 2010) rather than policy responses (Hedensted Lund et al., 2012; Rudberg et al., 2012). Climate variability and extreme events are found to be salient drivers of adaptation (Berrang-Ford *et al.*, 2011; Dannevig *et al.*, 2012; Amundsen et al., 2010).

The lack of local scale climate projections, combined with uncertainties in future economic, social and technological developments often act as barriers to adaptation. These barriers, together with other societal determinants such as ethics, cultures, and attitudes towards risk may cause inaction (Adger *et al.*, 2009; West and Hovelsrud, 2010). Resolving divergent values across and within different communities poses a challenge for governance regimes. A determining factor in building adaptive capacity is the flexibility of enabling institutions to develop robust options (Keskitalo *et al.*, 2009; Hovelsrud and Smit 2010; Forbes *et al.*, 2009; Ford and Goldhar, 2012; Whyte, 2013). In the North American and Scandinavian context, adaptive co-management responses have been developed through land claims settlements and/or multi-scale institutional cooperation to foster social learning (Berkes, 2009; Armitage et *al.*, 2008).

Indigenous Peoples

While Arctic indigenous peoples with traditional lifestyles are facing unprecedented impacts to their ways of life from climate change and resource development (oil and gas, mining, forestry, hydropower, tourism, etc.), they are already implementing creative ways of adapting (Cruikshank, 2001; Forbes *et al.*, 2006; Krupnik and Ray, 2007; Salick and Ross, 2009; Green and Raygorodetsky, 2010; Cullen-Unsworth *et al.*, 2011; Alexander *et al.*, 2011; Bongo *et al.*, 2012). Examples of indigenous adaptation strategies have included changing resource bases, shifting land use and/or settlement areas, combining technologies with traditional knowledge, changing timing and location of hunting, gathering, herding, and fishing areas, and improving communications and education (Galloway McLean, 2010; Bongo *et al.*, 2012). Protection of grazing land will be the most important adaptive strategy for reindeer herders under climate change (Forbes *et al.*, 2009; Magga *et al.*, 2011; Kumpula *et al.*, 2012; Degteva and Nellemann, 2013).

The adaptive capacity of Arctic indigenous peoples is largely due to an extensive traditional knowledge and cultural repertoire, and flexible social networks (see Chapter 12, section 12.3) (Williams and Hardison, 2013). The dynamic nature of traditional knowledge is valuable for adapting to current conditions (Kitti *et al.*,. 2006; Tyler *et al.*, 2007; *Eira et al.*, 2012). The sharing of knowledge ensures rapid responses to crises (Ford *et. al.*, 2007). In addition, cultural values such as sharing, patience, persistence, calmness, respect for elders and the environment are important. Some studies suggest that traditional knowledge may not always be sufficient to meet the rapid changes in climate (see also Chapter 12) and it may be perceived to be less reliable because the changing conditions are beyond the current knowledge range (Ingram et al., 2002; Ford et al., 2006; Valdivia et al., 2010; Hovelsrud et al., 2010).

Over the last half-century, the adaptive capacity in some indigenous communities has been challenged by the transition from semi-nomadic hunting groups to permanent settlements (Ford et al., 2010). Forced or voluntary migration as an adaptation response can have deep cultural impacts (Shearer, 2011,2012; Maldonado *et al*., 2013).The establishment of permanent communities, particularly those associated with new industrial development, can also lead to increasing employment opportunities and income diversification for indigenous peoples. The intergenerational transfers of knowledge and skills through school curricula, land camps, and involvement in community-based monitoring programmes may strengthen adaptive capacity (Bolton et al., 2011; Hovelsrud and Smit, 2010; Ford *et. al.*, 2007; Forbes 2007).

Renewable resource harvesting remains a significant component of Arctic livelihoods and with climate change hunting and fishing has become a riskier undertaking and many communities are already adapting (Gearheard *et al.*, 2011; Laidler *et al.*, 2011). Adaptation includes taking more supplies when hunting; constructing permanent shelters on land as refuges from storms; improved communications infrastructure; greater use of global positioning systems (GPS) for navigation; synthetic aperture radar (SAR) to provide estimates of sea-ice conditions (Laidler *et al.*, 2011) and the use of larger or faster vehicles (Ford *et al.*, 2010). Avoiding dangerous terrain can result in longer and time-consuming journeys which can be inconvenient to those with wage-earning employment (Ford *et al.*, 2007).

Reindeer herders have developed a wide range of adaptation strategies in response to changing pasture conditions. These include: moving herds to better pastures (Bartsch *et al.*, 2010); providing supplemental feeding (Helle and Jaakkola, 2008; Forbes and Kumpula, 2009); retaining a few castrated reindeer males to break through heavy ice-crust (Oskal, 2008; Reinert *et al.*, 2008); ensuring an optimal herd size (Forbes *et al.*, 2009; Tyler *et al.*, 2007); and creating multicultural initiatives combining traditional knowledge with scientific (Vuojala-Magga *et al.*, 2011; Bongo *et al.*, 2012). Coastal fishers have adapted to changing climate by targeting different species and diversifying income sources (Hovelsrud *et al.*, 2010).

In some Arctic countries indigenous peoples have successfully negotiated land claims rights and have become key players in addressing climate change (Abele *et al.*, 2009). In some instances this has given rise to tensions over land/water use between traditional livelihoods and new opportunities (e.g. tourism and natural resource development) (Forbes *et al.*, 2006; Hovelsrud and Smit, 2010). Some territorial governments in Northern Canada have promoted adaptation by providing hunter support programs (Ford *et al.*, 2006, 2010).

The health of many indigenous people is being affected by the interaction of changes in the climate with ongoing changes in human, economic and biophysical systems (Donaldson et al., 2010). The distribution of traditional foods between communities and the use of community freezers in the Canadian Arctic has improved food security, an important factor for health (Ford et al., 2010). While wage employment may enhance the possibilities for adaptive capacity, greater involvement in full time jobs can threaten social and cultural cohesion and mental well-being by disrupting the traditional cycle of land-based practices (Berner et al., 2005; Furgal, 2008).

28.5. Research and Data Gaps

There remains a poor knowledge of coupling among, and thresholds within, bio-geophysical and socio-economic processes to fully assess the effects of a changing climate, and to separate them from those due to other environmental stressors:

- Existing integrative models are either lacking or insufficiently validated to project and to assess the cascading effects on, and feedbacks from the systems in the Polar Regions, in particular socio-economic systems.
- There is a need to enhance or establish a coordinated network of long-term representative sites for monitoring and assessment of climate change detection and attribution studies in Polar Regions. Regional differences and confounding variables will need to be considered in designing field and modelling studies. Standardised methods and approaches of biophysical and socio-economic analysis along with coordinated sampling in more regions will be necessary.

There are more specific research gaps, including:

- Many mechanisms of how climate change and ocean acidification may be affecting polar ecosystems have been proposed but few studies of physiological tolerances of species, long term field studies of ecosystem effects and ecosystem modelling studies are available to be able to attribute with high confidence current and future change in these ecosystems to climate change.
- More comprehensive studies including long-term monitoring on the increasing impacts from climate changes on Arctic communities (urban and rural) and their health, well-being, traditional livelihoods and life ways are needed. There is a need to assess more fully vulnerabilities and to develop response capacities at the local and regional level.

Frequently Asked Questions

FAQ 28.1: What will be the net socio-economic impacts of change in the polar regions?
[to remain at the end of the chapter]
Climate change will have costs and benefits for Polar Regions. Climate change, exacerbated by other large-scale changes, can have potentially large effects on Arctic communities, where relatively simple economies leave a narrower range of adaptive choices.

In the Arctic, positive impacts include new possibilities for economic diversification, marine shipping, agricultural production, forestry, and tourism. The Northern Sea Route is predicted to have up to 125 days per year suitable for navigation by 2050, while the heating energy demand in the populated Arctic areas is predicted to decline by 15%. In addition, there could be greater accessibility to offshore mineral and energy resources although challenges related to environmental impacts and traditional livelihoods are possible.

Changing sea ice condition and permafrost thawing may cause damage to bridges, pipelines, drilling platforms, hydropower and other infrastructure. This poses major economic costs and human risks, although these impacts are closely linked to the design of the structure. Furthermore, warmer winter temperatures will shorten the accessibility of ice roads that are critical for communications between settlements and economic development and have implications for increased costs.. Statistically, a long-term mean increase of 2 to 3°C in autumn and spring air temperature produces an approximate 10 to 15 day delay in freeze-up and advance in break-up, respectively.

Particular concerns are associated with projected increase in the frequency and severity of ice-jam floods on Siberian rivers. They may have potentially catastrophic consequences for the villages and cities located in the river plain, as exemplified by the 2001 Lena River flood, which demolished most of the buildings in the city of Lensk.

Changing sea ice conditions will impact indigenous livelihoods, and changes in resources, including marine mammals, could represent a significant economic loss for many local communities. Food security and health and well-being are expected to be impacted negatively.

In the Antarctic, tourism is expected to increase, and risks exist of accidental pollution from maritime accidents, along with an increasing likelihood of the introduction of alien species to terrestrial environments. Fishing for Antarctic krill near to the Antarctic continent is expected to become more common during winter months in areas where there is less winter sea ice.

FAQ 28.2: Why are changes in sea ice so important to the polar regions? *[to remain at the end of the chapter]*
Sea ice is a dominant feature of Polar Oceans. Shifts in the distribution and extent of sea ice during the growing season impacts the duration, magnitude and species composition of primary and secondary production in the Polar Regions. With less sea ice many marine ecosystems will experience more light, which can accelerate the growth of phytoplankton, and shift the balance between the primary production by ice algae and water-borne phytoplankton,

with implications for Arctic food webs. In contrast, sea ice is also an important habitat for juvenile Antarctic krill, providing food and protection from predators. Krill is a basic food source for many species in polar marine ecosystems.

Changes in sea ice will have other impacts, beyond these "bottom-up" consequences for marine foodwebs. Mammals and birds utilize sea ice as haul-outs during foraging trips (seals, walrus, and polar bears in the Arctic and seals and penguins in the Antarctic). Some seals (e.g. Bearded seals in the Arctic and crabeater and leopard seals in the Antarctic) give birth and nurse pups in pack ice. Shifts in the spatial distribution and extent of sea ice will alter the spatial overlap of predators and their prey. According to model projections, within 50-70 years loss of hunting habitats may lead to elimination of polar bears from seasonally ice-covered areas, where two thirds of their world population currently live. The vulnerability of marine species to changes in sea ice will depend on the exposure to change, which will vary by location, as well as the sensitivity of the species to changing environmental conditions and the adaptive capacity of each species. More open waters and longer ice-free period in the northern seas enhance the effect of wave action and coastal erosion with implications for coastal communities and infrastructure.

While the overall sea ice extent in the Southern Ocean has not changed markedly in recent decades, there have been increases in oceanic temperatures and large regional decreases in winter sea ice extent and duration in the western Antarctic Peninsula region of West Antarctica and the islands of the Scotia Arc.

Executive Summary

Current and future climate-related drivers of risk for small islands during the 21st century include sea-level rise, tropical and extra-tropical cyclones, increasing air and sea surface temperatures, and changing rainfall patterns (*high confidence, robust evidence, high agreement*) [WGI 14, Table 29-1]. Current impacts associated with these changes confirm findings reported on small islands from the AR4 and previous IPCC assessments. The future risks associated with these drivers include loss of adaptive capacity [29.6.2.1, 29.6.2.3] and ecosystem services critical to lives and livelihoods in small islands [29.3.1, 29.3.2, 29.3.3].

Sea-level rise poses one of the most widely recognized climate change threats to low-lying coastal areas on islands and atolls (*high confidence, robust evidence and high agreement*) [29.3.1]. It is *virtually certain* that global mean sea-level rise rates are accelerating [WGI 13.2.2.1]. Projected increases to the year 2100 (RCP 4.5: 0.35m to 0.70m, WGI 13.5.1, Table 29-1) superimposed on extreme sea-level events (e.g. swell waves, storm surges, ENSO) present severe sea-flood and erosion risks for low-lying coastal areas and atoll islands (*high confidence*). Likewise, there is *high confidence* that wave over-wash of sea water will degrade fresh ground water resources [29.3.2] and that sea surface temperature rise will result in increased coral bleaching and reef degradation [29.3.1.2]. Given the dependence of island communities on coral reef ecosystems for a range of services including coastal protection, subsistence fisheries and tourism, there is *high confidence* that coral reef ecosystem degradation will negatively impact island communities and livelihoods.

Given the inherent physical characteristics of small islands, the AR5 reconfirms the high level of vulnerability of small islands to multiple stressors, both climate and non-climate (*high confidence, robust evidence, high agreement*). However, the distinction between *observed* and *projected* impacts of climate change is often not clear in the literature on small islands (*high agreement)* [29.3]. There is evidence that this challenge can be partly overcome through improvements in baseline monitoring of island systems and downscaling of climate-model projections, which would heighten confidence in assessing recent and projected impacts [WGI 9.6, 29.3, 29.4, 29.9].

Small islands do not have uniform climate change risk profiles (*high confidence*). Rather their high diversity in both physical and human attributes and their response to climate-related drivers means that climate change impacts, vulnerability and adaptation will be variable from one island region to another and between countries in the same region [Fig 29.1; Table 29.3]. In the past, this diversity in potential response has not always been adequately integrated in adaptation planning.

There is increasing recognition of the risks to small islands from climate-related processes originating well beyond the borders of an individual nation or island. Such trans-boundary processes already have a negative impact on small islands (*high confidence, robust evidence, medium agreement)*. These include: airborne dust from the Sahara and Asia, distant-source ocean swells from mid- high latitudes, invasive plant and animal species and the spread of aquatic pathogens. For island communities the risks associated with existing and future invasive species and human health challenges are projected to increase in a changing climate [29.5.4].

Adaptation to climate change generates larger benefit to small islands when delivered in conjunction with other development activities, such as disaster risk reduction and community based approaches to development *(medium confidence*) [29.6.4]. Addressing the critical social, economic and environmental issues of the day, raising awareness and communicating future risks to local communities [29.6.3] will *likely* increase human and environmental resilience to the longer-term impacts of climate change [29.6.1, 29.6.2.3, Figure 29-5].

Adaptation and mitigation on small islands are not always trade-offs, but can be regarded as complementary components in the response to climate change (*medium confidence).* Examples of adaptation-mitigation inter-linkages in small islands include energy supply and use, tourism infrastructure and activities, and functions and services associated with coastal wetlands. The alignment of these sectors for potential emission reductions together with adaptation, offer co-benefits and opportunities in some small islands [29.7.2, 29.8]. Lessons learned from adaptation and mitigation experiences in one island may offer some guidance to other small island states, though there is *low confidence* in the success of wholesale transfer of adaptation and mitigation options when the local lenses through which they are viewed differ from one island state to the next, given the diverse cultural, socio-economic, ecological and political values [29.6.2, 29.8].

The ability of small islands to undertake adaptation and mitigation programs, and their effectiveness, can be substantially strengthened through appropriate assistance from the international community (*medium confidence*). However, caution is needed to ensure such assistance is not driving the climate change agenda in small islands, as there is a risk that critical challenges confronting island governments and communities may not be addressed . Opportunities for effective adaptation can be found by, for example, empowering communities and optimizing the benefits of local practices that have proven to be efficacious through time, and working synergistically to progress development agendas [29.8, 29.6.2.3, 29.6.3].

29.1. Introduction

It has long been recognized that greenhouse gas emissions from small islands are negligible in relation to global emissions, but that the threats of climate change and sea-level rise to small islands are very real. Indeed, it has been suggested that the very existence of some atoll nations is threatened by rising sea levels associated with global warming. Whilst such scenarios are not applicable to all small island nations, there is no doubt that on the whole the impacts of climate change on small islands will have serious negative effects especially on socio-economic conditions and bio-physical resources – although impacts may be reduced through effective adaptation measures.

The small islands considered in this chapter are principally sovereign states and territories located within the tropics of the southern and western Pacific Ocean, central and western Indian Ocean, the Caribbean Sea, and the eastern Atlantic off the coast of west Africa, as well as in the more temperate Mediterranean Sea.

Although these small islands nations are by no means homogenous politically, socially, or culturally, or in terms of physical size and character or economic development, there has been a tendency to generalise about the potential impacts on small islands and their adaptive capacity. In this chapter we attempt to strike a balance between identifying the differences between small islands as well as recognising that small islands tend to share a number of common characteristics that have distinguished them as a particular group in international affairs. Also in this chapter we reiterate some of the frequently voiced and key concerns relating to climate change impacts, vulnerability and adaptation whilst emphasising a number of additional themes that have emerged in the literature on small islands since the IPCC Fourth Assessment. These include the relationship between climate change policy, activities and development issues; externally generated trans-boundary impacts; and the implications of risk in relation to adaptation and the adaptive capacity of small island nations.

29.2. Major Conclusions from Previous Assessments

Small islands were not given a separate chapter in the IPCC First Assessment (FAR) in1990 though they were discussed in the chapter on 'World Oceans and Coastal Zones' (Tsyban *et al*., 1990). Two points were highlighted. First, that a 30-50 cm sea-level rise projected by 2050 would threaten low islands, and that a 1 m rise by 2100 'would render some island countries uninhabitable' (Tegart *et al*., 1990). Second, the costs of protection works to combat sea-level rise would be extremely high for small island nations. Indeed, as a percentage of GDP the Maldives, Kiribati, Tuvalu, Tokelau, Anguilla, Turks and Caicos, Marshall Islands and Seychelles were ranked among the ten nations with the highest protection costs in relation to GDP (Tsyban *et al*., 1990). Over twenty years later these two points continue to be emphasized. For instance, although small islands represent only a fraction of total global damage projected to occur due to a sea-level rise of 1.0 m by 2100 (SRES A1 scenario) the actual damage costs for the small island states is enormous in relation to the size of their economies with several small island nations being included in the group of ten countries with the highest relative impact projected for 2100 (Anthoff *et al*., 2010).

The Second Assessment (SAR) in 1995 confirmed the vulnerable state of small islands, now included in a specific chapter titled 'Coastal Zones and Small Islands' (Bijlsma *et al*., 1996). However, importantly the SAR recognized that both vulnerability and impacts would be highly variable between small islands and that impacts were 'likely to be greatest where local environments are already under stress as a result of human activities' (Bijlsma *et al*., 1996). The report also summarized results from the application of a common methodology for vulnerability and adaptation analysis that gave new insights into the socio-economic implications of sea-level rise for small islands including: negative impacts on virtually all sectors including tourism, freshwater resources, fisheries and agriculture, human settlements, financial services and human health; protection is likely to be very costly; and, adaptation would involve a series of tradeoffs. It also noted that major constraints to adaptation on small islands included: lack of technology and human resource capacity, serious financial limitations, lack of cultural and social acceptability and uncertain political and legal frameworks. Integrated coastal and island management was seen as a way of overcoming some of these constraints.

The Third Assessment (TAR) in 2001 included a specific chapter on 'Small Island States'. In confirming previously identified concerns of small island states two factors were highlighted, the first relating to sustainability noting that 'with limited resources and low adaptive capacity, these islands face the considerable challenge of meeting the social and economic needs of their populations in a manner that is sustainable' (Nurse *et al*., 2001). And the second, that there were other issues faced by small island states concluding that 'for most small islands the reality of climate change is just one of many serious challenges with which they are confronted' (Nurse *et al*., 2001). Both of these themes are raised again and assessed in the light of recent findings in the present chapter.

Until the Fourth Assessment (AR4) in 2007, sea-level rise had dominated vulnerability and impact studies of small island states. Whilst a broader range of climate change drivers and geographical spread of islands was included in the 'Small Islands' chapter, Mimura *et al.* (2007) prefaced their assessment by noting that the number of 'independent scientific studies on climate change and small islands since the TAR' had been quite limited and in their view 'the volume of literature in refereed international journals relating to small islands and climate change since publication of the TAR is rather less than that between the SAR in 1995 and TAR in 2001' (Mimura *et al*., 2007).

Since AR4 the literature on small islands and climate change has increased substantially. A number of features distinguish the literature we review here from that included in earlier assessments. First, the literature appears more sophisticated and does not shirk from dealing with the complexity of small island vulnerability, impacts and adaptation or the differences between islands and island states. Second, and related to the first, the literature is less one-dimensional, and deals with climate change in a multidimensional manner as just one of several stressors on small island nations. Third, the literature also critiques some aspects of climate change policy, notably in relation to critical present-day development and security needs of small islands [29.3.3.1] as well as the possibility that some proposed adaptation measures may prove to be maladaptive [29.8]. Fourth, many initiatives have been identified in recent times that will reduce vulnerability and enhance resilience of small islands to on-going global change including improving risk knowledge and island resource management while also strengthening socio-economic systems and livelihoods (Hay, 2013).

29.3. Observed Impacts of Climate Change, including Detection and Attribution

The distinction between *observed* impacts of climate change and *projected* impacts is often unclear in the small islands literature and discussions. Publications frequently deal with both aspects of impacts interchangeably, and use observed impacts from, for instance an extreme event, as an analogy to what may happen in the future due to climate change (e.g. Lo-Yat *et al.,* 2011). The key climate and ocean drivers of change that impact small islands include variations in air and ocean temperatures, ocean chemistry, rainfall, wind strength and direction, sea-levels and wave climate and particularly the extremes such as tropical cyclones, drought and distant storm swell events. All have varying impacts, dependent on the magnitude, frequency, temporal and spatial extent of the event, as well as on the bio-physical nature of the island (Figure 29.1) and its social, economic and political setting.

[INSERT FIGURE 29-1 HERE
Figure 29-1: Representative tropical island typologies. From top-left: a young, active volcanic island (with altitudinal zonation) and limited living perimeter reefs (purple zone at outer reef edge), through to an atoll (centre bottom) and raised limestone island (bottom right) dominated by ancient reef deposits (brown + white fleck). Atolls have limited, low-lying land areas but well developed reef/lagoon systems. Islands composed of 'continental rocks' are not included in this figure, but see Table 29-3.]

29.3.1. Observed Impacts on Island Coasts and Marine Biophysical Systems

29.3.1.1. Sea-Level Rise, Inundation, and Shoreline Change on Small Islands

Sea-level rise poses one of the most widely recognized climate change threats to low-lying coastal areas (Church and White 2011; Cazenave and Llovel, 2010; Nicholls and Cazenave, 2010). This is particularly important in small islands where the majority of human communities and infrastructure is located in coastal zones with limited on-island relocation opportunities especially on atoll islands (Woodroffe, 2008) (Figure 29-1). Over much of the 20th Century, global mean sea level rose at a rate between 1.3 to 1.7 mm yr^{-1} and since 1993, at a rate between 2.8 to 3.6 mm yr^{-1} (WGI, Table 13.1) and acceleration is detected in longer records since 1870 (Merrifield *et al.,* 2009; Church and White, 2011; WGI, 13.2.2.1). Rates of sea-level rise are however not uniform across the globe and large regional differences have been detected including in the Indian Ocean and tropical Pacific, where in some parts rates have been significantly higher than the global average (Meyssignac *et al.,* 2012) (refer also to 5.3.2.2). In the tropical western Pacific where a large number of small island communities exist, rates up to four times the global average (approximately 12 mm yr^{-1}) have been reported between 1993 and 2009. These are generally thought to describe short-term variations associated with natural cyclic climate phenomena such as ENSO (El Niño-Southern Oscillation) which has a strong modulating effect on sea level variability with lower/higher-than-average sea level during El Nino/La Nina events of the order of ±20-30 cm (Becker *et al.,* 2012; Cazenave and Remy, 2011). Large interannual variability in sea level has also been demonstrated from the Indian Ocean (e.g. Chagos Archipelago, Dunne *et al.,* 2012) whilst Palanisamy *et al*. (2012) found that over the last 60 years the mean rate of sea-level rise in the Caribbean region was similar to the global average ~ 1.8mm yr^{-1}.

There are few long-term sea-level records available for individual small island locations. Reported sea flooding and inundation is often associated with transient phenomena, such as storm waves and surges, deep ocean swell and predicted astronomical tidal cycles (Vassie *et al.,* 2004; Zahibo *et al*., 2007; Komar and Allan, 2008; Haigh *et al*., 2011). For example, high spring tide floods at Fongafale Island, Funafuti Atoll, Tuvalu, have been well publicized and areas of the central portion of Fongafale are already below high spring tide level. However, rates of relative sea-level rise at Funafuti between 1950 – 2009 have been approximately three times higher than the global average (Becker *et al.,* 2012) and saline flooding of internal low-lying areas occurs regularly, and is expected to become more frequent and extensive over time (Yamano *et al.,* 2007).

Documented cases of coastal inundation and erosion often cite additional circumstances such as vertical subsidence, engineering works, development activities or beach mining as the causal process. Four examples can be cited. First, on the Torres Islands, Vanuatu communities have been displaced due to increasing inundation of low-lying settlement areas due to a combination of tectonic subsidence and sea-level rise (Ballu *et al.,* 2011). Second, on Anjouan Island, Comores in the Indian Ocean, Sinane *et al*. (2010) found beach aggregate mining was a major contributing factor influencing rapid beach erosion. Third, the intrinsic exposure of rapidly expanding settlements and agriculture in the low-lying flood prone Rewa Delta, Fiji is shown by Lata and Nunn (2012) to place populations in increasingly severe conditions of vulnerability to flooding and marine inundation. Fourth, Hoeke *et al*. (2013) describe a 2008 widespread inundation event that displaced some 63,000 people in Papua New Guinea and Solomon Islands alone. That event was primarily caused by remotely generated swell waves, and the severity of flooding was greatly increased by anomalously high regional sea levels linked with ENSO and on-going sea-level rise. Such examples serve to highlight that extreme events superimposed on a rising sea-level baseline are the main drivers that threaten the habitability of low-lying islands as sea levels continue to rise.

Since the AR4 a number of empirical studies have documented historical changes in island shorelines. Historical shoreline position change over 20 – 60 years on 27 central Pacific atoll islands showed that total land area remained relatively stable in 43 per cent of islands, whilst another 43 per cent had increased in area, and the rest showed a net reduction in land area (Webb and Kench, 2010). Dynamic responses were also found in a four year study of 17 relatively pristine islands on two other central Pacific atolls in Kiribati by Rankey (2011) who concluded that sea-level rise was not likely to be the main influencing factor in these shoreline changes. Similarly in French Polynesia Yates *et al*. (2013) showed mixed shoreline change patterns over the last 40 – 50 years with examples of both erosion and accretion in the 47 atoll islands assessed. Sea-level rise did not appear to be the primary control on shoreline processes on these islands. On uninhabited Raine Island on the Great Barrier Reef, Dawson and Smithers (2010) also found that shoreline processes were dynamic but that island area and volume increased 6 per cent and 4 per cent respectively between 1967 and 2007. Overall, these studies of observed shoreline change on reef islands conclude that for rates of change experienced over recent decades normal seasonal erosion and accretion processes appear to predominate over any long-term morphological trend or signal at this time. Ford's (2013) investigation of Wotje Atoll, Marshall Islands also found shoreline variability between 1945 and 2010 but that overall accretion had been more prevalent than erosion up until 2004. From 2004 to the present 17 out of 18 islands became net erosive, potentially corresponding to the high sea levels in the region over the last 10 years. On the high tropical islands of Kauai and Maui, Hawaii, Romine and Fletcher (2013) found shoreline change was highly variable over the last century but that recently chronic erosion predominated with over 70% of beaches now being erosive. Finally, it is important to note the majority of these studies warn that: (1) past changes cannot be simply extrapolated to determine future shoreline responses; and (2) rising sea level will incrementally increase the rate and extent of erosion in the future.

In many locations changing patterns of human settlement and direct impacts on shoreline processes present immediate erosion challenges in populated islands and coastal zones (Yamano *et al*., 2007; Storey and Hunter, 2010; Novelo-Casanova and Suarez, 2010) and mask attribution to sea-level rise. A study of Majuro atoll (Marshall Islands) found that erosion was widespread but attribution to sea-level rise was obscured by pervasive anthropogenic impacts to the coastal system (Ford, 2012) (see also 5.4.4). Similarly a study of three islands in the Rosario Archipelago (Colombia) reported shoreline retreat over a 50-55 year period and found Grande, Rosario, and Tesoro Islands had lost 6.7, 8.2 and 48.7 per cent of their land area respectively. Erosion was largely attributed to poor management on densely settled Grande Island, whilst sea-level rise and persistent northeast winds enhanced erosion on uninhabited Rosario and Tesoro (Restrepo *et al.,* 2012). Likewise, Cambers (2009) reported average beach erosion rates of 0.5 m yr^{-1} in eight Caribbean islands from 1985-2000. Whilst the study could not quantify the extent of attribution it noted that greater erosion rates were positively correlated with the number of hurricane events. Alternately, Etienne and Terry (2012) found a Category 4 tropical cyclone that passed within 30 km of Taveuni Island (Fiji) nourished shorelines with fresh coralline sediments despite localized storm damage. Whilst these studies contribute to improved understanding of island shoreline processes and change since AR4, the warning of increased vulnerability of small island shores and low-lying areas to inundation and erosion in response to sea-level rise and other potential climate change stressors is not diminished.

29.3.1.2. Coastal Ecosystem Change on Small Islands: Coral Reefs and Coastal Wetlands

Coral reefs are an important resource in small tropical islands and wellbeing of many island communities is linked to their on-going function and productivity. Reefs play a significant role in supplying sediment to island shores and in dissipating wave energy thus reducing the potential foreshore erosion. They also provide habitat for a host of marine species upon which many island communities are dependent for subsistence foods as well as underpinning beach and reef-based tourism and economic activity (Bell *et al.,* 2011; Perch-Nielsen, 2010). The documented sensitivity of coral reef ecosystems to climate change is summarised elsewhere (see Chap 5, Box CC-CR).

Increased coral bleaching and reduced reef calcification rates due to thermal stress and increasing CO_2 concentration are expected to affect the functioning and viability of living reef systems (Hoegh-Guldberg *et al.,* 2007; Eakin *et al.,* 2009). Some studies already implicate thermal stress in reduced coral calcification rates (Tanzil *et al*., 2009) and regional declines in calcification of corals that form reef framework (De'ath *et al*., 2009; Cantin *et al*., 2010). Unprecedented bleaching events have been recorded in the remote Phoenix Islands (Kiribati) with nearly 100 per cent coral mortality in the lagoon and 62 per cent mortality on the outer leeward slopes of the otherwise pristine reefs of Kanton Atoll during 2002 / 2003 (Alling *et al*., 2007). Similar patterns of mortality were observed in four other atolls in the Phoenix group and temperature-induced coral bleaching was also recorded in isolated Palmyra Atoll during the 2009 ENSO event (Williams *et al*., 2010). In 2005 extensive bleaching was recorded at 22 sites around Rodrigues Island in the western Indian Ocean with up to 75 per cent of the dominant species affected in some areas (Hardman *et al.,* 2007). Studies of the severe 1998 El Niño bleaching event in the tropical Indian Ocean showed reefs in the Maldives, Seychelles and Chagos Islands were among the most impacted (Cinner *et al.,* 2012; Tkachenko, 2012). In 2005 a reef survey around Barbados following a Caribbean regional bleaching event revealed the most severe bleaching ever recorded with approximately 70 per cent of corals impacted (Oxenford *et al.,* 2008). Globally, the incidence and implications of temperature-related coral bleaching in small islands is well documented and combined with the effects of increasing ocean acidification these stressors could threaten the function and persistence of island coral reef ecosystems (see Chap 5, Box CC-OA).

Island coral reefs have limited defences against thermal stress and acidification. However studies such as Cinner *et al*. (2012) and Tkachenko (2012) highlight that whilst recovery from bleaching is variable, some reefs show greater resilience than others. There is also some evidence to show that coral reef resilience is enhanced in the absence of other environmental stresses such as declining water quality. In Belize chronologies of growth rates in massive corals *(Montastraea faveolata)* over the past 75–150 years suggest that the bleaching event in 1998 was unprecedented and its severity appeared to stem from reduced thermal tolerance related to human coastal development (Carilli *et al*., 2010). Likewise a study over a 40 year period (1960s – 2008) in the Grand Recif of Tulear, Madagascar concluded that severe degradation of the reef was mostly ascribed to direct anthropogenic disturbance, despite an average 1 ^{0}C increase in temperature over this period (Harris *et al*., 2010). Coral recovery following the 2004 bleaching event in the central Pacific atolls of Tarawa and Abaiang (Kiribati) was also noted to be improved in the absence of direct human impacts (Donner *et al.*, 2010) and isolation of bleached reefs was shown by Gilmour *et al*. (2013) to be less inhibiting to reef recovery than direct human disturbance.

The loss of coral reef habitat has detrimental implications for coastal fisheries (Pratchett *et al.,* 2009) in small islands where reef-based subsistence and tourism activities are often critical to the wellbeing and economies of islands (Bell *et al.,* 2011). In Kimbe Bay, Papua New Guinea 65 per cent of coastal fish are dependent on living reefs at some stage in their life cycle and that following degradation of the reef fish abundance declined (Jones *et al.,* 2004). Even where coral reef recovery has followed bleaching, reef associated species composition may not recover to its original state (Pratchett *et al.*, 2009; Donner *et al.*, 2010). Sea Surface Temperature (SST) anomaly events can be associated with a lag in the larval supply of coral reef fishes, as reported by Lo-Yat *et al.* (2011) between 1996 and 2000 at Rangiroa Atoll, French Polynesia. Higher temperatures have also been implicated in negatively affecting the spawning of adult reef species (Munday *et al*., 2009; Donelson *et al*., 2010).

Like coral reefs, mangroves and sea grass environments provide a range of ecosystem goods and services (Polidoro *et al*., 2010; Waycott *et al*., 2009) and both habitats play a significant role in the wellbeing of small island communities. Mangroves in particular serve a host of commercial and subsistence uses as well as providing natural coastal protection from erosion and storm events (Ellison, 2009; Krauss *et al.*, 2010; Waycott *et al.*, 2011).

Sea-level rise is reported as the most significant climate change threat to the survival of mangroves (Waycott *et al.*, 2011). Loss of the seaward edge of mangroves at Hungry Bay, Bermuda has been reported by Ellison (1993) who attributes this process to sea-level rise and the inability of mangroves to tolerate increased water depth at the seaward margin. Elsewhere in the Caribbean and tropical Pacific observations vary in regards to the potential for sedimentation rates in mangroves forests to keep pace with sea-level rise (McKee *et al.*, 2007; Krauss *et al.*, 2003). In Kosrae and Pohnpei Islands (Federated States of Micronesia), Krauss *et al.* (2010) found significant variability in mangrove average soil elevation changes due to deposition from an accretion deficit of 4.95 mm y^{-1} to an accretion surplus of 3.28 mm y^{-1} relative to the estimated rate of sea-level rise. Such surpluses are generally reported from high islands where additional sediments can be delivered from terrestrial runoff. However, Rankey (2011) described natural seaward migration (up to 40m) of some mangrove areas between 1969 and 2009 in atolls in Kiribati suggesting sediment accretion can also occur in sediment rich reefal areas and in the absence of terrigenous inputs.

The response of seagrass to climate change is also complex, regionally variable and manifest in quite different ways. A study of seven species of sea grasses from tropical Green Island, Australia highlighted the variability in response to heat and light stress (Campbell *et al*., 2006). Light reduction may be a limiting factor to sea grass growth due to increased water depth and sedimentation (Ralph *et al.*, 2007). Ogston and Field (2010) observed that a 20 cm rise in sea-level may double suspended sediment loads and turbidity in shallow waters on fringing reefs of Molokai, Hawaiian Islands, with negative implications to photosynthetic species such as seagrass. Otherwise, temperature stress is most commonly reported as the main expected climate change impact on seagrass (e.g. Campbell *et al.*, 2006; Waycott *et al.*, 2011). Literature on seagrass diebacks in small islands is scarce but research in the Balearic Islands (Western Mediterranean) has shown that over a six-year study, seagrass shoot mortality and recruitment rates were negatively influenced by higher temperature (Marbá and Duarte, 2010). (See also Chapter 5.4.2.3 for further discussion of impacts on mangrove and sea grass communities).

29.3.2. Observed Impacts on Terrestrial Systems: Island Biodiversity and Water Resources

Climate change impacts on terrestrial biodiversity on islands, frequently interacting with several other drivers (Blackburn *et al*., 2004; Didham *et al*., 2005), fall into three general categories namely: (a) ecosystem and species horizontal shifts and range decline; (b) altitudinal species range shifts and decline mainly due to temperature increase on high islands; and (c) exotic and pest species range increase and invasions mainly due to temperature increase in high latitude islands. Due to the limited area and isolated nature of most islands, these effects are generally magnified compared to continental areas and may cause species loss especially in tropical islands with high numbers of endemic species. For example, in two low-lying islands in the Bahamas, Greaver and Sternberg (2010) found that during periods of reduced rainfall the shallow freshwater lens subsides and contracts landward and ocean water infiltrates further inland negatively impacting on coastal strand vegetation. Sea-level rise has also been observed to threaten the long-term persistence of freshwater-dependent ecosystems within low-lying islands in the Florida Keys (Goodman *et al*., 2012). On Sugarloaf Key, Ross *et al*. (2009) found pine forest area declined from 88 to 30 h from 1935 to 1991 due to increasing salinisation and rising ground water, with vegetation transitioning to more saline tolerant species such as mangroves.

Whilst there are many studies that report observations associated with temperature increases in mid- and high-latitude islands, such as the Falkland Islands and Marion Islands in the south Atlantic and south Indian ocean respectively (Bokhorst *et al*., 2007, 2008; Le Roux *et al*., 2005) and Svalbard in the Arctic (Webb *et al*., 1998) there are few equivalent studies in tropical small islands. A recent study of the tropical Mauritius kestrel indicate changing rainfall conditions in Mauritius over the last 50 years have resulted in this species having reduced reproductive success due to a mismatch between the timing of breeding and peak food abundance (Senapathi *et al*., 2011).

Increasing global temperatures may also lead to altitudinal species range shifts and contractions within high islands with an upward creep of the tree line and associated fauna (Benning *et al*., 2002; Krushelnycky *et al*., 2013). A study in the Hawaiian Islands which assessed data from 21 stations over 85 years showed a rapid rise in surface temperatures over the last 30 years with stronger warming in mountain areas (CCSP, 2008). Comparative vegetation distribution and composition studies in sub-Antarctic Marion Island, found an altitudinal shift of 3.4 m yr^{-1} for plant species (Parolo and Rossi, 2008). Comparable effects also occur in the tropics such as in Hawaii Volcano National Park where comparison of sample plots over a 40 year period from 1966-67 to 2008 show fire-adapted grasses expanded upward along a warming tropical elevation gradient (Angelo and Daehler, 2013). Reduction in the numbers and sizes of endemic populations caused by such habitat constriction and changes in species composition in mountain systems may result in the demise and possibly extinction of endemic species (Chen *et al*., 2009; Pauli *et al*., 2007; Sekercioglu *et al.*, 2008; Krushelnycky *et al.*, 2013). Altitudinal temperature change has also been reported to influence the distribution for disease vectors such as mosquitoes potentially threatening biota unaccustomed to such vectors (Freed *et al*., 2005; Atkinson and LaPointe, 2009).

Freshwater supply in small island environments has always presented challenges and has been an issue raised in all previous IPCC reports. On high volcanic and granitic islands small and steep river catchments respond rapidly to rainfall events and watersheds generally have restricted storage capacity. On porous limestone and low atoll islands surface runoff is minimal and water rapidly passes through the substrate into the groundwater lens. Rainwater harvesting is also an important contribution to freshwater access and alternatives like desalination have had mixed success in small island settings due to operational costs (White and Falkland, 2010).

Rapidly growing demand, land use change, urbanisation and tourism are already placing significant strain on the limited freshwater reserves in small island environments (Cashman *et al*., 2010; Emmanuel and Spence, 2009; White and Falkland, 2010). In the Caribbean, where there is considerable variation in the types of freshwater supplies utilised, concern over the status of freshwater availability has been expressed for at least the past 30 years (Cashman *et al*., 2010). There have also been economic and management failures in the water sector not only in the Caribbean (Mycoo, 2007) but also in small islands in the Indian (Payet and Agricole, 2006) and Pacific oceans (Moglia *et al.*, 2008a, 2008b; White *et al.*, 2007).

These issues also occur on a background of decreasing rainfall and increasing temperature. Rainfall records averaged over the Caribbean region for 100 years (1900-2000) show a consistent 0.18 mm yr^{-1} reduction in rainfall, a trend that is projected to continue (Jury and Winter, 2010). In contrast, analysis of rainfall data over the past 100 years from the Seychelles has shown substantial variability related to ENSO. Nevertheless an increase in average rainfall from 1959 to 1997 and an increase in temperature of ~ 0.25 ^{o}C per decade have occurred (Payet and Agricole, 2006). Long-term reduction in streamflow (median reduction of 22 – 23%) has been detected in the Hawaiian Islands over the period 1913 – 2008, resulting in reduced freshwater availability for both human use and ecological processes (Bassiouni and Oki 2013). Detection of long-term statistical change in precipitation is an important prerequisite towards a better understanding the impacts of climate change in small island hydrology and water resources.

There is a paucity of empirical evidence linking saline (sea-water) intrusion into fresh groundwater reserves due simply to incremental sea-level rise at this time (e.g. Rozell and Wong, 2010). However this dynamic must be the subject of improved research given the importance of groundwater aquifers in small island environments. White and Falkland’s (2010) review of existing small island studies indicates that a sea-level increase of up to 1 m would have negligible salinity impacts on atoll island groundwater lenses so long as there is adequate vertical accommodation space, island shores remain intact, rainfall patterns do not change and direct human impacts are managed. However, wave overtopping and washover can be expected to become more frequent with sea-level rise and this has been shown to impact freshwater lenses dramatically. On Pukapuka Atoll, Cook Islands storm surge over-wash occurred in 2005. This caused the freshwater lenses to become immediately brackish and took 11 months to recover to conductivity levels appropriate for human use (Terry and Falkland, 2010). The ability of the freshwater lens to float upwards within the substrate of an island in step with incremental sea-level rise also means that in low-lying and central areas of many atoll islands the lens may pond at the surface. This phenomenon already occurs in central areas of Fongafale Island, Tuvalu, and during extreme high 'king' tides large areas of the inner part of the island become inundated with brackish waters (Yamano *et al*., 2007; Locke, 2009).

29.3.3. Observed Impacts on Human Systems in Small Islands

29.3.3.1. Observed Impacts on Island Settlements and Tourism

Whilst traditional settlements on high islands in the Pacific were often located inland, the move to coastal locations was encouraged by colonial and religious authorities and more recently through the development of tourism (Barnett and Campbell, 2010). Now the majority of settlement, infrastructure and development are located on lowlands along the coastal fringe of small islands. In the case of atoll islands, all development and settlement is essentially coastal. It follows that populations, infrastructure, agricultural areas and fresh groundwater supplies are all vulnerable to extreme tides, wave and surge events and sea-level rise (Walsh *et al*., 2012). Population drift from outer islands or from inland, together with rapid population growth in main centres and lack of accommodation space drives growing populations into ever more vulnerable locations (Connell, 2012). Additionally, without adequate resources and planning, engineering solutions such as shoreline reclamation also place communities and infrastructure in positions of increased risk (Duvat, 2013; Yamano *et al*., 2007).

Many of the environmental issues raised by the media relating to Tuvalu, the Marshall Islands and Maldives are primarily relevant to the major population centre and its surrounds, which are Funafuti, Majuro and Male respectively. As an example Storey and Hunter (2010) indicate the 'Kiribati' problem does not refer to the whole of Kiribati but rather to the southern part of Tarawa atoll where pre-existing issues of severe overcrowding, proliferation of informal housing and unplanned settlement, inadequate water supply, poor sanitation and solid waste disposal, pollution and conflict over land ownership are of concern. They argue that these problems require immediate resolution if the vulnerability of the South Tarawa community to the 'real and alarming threat' of climate change is to be managed effectively (Storey and Hunter, 2010).

On Majuro atoll, rapid urban development and the abandonment of traditional settlement patterns has resulted in movement from less vulnerable to more vulnerable locations on the island (Spennemann, 1996). Likewise, geophysical studies of Fongafale Island, the capital of Tuvalu, show that engineering works during World War II, and rapid development and population growth since independence, has led to the settlement of inappropriate shoreline and swampland areas, leaving communities in heightened conditions of vulnerability (e.g. Yamano *et al*., 2007). Ascribing direct climate change impacts in such disturbed environments is problematic due to the existing multiple lines of stress on the island's biophysical and social systems. However, it is clear that such pre-existing conditions of vulnerability add to the threat of climate change in such locations. Increased risk can also result from lack of awareness, particularly in communities in rural areas and outer islands ('periphery') of archipelagic countries such as Cook Islands, Fiji, Kiribati and Vanuatu, whose climate change knowledge often contrasts sharply with that of communities in the major centres ('core'). In the core, communities tend to be better informed and have higher levels of awareness about the complex issues associated with climate change than in the periphery (Nunn *et. al.*, 2013).

The issue of 'coastal squeeze' remains a concern for many small islands as there is a constant struggle to manage the requirements for physical development against the need to maintain ecological balance (Fish *et al.*, 2008; Gero *et al*., 2011; Mycoo, 2011). Martinique in the Caribbean exemplifies the point, where physical infrastructure prevents the beach and wetlands from retreating landward as a spontaneous adaptation response to increased rates of coastal erosion (Schleupner, 2008). Moreover, intensive coastal development in the limited coastal zone combined with population growth and tourism has placed great stress on the coast of some islands and has resulted in dense aggregations of infrastructure and people in potentially vulnerable locations.

Tourism is an important weather and climate-sensitive sector on many small islands and has been assessed on several occasions, including in previous IPCC assessments. There is currently no evidence that observed climatic changes in small island destinations or source markets have permanently altered patterns of demand for tourism to small islands, and the complex mix of factors that actually determines destination choices under a changing climate still need to be fully evaluated (Scott *et al.*, 2012a). However, there are cases reported that clearly show severe weather-related events in a destination country (e.g. heavy, persistent rainfall in Martinique: Hubner and Gössling, 2012; Hurricanes in Anguilla: Forster *et al*., 2012) can significantly influence visitors' perception of the desirability of the location as a vacation choice.

Climate can also impact directly on environmental resources that are major tourism attractions in small islands. Widespread resource degradation challenges such as beach erosion and coral bleaching have been found to negatively impact the perception of destination attractiveness in various locations, for example in Martinique (Schleupner, 2008), Barbados and Bonaire (Uyarra *et al*., 2005). Similarly dive tourists are well aware of coral bleaching, particularly the experienced diver segment (Gössling *et al*., 2012a; Klint *et al.*, 2012). Therefore more acute impacts are felt by tourism operators and resorts that cater to these markets. Houston (2002) and Buzinde *et al.* (2010) also indicate that beach erosion may similarly affect accommodation prices in some destinations. Consequently, some countries have begun to invest in a variety of resource restoration initiatives including artificial beach nourishment, coral and mangrove restoration and the establishment of marine parks and protected areas (McClanahan *et al*., 2008; Mycoo and Chadwick, 2012). There is no analysis of how widespread such investments are or their capability to cope effectively with future climate change. The tourism industry and investors are also beginning to consider the climate risk of tourism operations (Scott *et al.,* 2012b) including those associated with the availability of freshwater. Freshwater is limited on many small islands, and changes in its availability or quality during drought events linked to climate change have adverse impacts on tourism operations (UNWTO 2012). Tourism is a seasonally significant water user in many island destinations and in times of drought, concerns over limited supply for residents and other economic activities become heightened (Gössling *et al.*, 2012b). The increasing use of desalination plants is one adaptation to reduce the risk of water scarcity in tourism operations.

29.3.3.2. Observed Impacts on Human Health

Globally, the effects of climate change on human health will be both direct and indirect, and are expected to exacerbate existing health risks, especially in the most vulnerable communities where the burden of disease is already high (refer to Chapter 11.3, 11.5 and 11.6.1, this volume). Many small island states currently suffer from climate-sensitive health problems, including morbidity and mortality from extreme weather events, certain vector- and food- and water-borne diseases (Lozano, 2006; Barnett and Campbell, 2010; Cashman *et al.*,2010; Pulwarty *et al.*, 2010; McMichael and Lindgren, 2011). Extreme weather and climate events such as tropical cyclones, storm surges, flooding, and drought can have both short- and long-term effects on human health, including drowning, injuries, increased disease transmission, and health problems associated with deterioration of water quality and quantity. Most small island nations are in tropical areas with weather conducive to the transmission of diseases such as malaria, dengue, filariasis and schistosomiasis.

The linkages between human health, climate variability and seasonal weather have been demonstrated in several recent studies. The Caribbean has been identified as a 'highly endemic zone for leptospirosis' with Trinidad and Tobago, Barbados and Jamaica representing the highest annual incidence (12, 10 and 7.8 cases per 100,000 population) in the world with only the Seychelles being higher (43.2 per 100,000 population) (Pappas *et al.*, 2008). Studies conducted in Guadeloupe demonstrated a link between El Niño occurrence and leptospirosis incidence with rates increasing to 13 per 100,000 population in El Nino years as opposed to 4.5 cases per 100,000 inhabitants in La Niña and neutral years (Herrmann-Storck *et al.*, 2008). In addition, epidemiological studies conducted in Trinidad reviewed the incidence of leptospirosis during the period 1996-2007 and showed seasonal patterns in the occurrence of confirmed leptospirosis cases, with significantly ($P<0.001$) more cases occurring in the wet season, May to November (193 cases), than during the dry season, December to May (66 cases) (Mohan *et al*., 2009). Recently changes in the epidemiology of leptospirosis have been detected especially in tropical islands with the main factors being climatic and anthropogenic ones (Pappas *et al*., 2008). These factors may be enhanced with increases in ambient temperature and changes in precipitation, vegetation and water availability as a consequence of climate change (Russell, 2009).

In Pacific islands the incidence of diseases such as malaria and dengue fever has been increasing, especially endemic dengue in Samoa, Tonga and Kiribati (Russell, 2009). While studies conducted so far in the Pacific have only established a direct link between malaria, dengue and climate variability, these and other health risks including from cholera, are projected to increase as a consequence of climate change (Russell, 2009; refer also to Chapter 11.2.4 and 11.2.5 this volume, for detailed discussion on the link between climate change and projected increases in the outbreak of dengue and cholera). Dengue incidence is also a major health concern in other small island countries, including Trinidad and Tobago, Singapore, Cape Verde, Comoros and Mauritius (Chadee 2009; Koh *et al.,* 2008; Van Kleef *et al.,* 2010; Teles, 2011). In the specific cases of Trinidad and Tobago and Singapore the outbreaks have been significantly correlated with rainfall and temperature, respectively (Chadee *et al.,* 2007; Koh *et al.,* 2008).

Previous IPCC assessments have consistently shown that human health on islands can be seriously compromised by lack of access to adequate, safe, freshwater and adequate nutrition (Nurse *et al.*, 2001; Mimura *et al.*, 2007). Lovell (2011) notes that in the Pacific many of the anticipated health effects of climate change are expected to be indirect, connected to the increased stress and declining well-being that comes with property damage, loss of economic livelihood and threatened communities. There is also a growing concern in island communities in the Caribbean and Pacific and Indian oceans, that fresh water scarcity, more intense droughts and storms could lead to a deterioration in standards of sanitation and hygiene (Cashman *et al*., 2010; McMichael and Lindgren, 2011). In such circumstances, increased exposure to a range of health risks including communicable (transmissible) diseases would be a distinct possibility.

Ciguatera fish poisoning (CFP) occurs in tropical regions and is the most common non-bacterial food-borne illness associated with consumption of fish. Distribution and abundance of the organisms that produce these toxins, chiefly dinoflagellates of the genus *Gambierdiscus*, are reported to correlate positively with water temperature. Consequently, there is growing concern that increasing temperatures associated with climate change could increase the incidence of CFP in the island regions of the Caribbean (Morrison *et al.*, 2008; Tester *et al.*, 2010), Pacific (Rongo and van Woesik, 2011; Chan *et al.*, 2011), the Mediterranean *(*Aligizaki and Nikolaidis, 2008; refer also to section 29.5.5), and the Canary Islands in the Atlantic (Pérez-Arellano *et al*., 2005). A recent Caribbean study sought to characterise the relationship between sea surface temperatures (SSTs) and CFP incidence and to determine the effects of temperature on the growth rate of organisms responsible for CFP. Results from this work show that in the Lesser Antilles high rates occur in areas that experience the warmest water temperatures and which show the least temperature variability (Tester *et al*., 2010). There are also high rates in the Pacific in Tokelau, Tuvalu, Kiribati, Cook Islands and Vanuatu (Chan *et al*., 2011).

The influence of climatic factors on malaria vector density and parasite development is well established (Béguin *et al.,* 2011; Chaves and Koenraadt, 2010). Previous studies have assessed the potential influence of climate change on malaria, using deterministic or statistical models (Hay *et al.,* 2009; Martens *et al*., 1999; Parham and Michael, 2010; Pascual *et al*., 2006). While the present incidence of malaria on small islands is not reported to be high, favourable environmental and social circumstances for the spread of the disease are present in some island regions and are expected to be enhanced under projected changes in climate in Papua New Guinea, Guyana, Suriname and French Guyana **(**Michon *et al.*, 2007; Rawlins *et al.*, 2008; Figueroa, 2008). In the Caribbean, the occurrence of autochthonous malaria in non-endemic island countries in the last ten years suggests that all of the essential malaria transmission conditions now exist. Rawlins *et al*. (2008) call for enhanced surveillance, recognizing the possible impact of climate change on the spread of the anopheles mosquito vector and malaria transmission.

29.3.3.3. Observed Impacts of Climate Change on Relocation and Migration

Evidence of human migration as a response to climate change is scarce for small islands. While there is general agreement that migration is usually driven by multiple factors (Black et al., 2011), several authors highlight the lack of empirical studies of the effect of climate-related factors, such as sea-level rise, on island migration (Lilleør and Van den Broeck, 2011; Mortreux and Barnett, 2009). Furthermore, there is no evidence of any government policy that allows for climate ‘refugees’ from islands to be accepted into another country (Bedford and Bedford, 2010). This finding contrasts with the early desk-based estimates of migration under climate change such as the work of

Myers (2002). These early studies have been criticised as they fail to acknowledge the reality of climate impacts on islands, the capacity of islands and islanders to adapt, or the actual drivers of migration (Barnett and O'Neill, 2012).

Studies of island migration commonly reveal the complexity of a decision to migrate and rarely identify a single cause. For example, when looking at historical process of migration within the Mediterranean it appears that rising levels of income, coupled with a decreased dependence on subsistence agriculture has left the Mediterranean less vulnerable to all environmental stressors, resulting in a reduced need for mobility to cope with environmental or climatic change (de Haas, 2011). Studies from the Pacific have also shown that culture, lifestyle and a connection to place are more significant drivers of migration than climate (Barnett and Webber, 2010). For example, a Pacific Access Category of migration has been agreed between New Zealand and Tuvalu that permits 75 Tuvaluans to migrate to New Zealand every year (Kravchenko, 2008). Instead of enabling climate driven migration, this agreement is designed to facilitate economic and social migration as part of the Pacific island lifestyle (Shen and Gemenne, 2011). To date there is no unequivocal evidence that reveals migration from islands is being driven by anthropogenic climate change.

There is however some evidence that environmental change has played a role in Pacific Island migration in the past (Nunn, 2007). In the Pacific environmental change has been shown to affect land use and land rights, which in turn have become drivers of migration (Bedford and Bedford, 2010). In a survey of 86 case studies of community relocations in Pacific islands, Campbell *et al*. (2005) found that environmental variability and natural hazards accounted for 37 communities relocating. In the Pacific, where land rights are a source of conflict, climate change could increase levels of stress associated with land rights and impact on migration (Campbell, 2010; Weir and Virani, 2011). While there is not yet a climate fingerprint on migration and resettlement patterns in all small islands, it is clear that there is the potential for human movement as a response to climate change. To better understand the impact of climate change on migration there is an urgent need for robust methods to identify and measure the effects of the drivers of migration on migration and resettlement.

29.3.3.4. Observed Impacts on Island Economies

The economic and environmental vulnerabilities of small islands states are well documented (Briguglio *et al.,* 2009, Bishop, 2012). Such vulnerabilities, which render the states at risk of being harmed by economic and environmental conditions, stem from intrinsic features of these vulnerable states, and are not usually governance induced. However, governance does remain one of the challenges for island countries in the Pacific in the pursuit of sustainable development through economic growth (Prasad, 2008). Economic vulnerability is often the result of a high degree of exposure to economic conditions often outside the control of small island states, exacerbated by dependence on a narrow range of exports and a high degree of dependence on strategic imports, such as food and fuel (Briguglio *et al.,* 2009). This leads to economic volatility, a condition that is harmful for the economy of the islands (Guillaumont, 2010).

There are other economic downsides associated with small size and insularity. Small size leads to high overhead cost per capita, particularly in infrastructural outlays. This is of major relevance to climate change adaptation that often requires upgrades and redesign of island infrastructure. Insularity leads to high cost of transport per unit, associated with purchases of raw materials and industrial supplies in small quantities, and sales of local produced products to distant markets. These disadvantages are associated with the inability of small islands to reap the benefits of economies of scale resulting in a high cost of doing business in small islands (Winters and Martins, 2004).

High costs are also associated with the small size of island states when impacted by extreme events such as hurricanes and droughts. On small islands such events often disrupt most of the territory, especially on single-island states, and have a very large negative impact on the state’s GDP, in comparison with larger and more populous states where individual events generally only affect a small proportion of the country and have a small impact on its GDP (Anthoff *et al.*, 2010). Moreover, the dependence of many small islands on a limited number of economic sectors such as tourism, fisheries and agricultural crops, all of which are climate-sensitive, means that on the one hand climate change adaptation is integral to social stability and economic vitality but that government adaptation efforts are constrained because of the high cost on the other.

29.3.4. Detection and Attribution of Observed Impacts of Climate Change on Small Islands

While exceptional vulnerability of many small islands to future climate change is widely accepted, the foregoing analysis indicates that the scientific literature on observed impacts is quite limited. Detection of past and recent climate change impacts is challenging due to the presence of other anthropogenic drivers, especially in the constrained environments of small islands. Attribution is further challenged by the strong influence of natural climate variability compared to gradual incremental change of climate drivers. Notwithstanding these limitations a summary of the relationship between detection and attribution to climate change of several of the phenomena described in the above sections has been prepared. Figure 29-2 reflects the degree of confidence in the linkage between observed changes in several components of the coastal, terrestrial and human systems of small islands and the drivers of climate change.

[INSERT FIGURE 29-2 HERE
Figure 29-2: A comparison of the degree of confidence in the detection of observed impacts of climate change on tropical small islands with the degree of confidence in attribution to climate change drivers at this time. For example, the blue symbol No. 2 (Coastal Systems), indicates there is *very high confidence* in both the detection of 'sea-level rise consistent with global means' and its attribution to climate change drivers; whereas the red symbol No. 17 (Human Systems) indicates whilst detection of 'casualties and damage during extreme events' is *very high*, there is presently *low confidence* in the attribution to climate change. It is important to note that *low confidence* in attribution frequently arises due to the limited research available on small island environments.]

29.4. Projected Integrated Climate Change Impacts

Small islands face many challenges in using climate change projections for policy development and decision-making (Keener *et al*., 2012). Among these is the inaction inherent in the mismatch of the short-term time scale on which government decisions are generally taken compared with the long-term time scale required for decisions related to climate change. This is further magnified by the general absence of credible regional socio-economic scenarios relevant at the spatial scale at which most decisions are taken. Scenarios are an important tool to help decision makers disaggregate vulnerability to the direct physical impacts of the climate signal from the vulnerability associated with socio-economic conditions and governance. There is however a problem in generating formal climate scenarios at the scale of small islands since they are generally much smaller than the resolution of the global climate models. This is because the grid squares in the Global Circulation Models (GCMs) used in the SRES scenarios over the last decade, were between 200 and 600 km^2 that provides inadequate resolution over the land areas of most small islands. This has recently improved with the new RCP scenario GCMs with grid boxes generally between 100 and 200 km^2 in size.

The scale problem has been usually addressed by the implementation of statistical downscaling models that relate GCM output to the historical climate of a local small island datapoint. The limitation of this approach is the need for observed data ideally for at least three decades for a number of representative points on the island, in order to establish the statistical relationships between GCM data and observations. In most small islands long-term quality-controlled climate data are generally sparse, so that in widely dispersed islands such as in the Pacific, observational records are usually supplemented with satellite observations combined with dynamical downscaling computer models (Australian Bureau of Meteorology [ABoM] and CSIRO, 2011a; Keener *et al*., 2012). However where adequate local data are available for several stations for at least 30 years, downscaling techniques have demonstrated that they can provide projections at fine scales ranging from about 10 – 25 km^2 (e.g. Charlery and Nurse, 2010; ABoM and CSIRO, 2011a). Even so, most projected changes in climate for the Caribbean, Pacific, Indian Ocean and Mediterranean islands, generally apply to the region as a whole and this may be adequate to determine general trends in regions where islands are close together.

29.4.1. Non-Formal Scenario-Based Projected Impacts

Scenarios are often constructed by using a qualitative or broad order of magnitude climate projections approach based on expected changes in some physical climate signal from literature review rather than projections based on direct location specific modelling. Usually this is proposed as a 'what if' question which is then quantified using a numerical method. For example in the Pacific, digital elevation models of Fiji's islands have been used to identify high risk areas for flooding based on six scenarios for sea-level rise from 0.09 to 0.88 m in combination with six scenarios for storm surge with return intervals from 1 to 50 years (Gravelle and Mimura, 2008). Another example of qualitative modelling from the Pacific is a case study from Nauru which uses local data and knowledge of climate to assess the GCM projections. It suggests that Nauru should plan for continued ENSO variability in the future with dry years during La Niña and an overall increase in mean rainfall and extreme rainfall events. Climate adaptation concerns which arise include water security and potential changes in extreme wet events which affect infrastructure, and human health (Brown *et al.,* 2013a). Climate change also poses risks for food security in the Pacific islands, including agriculture and fisheries (Barnett, 2011) Projections have also been used in the islands of the Republic of Baharain to estimate proness to inundation for sea-level rise of 0.5, 1.0 and 1.5 m (Al-Jeneid *et al*., 2008). Similarly, in the Caribbean the elevation equivalent of a projected sea-level rise of 1 m has been superimposed on topographic maps to estimate that 49-60% of tourist resort properties would be damaged, potentially transforming the competitive position and sustainability of coastal tourism destinations in the region (Scott *et al*., 2012c). This method has also been used to quantify the area loss for over 12 900 islands and over 3000 terrestrial vertebrates in the tropical Pacific region for three sea-level rise scenarios. The study estimated that for sea-level rise of 1 m, 37 island endemic species in this region risk complete inundation (Wetzel *et al*., 2013).

29.4.2. Projected Impacts for Islands based on Scenario Projections

Another approach to scenario development is to use the region specific projections more directly. It is worth noting that the broad synthesis in the AR4 of medium emissions climate scenario projections for small island regions (Mimura *et al*., 2007) shows concordance with the new RCP scenarios (see Table 29-1 and new RCP projections in Figure 29-3). For example, the SRES A1B medium emissions scenario suggests about a 1.8 to 2.3 °C median annual increase in surface temperature in the Caribbean, Indian Ocean and Pacific Ocean small islands regions by 2100 compared to a 1980-1999 baseline, with an overall annual decrease in precipitation of about 12% in the Caribbean (Table 11.1 in AR4 WG1; AR5 WG 1, 14.7.4) and a 3-5 per cent increase in the Indian and Pacific Oceans small island regions. Comparative projections for the new RCP4.5 scenario suggests about a 1.2 to 2.3 °C increase in surface temperature by 2100 compared to a 1986-2005 baseline and a decrease in precipitation of about 5 or 6 per cent in the Caribbean and Mediterranean respectively signaling potential future problems for agriculture and water availability compared to a 1-9 per cent increase in the Indian Ocean and Pacific Ocean small islands regions (Table 29.1). However, there are important spatial and high-island topography differences. Thus for example, among the more dispersed Pacific islands where the equatorial regions are *likely* to get wetter and the sub-tropical high pressure belts drier (as reported by AR5 WG I) in regions directly affected by the South Pacific Convergent Zone (SPCZ) and western portion of the Inter-Tropical Convergent Zone (ITCZ), the rainfall outlook is uncertain (AR5 WG1, 14.7.13). Projections for the Mediterranean islands also differ from those for the tropical small islands. Throughout the Mediterranean region, the length, frequency, and/or intensity of warm spells or heat waves are *very likely* to increase to the year 2100 (AR5 WGI, 14.7.6). Sea-level rise projections in the small islands regions for RCP4.5 are similar to the global projections of 0.41 to 0.71m (WGI AR5 13.5.1) ranging from 0.5-0.6 m by 2100 compared to 1986-2005 in the Caribbean, Pacific and Indian Ocean to 0.4-0.5 m in the Mediterranean and North Indian Ocean (Table 29-1).

[INSERT TABLE 29-1 HERE
Table 29-1: Climate change projections for the intermediate low (500-700 ppm CO_2-e) RCP4.5 scenario for six Small Islands regions. The table shows the 25th, 50th (median) and 75th percentiles for surface air temperature and precipitation based on averages from 42 CMIP5 global models (adapted from WGI AR5 Table 14.1). Mean net regional sea-level change is evaluated from 21 CMIP5 models and includes regional non-scenario components (adapted from WGI AR5 Figure 13-20).]

In the main regions in which most tropical or sub-tropical small island states are located, there are few independent peer reviewed scientific publications providing downscaled climate data projections, and even less illustrating the experience gained from their use for policy making. A possible 2 °C temperature increase by the year 2100 has potentially far reaching consequences for sentinel ecosystems such as coral reefs that are important to tropical islands (see Chapter 6.2.2.4.4.). This is because 'Degree Heating Months' (DHM) >2 °C-month are the determining threshold for severe coral bleaching (Donner, 2009). For example in a study of sea surface temperature (SST) across all coral reef regions using GCM ensemble projections forced with five different SRES future emissions scenarios, Donner (2009) concluded that even warming in the future from the current accumulation of greenhouse gases in the atmosphere could cause over half of the world's coral reefs to experience harmfully frequent thermal stress by 2080. Further, this timeline could be brought forward to as early as 2030 under the A1B medium emissions scenario. He further stated that thermal adaptation of 1.5 °C would only delay the thermal stress forecast by 50–80 years. Donner (2009) also estimated the year of likelihood of a severe mass coral bleaching event due more than once every 5 years, to be 2074 in the Caribbean, 2088 in the western Indian Ocean, 2082 in the central Indian Ocean, 2065 in Micronesia, 2051 in the central Pacific, 2094 in Polynesia and 2073 in the eastern Pacific small islands regions. Using the new RCP scenarios by comparison, van Hooidonk *et al*. (2013) found that the onset of annual bleaching conditions is associated with about 510 ppm CO^2 equivalent. The conclusion based on outputs from a wide range of emissions scenarios and models is that preserving >10 per cent of coral reefs worldwide would require limiting warming to less than 1.5±1.3 °C compared to pre-industrial levels (Frieler *et al*., 2013).

Small island economies can also be objectively shown to be at greater risk from sea-level rise in comparison to other geographic areas since most of their population and infrastructure are in the coastal zone. This is demonstrated in a study using the Climate Framework for Uncertainty, Negotiation and Distribution (FUND) model to assess the economic impact of substantial sea-level rise in a range of socio-economic scenarios downscaled to the national level, including the four SRES storylines (Anthoff *et al*., 2010). Although this study showed that in magnitude, a few regions will experience most of the absolute costs of sea-level rise by 2100, especially East Asia, North America, Europe and South Asia, these same results when expressed as percent of GDP showed that most of the top ten and four of the top five most impacted are small islands from the Pacific (Federated States of Micronesia, Palau, Marshall Islands, Nauru) and Caribbean (Bahamas). The point is made that the damage costs for these small island states are enormous in relation to the size of their economies (Nicholls and Tol, 2006) and that together with deltaic areas they will find it most difficult to locally raise the finances necessary to implement adequate coastal protection (Anthoff *et al*., 2010).

In the Caribbean, downscaled climate projections have been generated for some islands using the Hadley Centre PRECIS regional model (Taylor *et al*., 2007; Stephenson *et al*., 2008). For the SRES A2 and B2 scenarios the PRECIS regional climate model projects an increase in temperature across the Caribbean of 1–4 °C compared to a 1960-1990 baseline, with increasing rainfall during the latter part of the wet season from November–January, in the northern Caribbean (i.e. north of 22°N) and drier conditions in the southern Caribbean linked to changes in the Caribbean Low Level Jet (CLLJ) with a strong tendency to drying in the traditional wet season from June–October (Whyte *et al*., 2008; Campbell *et al*., 2011; Taylor *et al*., 2013). Projected lengthening seasonal dry periods, and increasing frequency of drought are expected to increase demand for water throughout the region under the SRES A1B scenario (Cashman *et al*., 2010). Decrease in crop yield is also projected in Puerto Rico for the SRES B1 (low), A2 (mid-high) and A1F1 scenarios during September although increased crop yield is suggested during February (Harmsen *et al*., 2009). Using a tourism demand model linked to the SRES A1F1 A2 B1 and B2 scenarios, the projected climate change heating and drying impacts are also linked to potential aesthetic, physical and thermal effects that are estimated to cause a change in total regional tourist expenditure of about +321, +356, -118 and -146 million US dollars from the least to the most severe emissions scenario respectively (Moore, 2010).

In the Indian Ocean, representative downscaled projections have been generated for Australia's two Indian Ocean territories, the Cocos (Keeling) Islands and Christmas Island using the CSIRO Mark 3.0 climate model with the SRES A2 high emissions scenario (Maunsell Australia Pty Ltd., 2009). Future climate change projections for the two islands for 2070 include an approximate 1.8 °C increase in air temperature by 2070, probable drier dry seasons and wet seasons, about a 40 cm rise in sea-level and a decrease in the number of intense tropical cyclones.

In the western tropical Pacific, extensive climate projections have been made for several Pacific Island Countries based on downscaling from an ensemble of models (ABoM and CSIRO, 2011b). The temperature projections in this region dominated by oceans seem less than those seen globally, ranging from +1.5 to 2.0 °C for the B1 low emissions scenario to +2.5 to 3.0 °C for the A2 high emissions scenario by the year 2090 relative to a 20 year period centred on 1990. Notably, extreme rainfall events that currently occur once every 20 years on average are generally simulated to occur four times per 20-year period, on average, by 2055 and seven times per 20-year period, on average, by 2090 under the A2 (high emissions) scenario (ABoM and CSIRO, 2011b). The results are not very different from the tropical Pacific RCP4.5 projections with projected temperature increases of about +1.2 to 1.4 °C by 2100 and an increase in rainfall of about 4% (Table 29-1). A comprehensive assessment of the vulnerability of the fisheries and aquaculture sectors to climate change in 22 Pacific island countries and territories focused on two future time-frames (2035 and 2100) and two SRES emissions scenarios, B1 (low emissions) and A2 (high emissions) (Bell *et al*., 2013). Many anticipated changes in habitat and resource availability such as coral reef-based fisheries are negative. By contrast, projected changes in tuna fisheries and freshwater aquaculture/fisheries can be positive with implications for government revenue and island food security (Bell *et al*., 2013). Simulation studies on changes in stocks of skipjack and bigeye tuna in the tropical Pacific area summarized in Table 29-2 and also discussed in 7.4.2.1 and 30.6.2.1.1. Some of these projected changes may favour the large international fishing fleets that can shift operations over large distances compared to local, artisanal fishers (Polovina *et al*., 2011).

[INSERT TABLE 29-2 HERE
Table 29-2: Summary of projected percentage changes in tropical Pacific tuna catches by 2035 and 2100 relative to 1980-2000 and the estimated resulting percentage changes to government revenue (After Bell *et al.*, 2011).]

In the Mediterranean islands of Mallorca, Corsica, Sardinia, Crete and Lesvos, Gritti *et al*. (2006) simulated the terrestrial vegetation biogeography and distribution dynamics under the SRES A1F1 and B1 scenarios to the year 2050. The simulations indicate that the effects of climate change are expected to be negligible within most ecosystems except for mountainous areas. These areas are projected to be eventually occupied by exotic vegetation types from warmer, drier conditions. Cruz *et al*. (2009) report similar results for the terrestrial ecosystems of Madeira Island in the Atlantic. Downscaled SRES A2 and B2 scenarios for the periods 2040 – 2069 and 2070 – 2099 suggest that the higher altitude native humid forest called the Laurissilva, may expand upwards in altitude, which could lead to a severe reduction of the heath woodland which because it has little upward area to shift may reduce in range or disappear at high altitudes resulting in the loss of rare and endemic species within this ecosystem.

29.4.3. RCP Projections and Implications for Small Islands

Utilizing updated historical greenhouse gas emissions data the scientific community has produced future projections for four plausible new global Representative Concentration Pathways (RCPs) in order to explore a range of global climate signals up to the year 2100 and beyond (e.g. Moss *et al*., 2010). Typical model ensemble representations of low, intermediate low, intermediate high and high RCP projections for annual temperature and precipitation in some small islands regions are presented in Figure 29-3. Highlighted in Figure 29-3 is the ensemble mean of each RCP. A more comprehensive compilation of quarterly global RCP projections can be found in the Annex I Atlas of Global and Regional Climate Projections in the WGI AR5 Report.

[INSERT FIGURE 29-3 HERE
Figure 29-3: Time series of RCP scenarios annual projected temperature and precipitation change relative to 1986-2005 for six small islands regions (using regions defined in AR5 WG1, Annex 1: Atlas of Global and Regional Climate Projections).] Thin lines denote one ensemble member per model, thick lines the CMIP5 multi-model mean. On the right-hand side the 5th, 25th, 50th (median), 75th and 95th percentiles of the distribution of 20-yr mean changes are given for 2081–2100 in the four RCP scenarios. Note that the model ensemble averages in the figure are for grid points over wide areas and encompass many different climate change signals. To get projections for a specific location and time period use the maps in the Atlas or the online interactive version at but please note that in regions with small islands the models basically simulate the climate of the surrounding ocean and local conditions on land may differ.]

During negotiations towards a new multi-lateral climate change regime Small Island Developing States (SIDS) have advocated that any agreement should be based on Global Mean Surface Temperature (GMST) increase 'well below' 1.5 °C above pre-industrial levels (Hare *et al*., 2011; Riedy and McGregor, 2011). Inspection of column 1 in Figure 29-3 suggests that for the Caribbean, Indian Ocean and Pacific SIDS in the tropics, the median projected regional increase is in the range 0.5-0.9 °C by 2100 compared to 1986-2005. This together with the temperature change that has already occurred since the industrial revolution suggests that a temperature 'well below' 1.5 °C is unlikely to be achieved with the lowest RCP2.6 projection (Peters *et al.*, 2013). By comparison temperature projections for the intermediate low RCP4.5 scenario, Table 29-1 and Figure 29-3 suggest possible 1.2-1.5 °C temperature increases in Caribbean, Indian Ocean and Pacific SIDS by 2100 compared to 1986-2005. Similarly, the projections for the Mediterranean would be about a 2.3 °C increase by 2100 compared to 1986-2005 that would represent a 2.7 °C increase compared to pre-industrial temperatures. Associated with this change, the Caribbean and Mediterranean regions may experience a noticeable decrease in mean rainfall while the Indian and Pacific Ocean SIDS may experience increased rainfall. These trends accelerate moderately for RCP 6.0 and steeply for RCP 8.5 (Table 29-1).

29.5. Inter- and Intra-Regional Trans-Boundary Impacts on Small Islands

Available literature since AR4 has highlighted previously less well understood impacts on small islands that are generated by processes originating in another region or continent well beyond the borders of an individual archipelagic nation or small island. These are inter-regional trans-boundary impacts. Intra-regional trans-boundary impacts originate from a within-region source (e.g. within the Caribbean). Some trans-boundary processes may have positive effects on the receiving small island or nation, though most that are reported have negative impacts. Deciphering a climate change signal in inter- and intra-regional trans-boundary impacts on small islands is not easy and usually involves a chain of linkages tracing back from island-impact to a distant climate or climate-related bio-physical or human process. Some examples are given below.

29.5.1. Large Ocean Waves from Distant Sources

Unusually large deep ocean swells, generated from sources in the mid- and high-latitudes by Extra-Tropical Cyclones (ETC) cause considerable damage on the coasts of small islands thousands of kilometres away in the tropics. Impacts include sea-flooding and inundation of settlements, infrastructure and tourism facilities as well as severe erosion of beaches (see also 5.4.3.4). Examples from small islands in the Pacific and Caribbean are common though perhaps the most significant instance, in terms of a harbinger of climate change and sea-level rise, occurred in the Maldives in April 1987 when long period swells originating from the Southern Ocean some 6000 km away caused major flooding, damage to property, destruction of sea defences and erosion of reclaimed land and islands (Harangozo, 1992). The Maldives and several other island groups in the Indian Ocean have been subject to similar ocean swell events more recently, most notably in May 2007 (Department of Meteorology, 2007).

In the Caribbean, northerly swells affecting the coasts of islands have been recognized as a significant coastal hazard since the 1950s (Donn and McGuinness, 1959). They cause considerable seasonal damage to beaches, marine ecosystems and coastal infrastructure throughout the region (Cambers, 2009; Bush *et al.*, 2009). These high-energy events manifest themselves as long period high-amplitude waves that occur during the northern hemisphere winter and often impact the normally sheltered, low-energy leeward coasts of the islands. Such swells have even reached the shores of Guyana on the South American mainland as illustrated by a swell event in October 2005 that caused widespread flooding and overtopping and destruction of sea defences (van Ledden *et al.*, 2009).

Distant origin swells differ from the 'normal' wave climate conditions experienced in the Caribbean, particularly with respect to direction of wave approach, wave height and periodicity and in their morphological impact (Cooper *et al.*, 2013). Swells of similar origin and characteristics also occur in the Pacific (Fletcher *et al.*, 2008; Keener *et al.*, 2012). These events frequently occur in the Hawaiian island where there is evidence of damage to coral growth by swell from the north Pacific, especially during years with a strong El Nino signal (Fletcher *et al*., 2008). Hoeke *et al*. (2013) describe inundation from mid-high latitude north and south Pacific waves respectively at Majuro (Marshall

Islands) in November and December 1979 and along the Coral Coast (Fiji) in May 2011. They also describe in detail an inundation event in December 2008 that was widespread throughout the western and central Pacific and resulted in waves surging across low-lying islands causing severe damage to housing and infrastructure and key natural resources that affected about 100,000 people across the region. The proximate cause of this event was swell generated in mid-latitudes of the North Pacific Ocean, more than 4000 km from the furthest affected island (Hoeke *et al.*, 2013).

Whereas the origin of the long period ocean swells that impact small islands in the tropical regions come from the mid-and high-latitudes in the Pacific, Indian and Atlantic oceans, there are also instances of unusually large waves generated from tropical cyclones that spread into the mid- and high- latitudes. One example occurred during 1999 when tide gauges at Ascension and St. Helena Islands in the central south Atlantic recorded unusually large deep-ocean swell generated from distant Hurricane Irene (Vassie *et al*., 2004). The impacts of increasing incidence or severity of storms or cyclones is generally considered from the perspective of direct landfall of such systems, whereas all of these instances serve to show 'the potential importance of swells to communities on distant, low-lying coasts, particularly if the climatology of swells is modified under future climate change' (Vassie *et al*., 2004). From the perspective of those islands that suffer damage from this coastal hazard on an annual basis, this is an area that warrants further investigation. Projected changes in global wind-wave climate to 2070-2100, compared to a base period 1979-2009, show considerable regional and seasonal differences with both decreases and increases in annual mean significant wave height. Of particular relevance in the present context is the projected increase in wave activity in the Southern Ocean which influences a large portion of the global ocean as swell waves propagate northwards into the Pacific, Indian and Atlantic oceans (Hemer *et al.*, 2013).

Deep ocean swell waves and elevated sea-levels resulting from ETCs are examples of *inter-regional* trans-boundary processes; locally generated Tropical Cyclones (TCs) provide examples of *intra-regional* trans-boundary processes. Whilst hurricane force winds, heavy rainfall and turbulent seas associated with TCs can cause massive damage to both land and coastal systems in tropical small islands, the impacts of sea waves and inundation associated with far distant ETCs are limited to the coastal margins. Nevertheless both storm types result in a range of impacts covering island morphology, natural and ecological systems, island economies, settlements and human well-being (see Figure 29-4).

[INSERT FIGURE 29-4 HERE
Figure 29-4: Tropical and extra-tropical cyclone impacts on the coasts of small islands. Four types of impacts are distinguished here, black arrows showing the connections between them, based on the existing literature. An example of the chain of impacts associated with two extra-tropical cyclones centred to the east of Japan is illustrated by the red arrows. Swell waves generated by these events in December 2008 reached islands in the southwest Pacific and caused extensive flooding (3) that impacted soil quality (8), freshwater resources (9), and damaged crops (10), buildings (15), and transport facilities (16) in the region (Example based on Hoeke *et al*., 2013).

29.5.2. Trans-Continental Dust Clouds and their Impact

The transport of airborne Saharan dust across the Atlantic and into the Caribbean has engaged the attention of researchers for some time. The resulting dust clouds are known to carry pollen, microbes, insects, bacteria, fungal spores and various chemicals and pesticides (Prospero *et al*., 2005; Middleton *et al*., 2008; Monteil, 2008; López-Villarrubia *et al*., 2010; Garrison *et al*., 2006). During major events, dust concentrations can exceed 100 µg m^{-3} (Prospero, 2006). Independent studies using different methodologies have all found a strong positive correlation between dust levels in the Caribbean and periods of drought in the Sahara, while concentrations show a marked decrease during periods of higher rainfall. Consequently, it is argued that higher dust emissions due to increasing aridity in the Sahel and other arid areas could enhance climate change effects over large areas, including the eastern Caribbean and the Mediterranean (Prospero and Lamb, 2003). Similar findings have been reported at Cape Verde where dust emission levels were found to be a factor of nine lower during the decade of the 1950s when rainfall was at or above normal, compared to the 1980s, a period of intense drought in the Sahel region (Nicoll *et al*., 2011). Dust from the Sahara has also reached the eastern Mediterranean (e.g. Santese *et al*., 2010) whilst dust from Asia has been transported across the Pacific and Atlantic oceans and around the world (Uno *et al*., 2009).

There is also evidence that the trans-boundary movement of Saharan dust into the island regions of the Caribbean, Pacific and Mediterranean is associated with various human health problems (Griffin, 2007) including asthma admissions in the Caribbean (Monteil, 2008; Monteil and Antoine, 2009; Prospero *et al*., 2008), cardiovascular morbidity in Cyprus in the Mediterranean (Middleton *et al.*, 2008) and is found to be a risk factor in respiratory and obstructive pulmonary disease in the Cape Verde islands (Martins *et al*., 2009). These findings underscore the need for further research into the link between climate change, airborne aerosols and human health in localities such as oceanic islands far distant from the continental source of the particulates.

29.5.3. Movement and Impact of Introduced and Invasive Species across Boundaries

Invasive species are coloniser species that establish populations outside their normal distribution ranges. The spread of invasive alien species is regarded as a significant trans-boundary threat to the health of biodiversity and ecosystems, and has emerged as a major factor in species decline, extinction and loss of biodiversity goods and services worldwide. This is particularly true of islands, where both endemicity and vulnerability to introduced species tend to be high (Kenis *et al.*, 2009; Reaser *et al*., 2007; Westphal *et al*., 2008; Rocha *et al*., 2009; Kueffer *et al*., 2010). The extent to which alien invasive species successfully establish themselves at new locations in a changing climate will be dependent on many variables, but non-climate factors such as ease of access to migration pathways, suitability of the destination, ability to compete and adapt to new environments, and susceptibility to invasion of host ecosystems are deemed to be critical. This is borne out for example by Le Roux *et al*. (2008) who studied the effect of the invasive weed *Miconia calvescens* in New Caledonia, Society Islands and Marquesas Islands; by Gillespie *et al.* (2008) in an analysis of the spread of *Leucaena leucocephala*, *Miconia calvescens*, *Psidium sp*. and *Schinus terebinthifolius* in the Hawaiian islands; and by Christenhusz and Toivonen (2008) who showed the potential for rapid spread and establishment of the oriental vessel fern, *Angiopteris evecta*, from the South Pacific throughout the tropics. Mutualism between an invasive ant and locally honeydew-producing insects has been strongly associated with damage to the native and functionally important tree species, *Pisonia grandis* on Cousine Island, Seychelles (Gaigher, *et al*., 2011).

Whilst invasive alien species constitute a major threat to biodiversity in small islands, the removal of such species can result in recovery and return of species richness. This has been demonstrated in Mauritius by Baider and Florens (2011) where some forested areas were weeded of alien plants and after a decade the forest had recovered close to its initial condition, They concluded, given the severity of alien plant invasion in Mauritius, that their example can 'be seen as a relevant model for a whole swath of other island nations and territories around the world particularly in the Pacific and Indian Oceans' (Baider and Florens, 2011).

The movement of aquatic and terrestrial invasive fauna within and across regions will almost certainly exacerbate the threat posed by climate change in island regions, and could impose significant environmental, economic and social costs. Recent research has shown that the invasion of the Caribbean Sea by the Indo-Pacific lionfish (*Pterois volitans*), a highly efficient and successful predator, is a major contributor to observed increases in algal dominance in coral and sponge communities in the Bahamas and elsewhere in the region. The consequential damage to these ecosystems has been attributed to a significant decline in herbivores due to predation by lionfish (Schofield, 2010; Albins and Hixon, 2008; Lesser and Slattery, 2011; Green *et al.*, 2011). While there is no evidence that the lionfish invasion is climate-related, the concern is that when combined with pre-existing stress factors the natural resilience of Caribbean reef communities will decrease (Albins and Hixon, 2013; Green *et al*., 2012), making them more susceptible to climate change effects such as bleaching. Englund (2008) has documented the negative effects of invasive species on native aquatic insects on Hawai'i and French Polynesia, and their potential role in the extirpation of native aquatic invertebrates in the Pacific. Similarly, there is evidence that on the island of Oahu introduced slugs appear to be 'skewing species abundance in favour of certain non-native and native plants', by altering the 'rank order of seedling survival rates', thereby undermining the ability of preferred species (e.g. the endangered *C. Superba*) to compete effectively (Joe and Daehler, 2008).

29.5.4. Spread of Aquatic Pathogens within Island Regions

The mass mortality of the black sea urchin, *Diadema antillarum*, in the Caribbean basin during the early 1980s demonstrates the ease with which ecological threats in one part of a region can be disseminated to other jurisdictions thousands of kilometres away. The die-off was first observed in the waters off Panama around January 1983, and within 13 months the disease epidemic had spread rapidly through the Caribbean Sea affecting practically all island reefs, as far away as Tobago some 2000 km to the south and Bermuda, some 4000 km to the east. The diadema population in the wider Caribbean declined between 90-95 per cent as a consequence of this single episode (Lessios, 1988, 1995) As *D. antillarum* is one of the principal grazers that removes macroalgae from reefs and thus promotes juvenile coral recruitment, the collateral damage was severe, as the region's corals suffered from high morbidity and mortality for decades thereafter (Carpenter and Edmunds, 2006; Idjadi *et al*., 2010).

There are other climate-sensitive diseases such as yellow, white and black band, white plague and white pox that travel across national boundaries and infect coral reefs directly. This is variously supported by examples from the Indo-Pacific and Caribbean relating to the role of bacterial infections in white syndrome and yellow band disease (Piskorska *et al*., 2007; Cervino *et al*., 2008), the impact of microbial pathogens as stressors on benthic communities in the Mediterranean associated with warming seawater (Danovaro *et al*., 2009, and an increasing evidence of white, yellow and black band disease associated with Caribbean and Atlantic reefs (Rosenberg *et al*., 2009; Brandt and McManus, 2009; Miller *et al.*, 2009a; Weil and Croquer, 2009; Weil and Rogers, 2011).

29.5.5. Trans-Boundary Movements and Human Health

For island communities the trans-boundary implications of existing and future human health challenges are projected to increase in a changing climate. For instance, the aggressive spread of the invasive giant African snail, *Achatina fulica*, throughout the Caribbean, Indo-Pacific islands and Hawai'i is not only assessed to be a severe threat to native snails and other fauna (e.g. native gastropods), flora and crop agriculture, but is also identified as a vector for certain human diseases such as meningitis (Reaser *et al*., 2007; Meyer *et al*., 2008; Thiengo *et al*., 2010).

Like other aquatic pathogens, ciguatoxins that cause ciguatera fish poisoning may be readily dispersed by currents across and within boundaries in tropical and sub-tropical waters. Ciguatoxins are known to be highly temperature-sensitive and may flourish when certain sea water temperature thresholds are reached, as has been noted in the South Pacific (Llewellyn, 2010), Cook Islands (Rongo and van Woesik, 2011), Kiribati (Chan *et al*., 2011), the Caribbean and Atlantic (Otero *et al*., 2010; Tester *et al*., 2010) and Mediterranean (Aligizaki and Nikolaidis, 2008) (see also 29.3.3.2).

29.6. Adaptation and Management of Risks

Islands face risks from both climate-related hazards that have occurred for centuries, as well as new risks from climate change. There have been extensive studies of the risks associated with past climate-related hazards and adaptations to these, such as tropical cyclones, drought, and disease, and their attendant impacts on human health, tourism, fisheries and other areas (Bijlsma *et al*., 1996; Cronk 1997; Solomon and Forbes 1999; Pelling and Uitto 2001). There have also been many studies that have used a variety of vulnerability, risk and adaptation assessment methods particularly in the Pacific that have recently been summarized by Hay *et al*., (2013). But for most islands, there is very little published literature documenting the probability, frequency, severity or consequences of climate change risks such as sea-level rise, ocean acidification, and salinisation of freshwater resources – or associated adaptation measures. Projections of future climate change risks are limited by: the lack of model skill in projecting the climatic variables that matter to small islands, notably: tropical cyclone frequency and intensity, wind speed and direction, precipitation, sea-level, ocean temperature and ocean acidification (Brown *et al*., 2013b); inadequate projections of regional sea levels (Willis and Church, 2012), and a lack of long term baseline monitoring of changes in climatic risk, or to ground-truth models (Voccia, 2012), such as risk of saline intrusion, risk of invasive species, risk of biodiversity loss, or risk of large ocean waves. In their absence, qualitative studies have documented perceptions of change in current risks (Fazey *et al.*, 2011; Lata and Nunn, 2012), reviewed effective coping mechanisms for current stressors (Bunce *et al*. 2009; Campbell et al., 2011) and have considered future scenarios of change (Weir and Virani 2011). These studies highlight that change is occurring, but they do not quantify the probability, speed, scale or distribution of future climate risks. The lack of quantitative published assessments of climate risk for many small islands means that future adaptation decisions have to rely on analogues of responses to past and present weather extremes and climate variability, or assumed/hypothesised impacts of climate change based on island type (Table 29-3). Differences in island type and differences in exposure to climate forcing and hazards vary with island form that provides a framework for consideration of vulnerability and adaptation strategies. Critical is a place-based understanding of island landscapes and of processes operating on individual islands (Forbes *et al.*, 2013).

[INSERT TABLE 29-3 HERE
Table 29-3: Summary of island types in the Pacific region and implications for hydro-meteorological hazards.]

29.6.1. Addressing Current Vulnerabilities on Small Islands

Islands are heterogeneous in geomorphology, culture, ecosystems, populations and hence also in their vulnerability to climate change Vulnerabilities and adaptation needs are as diverse as the variety of islands between regions and even within nation states (e.g. in Solomon Islands, Rasmussen *et al.*, 2011), often with little climate adaptation occurring in peripheral islands, for example in parts of the Pacific (Nunn *et al*. 2013). Quantitative comparison of vulnerability is difficult due to the paucity of vulnerability indicators. Generic indices of national level vulnerability continue to emerge (Cardona, 2007) but only a minority are focused on small islands (e.g. Blancard and Hoarau, 2013). The island-specific indicators that exist often suffer from lack of data (Hughes *et al*., 2012; Peduzzi *et al*., 2009), use indicators that are not relevant in all islands (Barnett and Campbell, 2010), or use data of limited quality for islands, such as sea-level rise (as used in Wheeler, 2011). As a result indicators of vulnerability for small islands often misrepresent actual vulnerability Recent moves towards participatory approaches that link scientific knowledge with local visions of vulnerability (see Park *et al.*, 2012) offers an important way forward to understanding island vulnerability in the absence of certainty in model-based scenarios.

Island vulnerability is often a function of four key stressors: socio-economic, physical, socio-ecological and climate-induced , whose reinforcing mechanisms are important in determining the magnitude of impacts. Socio-economic vulnerabilities are related to on-going challenges of managing urbanisation, pollution and sanitation, both in small island states and non-sovereign islands as highlighted by Storey and Hunter (2010) in Kiribati, López-Marrero and

Yarnal (2010) in Puerto Rico, and in Mayotte (France) (Le Masson and Kelman, 2011). Geo-physical characteristics of islands (see Table 29-2; Figure 29-1) create inherent physical vulnerabilities. Thus, for example the Azores (Portugal) face seismic, landslide and tsunami risks (Coutinho *et al*., 2009). Socio-ecological stresses, such as habitat loss and degradation, invasive species (described in Sax and Gaines, 2008), overexploitation, pollution, human encroachment and disease can harm biodiversity (Caujape-Castells *et al*., 2010; Kingsford *et al.*, 2009), and reduce the ability of socio-ecological systems to bounce back after shocks. To understand climate vulnerability on islands, it is necessary to assess all of these dimensions of vulnerability (Rasmussen *et al*., 2011). For example, with individual ecosystems, such as coral reef ecosystems – those already under stress from non-climate factors are more at risk from climate change than those that are unstressed (Maina *et al*., 2011; Hughes *et al*., 2003). Evidence is starting to emerge that shows the same applies at the island scale. In Majuro atoll (Marshall Islands), 34-37 years of aerial photography shows that socio-ecological stress is exacerbating shoreline change associated with sea-level rise, especially on the lagoon-side of islands (Ford, 2012; see also 29.3.1.1). Islands faced with multiple stressors can therefore be assumed to be more at risk from climate impacts.

Despite the limited ability of continental scale models to predict climate risks for specific islands, or the limited capacity of island vulnerability indicators, scenario based damage assessments can be undertaken. Storm surge risks have been effectively modeled for the Andaman and Nicobar Islands (Kumar *et al*., 2008). Rainfall induced landslide risk maps have been produced for both Jamaica (Miller *et al*., 2009b) and the Chuuk Islands (Federated States of Micronesia) (Harp *et al*., 2009). However the probability of change in frequency and severity of extreme rainfall events and storm surges remains poorly understood for most small islands. Other risks, such as the climate change driven health risks from the spread of infectious disease, loss of settlements and infrastructure, and decline of ecosystems that affect island economies, livelihoods and human well-being also remain under-researched. Nevertheless, it is possible to consider these risks along with the threat of rising sea level and suggest a range of contemporary and future adaptation issues and prospects for small islands (Table 29-4).

[INSERT TABLE 29-4 HERE
Table 29-4: Selected key risks and potential for adaptation for small islands from the present-day to the long-term.]

29.6.2. Practical Experiences of Adaptation on Small Islands

There is disagreement about whether islands and islanders have successfully adapted to past weather variability and climate change. Nunn (2007) argues that past climate changes have had a ‘crisis effect’ on prehistoric societies in much of the Pacific Basin. In contrast a variety of studies argue that past experiences of hydro-meteorological extreme events have enabled islands to become resilient to weather extremes (Barnett, 2001). Resilience appears to come from both a belief in their own capacity (Kuruppu and Liverman, 2011; Adger and Brown, 2009), and a familiarity with their environment and understanding of what is needed to adapt (Tompkins *et al*., 2009; Le Masson and Kelman, 2011). For example, compared to communities in the larger countries of Madagascar, Tanzania and Kenya, the Indian Ocean islands – the Seychelles and Mauritius – were found to have: comparatively high capacity to anticipate change and prepare strategies; self-awareness of human impact on environment; willingness to change occupation; livelihood diversity; social capital; material assets; access to technology and infrastructure, all of which produced high adaptive capacity (Cinner *et al.,* 2012). Despite this resilience, islands are assumed to be generically vulnerable to long term future climate change (Parks and Roberts, 2006; Myers, 2002).

There are many ways in which *in-situ* climate adaptation can be undertaken: reducing socio-economic vulnerabilities, building adaptive capacity, enhancing disaster risk reduction, or building longer term climate resilience (e.g. see McGray *et al*., 2007; Eakin *et al.*, 2009). Figure 29-5 highlights the implications of the various options. Not all adaptations are equally appropriate in all contexts. Understanding the baseline conditions and stresses (both climate and other) are important in understanding which climate change adaptation option will generate the greatest benefits. On small islands where resources are often limited, recognising the starting point for action is critical to maximising the benefits from adaptation. The following section considers the benefits of pursuing the various options.

[INSERT FIGURE 29-5 HERE
Figure 29-5: The impact of alternative climate change adaptation actions or policies.]

29.6.2.1. Building Adaptive Capacity with Traditional Knowledge, Technologies, and Skills on Small Islands

As in previous IPCC Assessments, there is continuing strong support for the incorporation of indigenous knowledge into adaptation planning. However this is moderated by the recognition that current practices alone may not be adequate to cope with future climate extremes or trend changes The ability of a small island population to deal with current climate risks may be positively correlated with the ability to adapt to future climate change, but evidence confirming this remains limited (such as Lefale, 2010). Consequently, this section focuses on evidence for adaptive capacity that reduces vulnerability to existing stressors, enables adaptation to current stresses, and supports current disaster risk management.

Traditional knowledge has proven to be useful in short term weather forecasting (e.g. Lefale, 2010) although evidence is inconclusive on local capacity to observe long-term climate change (e.g. Hornidge and Scholtes, 2011). In Solomon Islands, Lauer and Aswani (2010) found mixed ability to detect change in spatial cover of seagrass meadows. In Jamaica, Gamble *et al*. (2010) reported a high level of agreement between farmers' perception of increasing drought incidence and statistical analysis of precipitation and vegetation data for the area. In this case farmers perceptions clearly validated the observational data and vice versa. Despite some claims that vulnerability reduction in indigenous communities in small islands may be best tackled by combining indigenous and Western knowledge in a culturally compatible and sustainable manner (Mercer *et al.*, 2007), given the small number of studies in this area, there is not sufficient evidence to determine the effectiveness and limits to the use of traditional methods of weather forecasting under climate change on small islands.

Traditional technologies and skills can be effective for current disaster risk management but there is currently a lack of supporting evidence to suggest that they will be equally appropriate under changing cultural conditions and future climate changes on islands. Campbell (2009) identified that traditional disaster reduction measures used in Pacific islands focused around maintaining food security, building community cooperation, and protecting settlements and inhabitants. Examples of actions to maintain food security include: the production and storage of food surpluses – such as yam and breadfruit buried in leaf-lined pits to ferment; high levels of agricultural diversity to minimise specific damage to any one crop; and the growth of robust famine crops – unused in times of plenty which could be used in emergencies (Campbell, 2009). Two discrete studies from Solomon Islands highlight the importance of traditional patterns of social organisation within communities to support food security under social and environmental change (Reenberg *et al.*, 2008; Mertz *et al.*, 2010). In both studies the strategy of relying on traditional systems of organization for farming and land use management have been shown to work effectively – largely as there has been little cultural and demographic change. Nonetheless there are physical and cultural limits to traditional disaster risk management. In relation to the ability to store surplus production on atoll islands, on Rongelap in the Marshall Islands, surpluses are avoided, or are redistributed to support community bonds (Bridges and McClatchey, 2009). Further, traditional approaches that Pacific island communities have used for survival for millennia (such as building elevated settlements and resilient structures; and working collectively), have been abandoned or forgotten due to processes of globalisation, colonialism and development (Campbell, 2009). Ongoing processes of rapid urbanization, and loss of language and tradition suggest that traditional approaches may not always be efficacious in longer-term adaptation.

Traditional construction methods have long been identified across the Pacific as a means of reducing vulnerability to tropical cyclones and floods in rural areas. In Solomon Islands traditional practices include: elevating concrete floors on Ontong Java to keep floors dry during heavy rainfall events; building 'low, aerodynamic houses with sago palm leaves as roofing material on Tikopia' as preparedness for tropical cyclones; and in Bellona local perceptions are that houses constructed from modern materials and practices are more easily destroyed by tropical cyclones, implying that traditional construction methods are perceived to be more resilient in the face of extreme weather (Rasmussen *et al.*, 2009). In parallel, Campbell (2009) documents the characteristics of traditional building styles (in Fiji, Samoa and Tonga) where relatively steep hipped roofs, well bound connections and joints, and airtight spaces with few windows or doors offer some degree of wind resistance. Traditional building measures can also reduce damages associated with earthquakes – as evidenced in Haiti (Audefroy, 2011). By reducing damage caused by other stresses (such as earthquakes), adaptive capacity is more likely to be maintained. The quality of home construction is critical to its wind-resistance. If inadequately detailed, home construction will fail irrespective of method. While some traditional measures could be challenged as potentially risky – for example using palm leaves, rather than metal roofs as a preparation for tropical cyclone impacts – the documentation of traditional approaches, with an evaluation of their effectiveness remains urgently needed. Squatter settlements in urban areas, especially on steep hillsides in the Caribbean often use poor construction practices frequently driven by poverty and inadequate building code enforcement (Prevatt *et al*., 2010).

Traditional systems appear less effective when multiple civilization-nature stresses are introduced. For example in Reunion and Mayotte, population growth, and consequent rises in land and house prices have led low-income families to settle closer to hazardous slopes that are prone to landslides and to river-banks which are prone to flooding (Le Masson and Kelman, 2011). Traditional belief systems can also limit adaptive capacity. Thus, for example in two Fijian villages, approximately half of survey respondents identified divine will as the cause of climate change (Lata and Nunn, 2012). These findings reinforce earlier studies in Tuvalu (Mortreux and Barnett, 2009), and more widely across the Pacific (Barnett and Campbell, 2010). The importance of taking into account local interests and traditional knowledge in adaptation in small islands is emphasised by Kelman and West (2009) and McNamara and Westoby (2011), yet evidence does not yet exist that reveals the limits to such knowledge, such as in the context of rapid socio-ecological change, or the impact of belief systems on adaptive capacity.

While there is clear evidence that traditional knowledge networks, technologies and skills can be used effectively to support adaptation in certain contexts, the limits to these tools are not well understood. To date research in the Pacific and Caribbean dominates small island climate change work. More detailed studies on small islands in the central and western Indian Ocean, the Mediterranean and the central and eastern Atlantic would improve understanding on this topic.

29.6.2.2. Addressing Risks on Small Islands

Relative to other areas, small islands are disproportionately affected by current hydro-meteorological extreme events, both in terms of the percentage of the population affected, and losses as a percentage of GDP (Anthoff *et al*., 2010; Table 29-5). Under climate change the risks of damage and associated losses are expected to continue to rise (Nicholls and Cazenave, 2010). Yet much of the existing literature on climate risk in small islands does not consider how to address high future risks, but instead focuses on managing present day risks through risk transfer, risk spreading or risk avoidance. Risk transfer is largely undertaken through insurance; risk spreading through access to and use of common property resources, livelihood diversification, or mutual support through networks (see 29.6.2.3); and risk avoidance through structural engineering measures or migration (see 29.6.2.4).

[INSERT TABLE 29-5 HERE
Table 29-5: Top ten countries in the Asia-Pacific region based on absolute and relative physical exposure to storms and impact on GDP (between 1998 and 2009).]

Risk transfer through insurance markets has had limited uptake in small islands, as insurance markets do not function as effectively as they do in larger locations, in part due to a small demand for the insurance products (Heger *et al*., 2008). In the case of insurance for farmers, researchers found that a lack of demand for insurance products (in their study countries: Grenada, Jamaica, Fiji and Vanuatu) meant an undersupply of customized food insurance products, which in turn contributed to a lack of demand for insurance (Angelucci and Conforti, 2010). Alternatives exist such as index-based schemes that provide payouts based on the crossing of a physical threshold, e.g. when rainfall drops below a certain level, rather than on drought damage sustained (Linnerooth-Bayer and Mechler, 2009). The potential for index-based insurance for climate stressors on islands is under-researched and there remains limited evidence of the long-term effectiveness of index-based or pooled-risk insurance in supporting household level adaptation. Small island governments also face expensive climate risk insurance. The Caribbean Catastrophe Risk Insurance Facility (CCRIF) which has been operating since 2007 pools Caribbean-wide country-level risks into a central, more diversified risk portfolio – offering lower premiums for participating national governments (CCRIF, 2008). The potential for a similar scheme in the Pacific is being explored (ADB, 2009; Cummins and Mahul, 2009).

Risk can be spread socially e.g. through social networks and familial ties (see also 29.6.2.3), or ecologically, e.g. by changing resource management approach. Social networks can be used to spread risk among households. In Fiji, after Tropical Cyclone *Ami* in 2003, households whose homes were not affected by the cyclone increased their fishing effort to support those whose homes were damaged (Takasaki, 2011) – mutual support formed a central pillar for community-based adaptation. In the case of natural systems, risks can be spread through enhancing representation of habitat types and replication of species e.g. through the creation of marine protected areas, around key refuges that protect a diversity of habitat, that cover an adequate proportion of the habitat and that protect critical areas such as nursery grounds and fish spawning aggregation areas (McLeod *et al.*, 2009). Locally Managed Marine Areas – which involve the local community in the management and protection of their local marine environment – have proven to be effective in increasing biodiversity, and in reducing poverty in areas dependent on marine resources in several Pacific islands (Techera, 2008; Game *et al*., 2011). By creating a network of protected areas supported by local communities the risks associated with some forms of climate change can be spread and potentially reduced (Mills *et al*., 2010) although such initiatives may not preserve thermally sensitive corals in the face of rising SST.

Risk avoidance through engineered structures can reduce risk from some climate-related hazards (*medium evidence, medium agreement*). In Jamaica, recommendations to reduce rainfall-driven land surface movements resulting in landslides include: engineering structures such as soil nailing, gabion baskets (i.e. cages filled with rocks), rip rapped surfaces (i.e. permanent cover with rock) and retaining walls together with engineered drainage systems (Miller *et al*., 2009b). Engineering principles to reduce residential damage from hurricanes have been identified, tested, and recommended for decades in the Caribbean. However, expected levels of success have often not been achieved due to inadequate training of construction workers, minimal inspection of new buildings, and lack of enforcement of building code requirements (Prevatt *et al.,* 2010). Some island states do not even have the technical or financial capacity to build effective shore protection structures as highlighted by a recent assessment in south Tarawa, Kiribati (Duvat, 2013). In addition not all engineered structures are seen as effective risk avoidance mechanisms. In the Azores archipelago, a proliferation of permanent engineered structures along the coastline to prevent erosion have resulted in a loss of natural shoreline protection against wave erosion (Calado *et al.,* 2011)). In Barbados it is recognized that seawalls can protect human assets in areas prone to high levels of erosion, however they can also cause sediment starvation in other areas, interfere with natural processes of habitat migration and cause coastal squeeze – which may render them less desirable for long term adaptation (Mycoo and Chadwick, 2012) (see also 5.4.2.1). To reduce erosion risk an approach with less detrimental downstream effects that also supports tourism is beach nourishment. This is increasingly being recommended, for example in the Caribbean (Mycoo and Chadwick, 2012), the Mediterranean (Anagnostou *et al*., 2011), and western Indian Ocean (Duvat, 2009). Beach nourishment however is not without its challenges, as requirements such as site-specific oceanographic and wave climate data, adequate sand resources and critical engineering design skills may not be readily available in some small islands.

29.6.2.3. Working Collectively to Address Climate Impacts on Small Islands

More attention is being focused on the relevance and application of community-based adaptation (CBA) principles to island communities, to facilitate adaptation planning and implementation (Warrick, 2009; Kelman *et al*., 2011) and to tackle rural poverty in resource dependent communities (Techera, 2008). CBA research is focusing on empowerment that helps people to help themselves e.g. through marine catch monitoring (Breckwoldt and Seidel, 2012), while addressing local priorities and building on local knowledge and capacity. This approach to adaptation is being promoted as an appropriate strategy for small islands, since it is something done 'with' rather than 'to' communities (Warrick, 2009). Nonetheless externally driven programs to encourage community-level action have produced some evidence of effective adaptation. Both Limalevu *et al*. (2010) and Dumaru (2010) describe the outcomes of externally-led pilot CBA projects (addressing water security and coastal management) implemented in villages across Fiji, notably: more effective management of local water resources through capacity building; enhanced knowledge of climate change; and, the establishment of mechanisms to facilitate greater access to technical and financial resources from outside the community. More long term monitoring and evaluation of the effectiveness of community level action is needed.

Collaboration between stakeholders can lessen the occurrence of simple mistakes that can reduce the effectiveness of adaptation actions (*medium evidence, medium agreement*). Evidence from the Eastern Caribbean suggests that adaptations taken by individual households to reduce landslide risk – building simple retaining walls – can be ineffective compared to community level responses (Anderson *et al*., 2011). Landslide risk can be significantly reduced through better hillside drainage. In the Eastern Caribbean, community groups, with input from engineers, have constructed these networks of drains to capture surface runoff, household roof-water and grey water. Case studies from Fiji and Samoa in which multi-stakeholder and multi-sector participatory approaches were used to help enhance resilience of local residents to the adverse impacts of disasters and climate change (Gero *et al.*, 2011) further support this view. In the case of community based disaster risk reduction (CBDRR), Pelling (2011) notes that buy-in from local and municipal governments is needed, as well as strong pre-existing relationships founded on routine daily activities, to make CBDRR effective. Research from both Solomon Islands and the Cayman Islands reinforce the conclusion that drivers of community resilience to hazard maps closely onto factors driving successful governance of the commons, that is: community cohesion; effective leadership; and, community buy-in to collective action (Schwarz *et al.*, 2011; Tompkins *et al*., 2008). Where community organisations are operating in isolation, or where there is limited coordination and collaboration community vulnerability is expected to increase (Ferdinand *et al*., 2012). Strong local networks, and trusting relationships between communities and government appear to be key elements in adaptation, in terms of maintaining sustainable agriculture and in disaster risk management (*medium evidence, high agreement*).

All of these studies reinforce the earlier work of Barnett (2001), providing empirical evidence that supporting community-led approaches to disaster risk reduction and hazard management may contribute to greater community engagement with anticipatory adaptation. However, it is not yet possible to identify the extent to which climate resilience is either a coincidental benefit of island lifestyle and culture, or a purposeful approach, such as the community benefits gained from reciprocity among kinship groups (Campbell, 2009).

29.6.2.4. Addressing Long-Term Climate Impacts and Migration on Small Islands

Sea-level rise poses one of the most widely recognized climate change threats to low-lying coastal areas on islands (29.3.1). However long term climate impacts depend on the type of island (see Figure 29-1) and the adaptation strategy adopted. Small island states have 16% of their land area in low elevation coastal areas (<10m) as opposed to a global average of 2%, and the largest proportion of low elevation coastal urban land area: 13% (along with Australia and New Zealand), in contrast to the global average of 8% (McGranahan *et al.*, 2007). Statistics like these underpin the widely held view about small islands being 'overwhelmed' by rising seas associated with sea-level rise (Loughry and McAdam, 2008; Yamamoto and Esteban, 2010; Gordon-Clark, 2012; Berringer, 2012; Dema, 2012; Lazrus, 2012; Laczko and Aghazarm, 2009). Yet there remains *limited evidence* as to which regions (Caribbean, Pacific, Indian Ocean, west African islands) will experience the largest sea-level rise (Willis and Church, 2012) and which islands will experience the worst climate impacts. Nicholls *et al*. (2011) have modeled impacts of 4°C warming, producing a 0.5 to 2.0m sea-level rise, to assess the impacts on land loss and migration. With no adaptation occurring, they estimate that this could produce displacement of between 1.2 and 2.2 million people from the Caribbean, Indian Ocean and Pacific Ocean. More research is needed to produce robust agreement on the impact of sea-level rise on small islands, and on the range of adaptation strategies that could be appropriate for different island types under those scenarios. Research into the possible un-inhabitability of islands has to be undertaken sensitively to avoid short-term risks (i.e. to avoid depopulation and ultimately island abandonment) associated with a loss of confidence in an islands future (McNamara and Gibson, 2009; McLeman, 2011).

Due to the high costs of adapting on islands it has been suggested that there will be a need for migration (Nicholls *et al.*, 2011; Gemenne, 2011; Biermann and Boas, 2010; Voccia 2012). Relocation and displacement are frequently cited as outcomes of sea-level rise, salinisation and land loss on islands (Byravan and Rajan, 2006; Kolmannskog and Trebbi, 2010; see also 29.3.3.3). Climate stress is occurring at the same time as the growth in rural to urban migration. The latter is leading to squatter settlements that strain urban infrastructure – notably: sewerage, waste management, transport and electricity (Jones, 2005; Connell and Lea, 2002). Urban squatters on islands often live in highly exposed locations, lacking basic amenities, leaving them highly vulnerable to climate risks (Baker, 2012). However, a lack of research in this area makes it difficult to draw clear conclusions on the impact of climate change on the growing number of urban migrants in islands.

Recent examples of environmental stress driven relocation and displacement provide contemporary analogues of climate-induced migration. Evidence of post-natural disaster migration has been documented in the Caribbean in relation to hurricanes (McLeman and Hunter, 2010), and in the Carteret Islands, Papua New Guinea – where during an exceptionally high inundation event in 2008 (see 29.5.1.1) islanders sought refuge on neighbouring Bougainville island (Jarvis, 2010). Drawing any strong conclusions from this literature is challenging as there is little understanding of how to measure the effect of the environmental signal in migration patterns (Afifi *et al*., 2013; Krishnamurthy, 2012). While the example of the Carteret Islands cannot be described as evidence of adaptation to climate change, it suggests that under some extreme scenarios island communities may need to consider relocating in the future (Gemenne, 2011). In reality, financial and legal barriers are expected to inhibit significant levels of international environmentally induced migration in the Pacific (Barnett and Chamberlain, 2010).

29.6.3. Barriers and Limits to Adaptation in Small Island Settings

Since publication of the IPCC SAR in 1996, significant barriers to climate change adaptation strategies in island settings have been discussed in considerable detail. Barriers include inadequate access to financial, technological and human resources, issues related to cultural and social acceptability of measures, constraints imposed by the existing political and legal framework, the emphasis on island development as opposed to sustainability, and a tendency to focus on addressing short term climate variability rather than long term climate change, and community preferences for “hard” adaptation measures such as seawalls instead of “soft” measures such as beach nourishment (Sovacool, 2012). Heger *et al*. (2008) recognised that more diversified economies have more robust responses to climate stress, yet most small islands lack economies of scale in production, thus specialising in niche markets and developing monocultures (e.g. sugar or bananas). Non-sovereign island states face additional exogenous barriers to adaptation. For example, islands like Réunion and Mayotte benefit from the provision of social services somewhat similar to what obtains in the Metropole, but not the level of enforcement of building codes and land use planning as in France (Le Masson and Kelman, 2011). Owing to their nature and complexity, these constraints will not be easily eliminated in the short term and will require on-going attention if their impact is to be minimized over time. Exogenous factors, such as the comparatively few assessments of social vulnerability to climate change, adaptation potential or resilience for island communities (Barnett, 2010) limit current understanding. In part this is due to the particularities of islands – both their heterogeneity and their difference from mainland locations – as well as the limitations of climate models in delivering robust science for small islands. It remains the case that thirteen years after Nurse *et al*. (2001) noted that downscaled global climate models do not provide a complete or necessarily accurate picture of climate vulnerabilities on islands, there is still little climate impacts research that reflects local concerns and contexts (Barnett *et al.,* 2008).

While lack of access to adequate financial, technological and human resources is often cited as the most critical constraint, experience has shown that endogenous factors such as culture, ethics, knowledge and attitudes to risk are important in constraining adaptation. Translating the word ‘climate’ into Marshallese implies cosmos, nature and culture as well as weather and climate (Rudiak-Gould, 2012). Such cultural misunderstandings can create both barriers to action and novel ways of engaging with climate change. The lack of local support (due to encroachment on traditional lands) for the development of new infiltration galleries to augment freshwater supply on Tarawa atoll, Kiribati, highlights the importance of social acceptability (Moglia *et al.,* 2008a, 2008b). Such considerations have led to the conclusion that there is still much to be learned about the drivers of past adaptation and how ‘mainstreaming’ into national programs and policies, widely acclaimed to be a virtually indispensable strategy, can practically be achieved (Mercer *et al.,* 2007; Adger *et al.,* 2009; Mertz *et al.,* 2009).

Notwithstanding the extensive and ever-growing body of literature on the subject, there is still a relatively low level of awareness and understanding at the community level on many islands about the nature of the threat posed by climate change (Nunn, 2009). Even where the threat has been identified, it is often not considered an urgent issue, or a local priority, as exemplified in Malta (Akerlof *et al.,* 2010) and Funafuti, Tuvalu (Mortreux and Barnett, 2009). Lack of awareness, knowledge and understanding can function as an effective barrier to the implementation and ultimate success of adaptation programs. This is borne out in both Fiji and Kiribati where researchers found that spiritual beliefs, traditional governance mechanisms, and a short term approach to planning were barriers to community engagement and understanding of climate change (Kuruppu, 2009; Lata and Nunn, 2012). Although widely acknowledged to be critical in small islands, few initiatives pay little more than perfunctory attention to the importance of awareness, knowledge and understanding in climate change adaptation planning. Hence, the renewed call for adaptation initiatives to include and focus directly on these elements on an ongoing basis (e.g., Crump, 2008; Kelman and West, 2009; Kelman, 2010; Kuruppu and Liverman, 2011; Gero *et al.,* 2011) is timely, if these barriers are to be eventually removed.

29.6.4. Mainstreaming and Integrating Climate Change into Development Plans and Policies

There is a growing body of literature that discusses the benefits and possibilities of mainstreaming or integrating climate change policies in development plans. Various mechanisms through which development agencies as well as donor and recipient countries can seek to capitalize on the opportunities to mainstream are beginning to emerge (see for example Klein *et al.,* 2007; Mertz *et al.,* 2009). Agrawala and van Aalst (2008) provide examples from Fiji and elsewhere, of where synergies (and trade-offs) can be found in integrating adaptation to climate change into development cooperation activities, notably in the areas of: disaster risk reduction, community-based approaches to development, and building adaptive capacity. Boyd *et al.* (2009) support the need for more rapid integration of adaptation into development planning, to ensure that adaptation is not side-lined, or treated separately from sectoral policies. Although there are synergies and benefits to be derived from the integration of climate change and development policies, care is needed to avoid institutional overlaps, and differences in language and approach – which can give rise to conflict (Schipper and Pelling, 2006). Overall, there appears to be an emerging consensus around the views expressed by Swart and Raes (2007) that climate change and development strategies should be considered as complementary, and that some elements such as land and water management and urban, peri-urban and rural planning provide important adaptation, development and mitigation opportunities. While the potential to deliver such an integrated approach may be reasonably strong in urban centres on islands, there appears to be limited capacity to mainstream climate change adaptation into local decision making in out-lying islands or peripheral areas (Nunn *et al*., 2013).

29.7. Adaptation and Mitigation Interactions

Greenhouse gas emissions from most small islands are negligible in relation to global emissions, yet small islands will most probably be highly impacted by climate change (Srinivasan, 2010). ‘However, many small island governments and communities have chosen to attempt to reduce their greenhouse gas emissions because of the cost andthe potential co-benefits and synergies. Malta and Cyprus are obliged to do so in line with EU climate and energy policies. This section considers some of the inter-linkages between adaptation and mitigation on small islands and the potential synergies, conflicts, trade-offs and risks. Unfortunately there is relatively little research on the emissions reduction potential of small islands, and far less on the inter-linkages between climate change adaptation and emissions reduction in small islands. Therefore in this section a number of assumptions are made about how and where adaptation and mitigation actions interact.

29.7.1. Assumptions/Uncertainties Associated with Adaptation and Mitigation Responses

Small islands are not homogeneous. Rather they have diverse geo-physical characteristics and economic structures (see Table 29-2, Figure 29-1). Following Nunn (2009) the combination of island geography and economic types informs the extent to which adaptation and mitigation actions might interact. The geography and location of islands affect their sensitivity to hydro-meteorological and related hazards such as cyclones, floods, droughts, invasive alien species, vector borne disease, and landslides. On the other hand the capacity of island residents to cope is often related to income levels, resources endowment, technology and knowledge (see 29.6.2).

The potential for mitigation and emissions reductions in islands depends to a large extent on their size and stage of economic development. In the small and less developed islands key 'mitigation' sectors including energy, transport, industry, built environment, agriculture, forestry, or waste management sectors are generally relatively small (Metz *et al.*, 2007; Swart and Raes, 2007). Hence opportunities for emissions reductions are usually quite limited and are mostly associated with electricity generation and utilization of vehicles. More mitigation opportunities should exist in more economically advanced and larger islands that rely on forms of production that utilize fossil fuels, including manufacturing, and where vehicle usage is extensive and electricity driven home appliances, such as air conditioners and water heaters, are extensively used.

In the absence of significant mitigation efforts at the global scale, adaptation interventions could become very costly and difficult to implement, once certain thresholds of change are reached (Nelson, 2011; Birkmann, 2011). Nicholls *et al*. (2011) make a similar observation with respect to coastal protection as a response to sea-level rise. They suggest that if global mean temperatures increase by around 4 ^{0}C (which may lead to sea-level rise between 0.5 m and 2 m) the likelihood of successful coastal protection in some locations such as low-lying small islands, will be low. Consequently, it is argued that the relocation of communities would be a likely outcome in such circumstances (Nicholls *et al.*, 2011).

29.7.2. Potential Synergies and Conflicts

Metz *et al.* (2007) suggest that adaptation and mitigation interactions occur in one of four main ways: adaptations that result in greenhouse emissions reduction; mitigation options that facilitate adaptation; policy decisions that couple adaptation and mitigation effects; and, trade-offs and synergies between adaptation and mitigation. Each of these opportunities is considered using three examples: coastal forestry, energy supply, and tourism.

Small islands have relatively large coastal zones (in comparison to land area) and most development (as well as potential mitigation and adaptation activities) are located in the coastal zone. Coastal ecosystems (coral reefs, sea grasses and mangroves) play an important role in protecting coastal communities from wave erosion, tropical cyclones, storm surges, and even moderate tsunami waves (Cochard *et al*., 2008). Whilst coastal forests including both endemic and exotic species especially mangroves are seen as effective adaptation options ('bioshields' Feagin *et al.*, 2010) in the coastal zones, they also play an important role in mitigation as carbon sinks (van der Werf *et al*., 2009). Thus, the management and conservation of mangrove forests has the potential to generate synergies between climate change adaptation and mitigation. However, despite this knowledge population, development and agricultural pressures have constrained the expansion of island forest carbon stocks (Fox *et al*., 2010) while Gilman *et al*. (2008) note that such pressures can also reduce the buffering capacity of coastal vegetation systems.

Renewable energy resources on small islands have only recently been considered within the context of long-term energy security (Praene *et al.,* 2012; Chen *et al.*, 2007). Stuart (2006) speculates that the lack of uptake of renewable technologies to date might be due to historical commitments to conventional fossil fuel-based infrastructure, and a lack of resources to undertake research and development of alternatives. Those islands that have introduced renewable energy technologies have often done so with support from international development agencies (Dornan, 2011). Despite this, there remain significant barriers to the wider institutionalization of renewable technologies in small islands. Research in Europe and the United States has shown the mitigation and cost savings benefits of Energy Service Companies (ESCOs): companies that enter into medium-to-long term performance-based contracts with energy users, invest in energy efficiency measures in buildings and firms, and profit from the ensuing energy savings measures for the premises (see for example Steinberger *et al.*, 2009). Potential benefits exist in creating the opportunity for ESCOs to operate in small islands. Preliminary evidence from Fiji suggests that if the incentive mechanisms can be resolved, and information asymmetries between service providers and users can be aligned, ESCOs could provide an opportunity to expand renewable technologies (Dornan, 2009). IPCC (2011) presents examples of opportunities for renewable energy, including wind energy sources, as deployed in the Canary Islands.

The transition towards renewable energy sources away from fossil fuel dependence has been partly driven by economic motives, notably to avoid oil price volatility and its impact. The development of hydro-power (in Fiji for example) necessitates protection and management of the water catchment zones, and thus could lead to improved management of the water resources – a critical adaptation consideration for areas expected to experience a decrease in average rainfall as a result of climate change. Whilst the cost effectiveness of renewable technologies is critical, placing it within the context of water adaptation could enhance project viability (Dornan, 2009). Cost-benefit analyses have shown that in southeast Mediterranean islands photovoltaic generation and storage systems may be more cost-effective than existing thermal power stations (Kaldellis, 2008; Kaldellis *et al*., 2009).

Energy prices in small islands are among the highest anywhere in the world, mainly due to their dependence on imported fossil fuel, and limited ability to reap the benefits of economies of scale including bulk buying. Recent studies show that the energy sectors in small islands may be transformed into sustainable growth entities mainly through the judicious exploitation of renewable energy sources, combined with the implementation of energy efficiency measures (van Alphen *et al.*, 2008; Banuri, 2009; Mohanty, 2012; Rogers *et al.*, 2012). Realising the potential for such transformation, the countries comprising the Alliance of Small Island States (AOSIS) launched SIDS Dock, which is intended to function as a 'docking station' to connect the energy sector in SIDS with the international finance, technology and carbon markets with the objective of pooling and optimizing energy efficiency goods and services for the benefit of the group. This initiative seeks to decrease energy dependence in SIDS, while generating financial resources to support low carbon growth and adaptation interventions.

Many small islands rely heavily on the foreign exchange from tourism to expand and develop their economies, including the costs of mitigation and adaptation. Tourism, particularly in small islands, often relies on coastal and terrestrial ecosystems to provide visitor attractions and accommodation space. Recognising the relationship between ecosystem services and tourism in Jamaica, Thomas-Hope and Jardine-Comrie (2007) suggest that sustainable tourism planning should include activities undertaken by the industry, that is tertiary treatment of waste, and re-use of water, as well as composting organic material and investing in renewable energy. Gössling and Schumacher (2010) and others who have examined the linkages between greenhouse gas emissions and sustainable tourism argue that the tourism sector (operators and tourists) should pay to promote sustainable tourism, especially where they benefit directly from environmental services sustained by these investments.

29.8. Facilitating Adaptation and Avoiding Maladaptation

While there is a clear consensus that adaptation to the risks posed by global climate change is necessary and urgent in small islands, the implementation of specific strategies and options is a complex process that requires critical evaluation of multiple factors, if expected outcomes are to be achieved (Kelman and West, 2009; Barnett and O'Neill, 2012). These considerations may include, *inter alia*, prior experience with similar or related threats, efficacy of the strategies or options and their co-benefits, costs (monetary and non-monetary), availability of alternatives and social acceptability. In addition, previous work (e.g. Adger *et al.,* 2005) has emphasised the relevance of scale as a critical factor when assessing the efficacy and value of adaptation strategies, as the extent to which an option is perceived to be a success, failure or maladaptive may be conditioned by whether it is being assessed as a response to climate variability (shorter-term) or climate change (longer-term).

As in other regions, adaptation in islands is locally delivered and context specific (Tompkins *et al.,* 2010). Yet, sectors and communities on small islands are often so intricately linked that there are many potential pathways that may lead to maladaptation, be it via increased greenhouse gas emissions, foreclosure of future options, or burdensome opportunity costs on local communities. There is also a concern that some types of interventions may actually be maladaptive. For example, Barnett and O'Neill (2012) suggest that strategies such as resettlement and migration should be regarded as options of 'last resort' on islands, as they may actually discourage viable adaptation initiatives, by fostering over-dependence on external support. They further argue that a priori acceptance of adaptation as an efficacious option for places like the Pacific islands, may also act as a disincentive for reducing greenhouse gas emissions (Barnett and O'Neill, 2012).

Notwithstanding the observations of Barnett and O'Neill (2012), there is a concern that early foreclosure of this option might well prove maladaptive, if location-specific circumstances show such action to be efficacious in the longer-term. For example, Bunce *et al*. (2009) have shown that as an adaptive response to poverty, young fishers from Rodrigues Island periodically resort to temporary migration to the main capital island, Mauritius, where greater employment prospects exist. The case study of the residents of Nauru who contemplated resettlement in Australia after the collapse of phosphate mining (their only revenue source) in the1950s, provides helpful insight about the complex social, economic and cultural challenges associated with environmentally triggered migration (Tabucanon and Opeskin, 2011). Negotiations with the Government of Australia collapsed before a mutually acceptable agreement was reached, and the Nauruans opted to abandon the proposal to relocate (Tabucanon and Opeskin, 2011). Overall however, it is suggested that states contemplating long term, off-island migration may wish to consider early proactive planning, as resettlement of entire communities might prove to be socially, culturally and economically disruptive (Campbell, 2010; McMichael *et al.,* 2012; refer also to 29.3.3.3). A related challenge facing small islands is the need to find the middle ground between resettlement and objective assessment of other appropriate adaptation choices.

Similarly, while insurance is being promoted as an element of the overall climate change response strategy in some island regions, e.g. the Caribbean, concerns have been expressed about possible linkages to maladaptation. The potential consequences include the imposition of exorbitant premiums that are beyond the capacity of resource-scarce governments as the perception of climate change risks increase, discriminatory coverage of sectors that may not align with local priorities, and tacit encouragement for the state, individuals and the private sector to engage in behavior that is not risk-averse, e.g. development in hazard-prone areas (Herweijer *et al.,* 2009; Linnerooth-Bayer *et al.,* 2011; van Nostrand and Nevius, 2011; Thomas and Leichenko, 2011). Likewise, although the exploitation of renewable energy is vital to the sustainable development of small islands, more attention needs to be paid to the development of energy storage technologies, if rapid transition from conventional fuels is to be achieved in an efficient manner. This is especially important in the case of intermittent energy sources (e.g. solar and wind), as the cost of current storage technologies can frustrate achievement of full conversion to renewable energy. Thus to avoid the possibility of maladaptation in the sector, countries may wish to consider engaging in comprehensive planning, including considerations relating to energy storage (Krajačić *et al.,* 2010; Bazilian *et al.,* 2011).

Recent studies have demonstrated that opportunities exist in island environments for avoiding maladaptation. Studies have shown for example that decisions about adaptation choices and their implementation are best facilitated where there is constructive engagement with the communities at risk, in a manner that fosters transparency and trust (López-Marrero, 2010; van Aalst *et al*., 2008). Further, some analysts argue that adaptation choices are often subjective in nature and suggest that participatory stakeholder involvement can yield valuable information about the priorities and expectations that communities attach to the sector for which adaptation is being sought. The point is underscored by Moreno and Becken (2009) whose study of the tourism sector on the Mamanuca islands (Fiji), which clearly demonstrates that approaches which explicitly integrate stakeholders into each step of the process from vulnerability assessment right through to consideration of alternatives measures can provide a sound basis for assisting destinations with the implementation of appropriate adaptation interventions. This view is supported by Dulal *et al.* (2009), who argue that the most vulnerable groups in the Caribbean - the poor, elderly, indigenous communities and rural children – will be at greater risk of being marginalized, if adaptation is not informed by equitable and participatory frameworks.

Other studies reveal that new paradigms whose adoption can reduce the risk of maladaptation in island environments, are emerging across various sectors. In the area of natural resource management, Hansen *et al.* (2010) suggest that the use of protected areas for climate refugia, reduction of non-climate stressors on ecosystems, adoption of adaptive management approaches combined with reduction of greenhouse gas emissions wherever possible, may prove to be more effective response strategies than traditional conservation approaches. Other strategic approaches, including the implementation of multi-sectoral and cross-sectoral measures, also facilitate adaptation in a more equitable, integrated and sustainable manner. Similarly, ‘*no-regret’* measures such as wastewater recycling, trickle irrigation, conversion to non-fossil fuel based energy and transportation which offer collateral benefits with or without the threat of climate change, and ‘*low-regret’* strategies, which may only increase existing operational costs marginally, are becoming increasingly attractive options to island governments (Gravelle and Mimura, 2008; Heltberg *et al.,* 2009; Howard *et al.*, 2010). Together, these constitute valid risk management approaches, as they are designed to assist communities in making prudent, but necessary decisions in the face of an uncertain future.

Some authors suggest that caution is needed to ensure that donors are not driving the adaptation and mitigation agenda in small islands, as there is a risk that donor-driven adaptation or mitigation may not always address the salient challenges on small islands, and may lead to inadequate adaptation or a waste of scarce resources (Barnett, 2010; Nunn, 2009). Others argue that donor-led initiatives may unintentionally cause enhanced vulnerability by supporting adaptation strategies that are externally derived, rather than optimizing the benefits of local practices that have proven to be efficacious through time (Reenberg *et al.,* 2008; Kelman and West, 2009; Campbell and Beckford, 2009).

29.9. Research and Data Gaps

Several advances have taken place in our understanding of the observed and potential effects of climate change on small islands since the AR4. These cover a range of themes including: dynamic downscaling of scenarios appropriate for small islands; impacts of trans-boundary processes generated well beyond the borders of an individual nation or island; barriers to adaptation in small islands and how they may be overcome; the relationships between climate change adaptation and disaster risk reduction; and, the relationships between climate change adaptation, maladaptation and sustainable development.

It is also evident that much further work is required on these themes in small island situations, especially comparative research. Important information and data gaps and many uncertainties still exist on impacts, vulnerability and adaptation in small islands. These include:

- **Lack of climate change and socio-economic scenarios and data at the required scale for small islands**. Although some advances have been made (ABoM and CSIRO, 2011a, 2011b; Taylor *et al*., 2007), much of the work in the Caribbean, Pacific, Indian Ocean and Mediterranean islands, is focused at the regional scale rather than being country specific. Since most socio-economic decisions are taken at the local level, there is need for a more extensive database of simulations of future small island climates and socio-economic conditions at smaller spatial scales.
- **Difficulties in detecting and attributing past impacts on small islands to climate change processes.** Further investigation of the observed impacts of weather, climate and ocean events that may be related to climate change is required to clarify the relative role of climate change and non-climate change drivers.
- **Uncertainty in the projections is not a sufficiently valid reason to postpone adaptation planning in small islands**. In several small islands adaptation is being progressed without a full understanding of past or potential impacts and vulnerability. Whilst assessment of future impacts is hampered because of uncertainty in climate projections at the local island level, alternative scenarios based on a general understanding of broad trends could be used in vulnerability and sensitivity studies to guide adaptation strategies.
- **Need for a range of climate change-related projections beyond temperature and sea-level.** Generally climate-model projections of temperature and sea-level have been satisfactory, but there are strong requirements for projections for other variables that are of critical importance to small islands. These include rainfall and drought, wind direction and strength, tropical storms and wave climate, and recognition that trans-boundary processes are also significant in a small island context. While some such work has been undertaken for some parts of the Pacific (ABoM and CSIRO, 2011a, 2011b), similar work still needs to be carried out in other small island regions. In addition, the reliability of existing projections for some of the other parameters needs to be improved and the data should be in suitable formats for use in risk assessments.
- **Need to acknowledge the heterogeneity and complexity of small island states and territories.** Although small islands have several characteristics in common, neither the variety nor complexity of small islands is sufficiently reflected in the literature. Thus, transferring data and practices from a continental situation, or from one small island state to another, needs to be done with care and in a manner that takes full cognizance of such heterogeneity and complexity.
- **Within country/territory differences need to be better understood**. Many of the environmental and human impacts reported in the literature on islands have been attributed to the whole country, when in fact they refer only to the major centre or town or region. There is need for more work on rural areas, outer islands and secondary communities. Several examples of such research have been cited in this chapter. Also

it should be noted that some small island states are single islands and others highly fragmented multiple islands.

- **Lack of investment and attention to climate and environmental monitoring frameworks in small islands**. A fundamental gap in the ability to improve empirical understanding of present and future climate change impacts is the lack of climate and environmental monitoring frameworks that in turn hampers the level of confidence with which adaptation responses can be designed and implemented.
- **Economic and social costs of climate change impacts and adaptation options are rarely known**. In small island states and territories the costs of past weather, climate and ocean events is poorly known and further research is required to identify such costs, and to determine the economic and societal costs of climate change impacts and the costs of adaptation options to minimize those impacts.

The foregoing list is a sample of the gaps, needs and research agenda that urgently need to be filled for small islands. While some countries have begun to fill these gaps, this work needs to be replicated and expanded across all island regions to improve the database available for ongoing climate change assessments. Such information would raise the level of confidence in the adaptation planning and implementation process in small islands.

Frequently Asked Questions

FAQ 29.1: Why is it difficult to detect and attribute changes on small islands to climate change?
[to be inserted in Section 29.3.1.1]
In the last two or three decades many small islands have undergone substantial changes in human settlement patterns and in socio-economic and environmental conditions. Those changes may have masked any clear evidence of the effects of climate change. For example, on many small islands coastal erosion has been widespread and has adversely affected important tourist facilities, settlements, utilities and infrastructure. But specific case studies from islands in the Pacific, Indian and Atlantic oceans and the Caribbean have shown that human impacts play an important role in this erosion, as do episodic extreme events that have long been part of the natural cycle of events affecting small islands. So while coastal erosion is consistent with models of sea-level rise resulting from climate change, determining just how much of this erosion might have been caused by climate change impacts is difficult. Given the range of natural processes and human activities that could impact the coasts of small islands in the future, without more and better empirical monitoring the role of climate change-related processes on small islands may continue to be difficult to identify and quantify.

FAQ 29.2: Why is the cost of adaptation to climate change so high in small islands?
[to be inserted after Section 29.3.3.4]
Adaptation to climate change that involves infrastructural works generally require large up-front overhead costs, which in the case of small islands cannot be easily downscaled in proportion to the size of the population or territory. This is a major socio-economic reality that confronts many small islands, notwithstanding the benefits that could accrue to island communities through adaptation. Referred to as ‘indivisibility’ in economics, the problem can be illustrated by the cost of shore protection works aimed at reducing the impact of sea-level rise. The unit cost of shoreline protection per capita in small islands is substantially higher than the unit cost for a similar structure in a larger territory with a larger population. This scale-reality applies throughout much of a small island economy including the indivisibility of public utilities, services and all forms of development. Moreover, the relative impact of an extreme event such as a tropical cyclone that can affect most of a small island’s territory has a disproportionate impact on that state’s GDP, compared to a larger country where an individual event generally affects a small proportion of its total territory and its GDP. The result is relatively higher adaptation and disaster risk reduction costs per capita in countries with small populations and areas, especially those that are also geographically isolated, have a poor resource base and high transport costs

FAQ 29.3: Is it appropriate to transfer adaptation and mitigation strategies between and within small island countries and regions? *[to be inserted after Section 29.7.2]*
While lessons learned from adaptation and mitigation experiences in one island or island region may offer some guidance, caution must be exercised to ensure that the transfer of such experiences is appropriate to local biophysical, social, economic, political, and cultural circumstances. If this approach is not purposefully incorporated

into the implementation process, it is possible that maladaptation and inappropriate mitigation may result. It is therefore necessary to carefully assess the risk profile of each individual island so as to ensure that any investments in adaptation and mitigation are context specific. The varying risk profiles between individual small islands and small island regions have not always been adequately acknowledged in the past.

Table 29-1: Climate change projections for the medium (500-700 ppm CO2-e) RCP4.5 scenario for the main Small Islands regions. The table shows the 25th, 50th (median) and 75th percentiles for surface temperature and precipitation based on averages from 42 CMIP5 global models (adapted from WGI AR5 Table 14.1). Mean net regional sea level change is evaluated from 21 CMIP5 models and includes regional non-scenario components (adapted from WGI AR5 Figure 13-20).

Small Island Region	RCP4.5 Annual Projected Change for 2081-2100 compared to 1986-2005						
	Temperature (^{O}C)			Precipitation (%)			Sea Level (m)
	25%	50%	75%	25%	50%	75%	Range
Caribbean	1.2	1.4	1.9	-10	-5	-1	0.5 – 0.6
Mediterranean	2.0	2.3	2.7	-10	-6	-3	0.4 - 0.5
Northern tropical Pacific	1.2	1.4	1.7	0	1	4	0.5 – 0.6
Southern tropical Pacific	1.1	1.2	1.5	0	2	4	0.5 – 0.6
North Indian Ocean	1.3	1.5	2.0	5	9	20	0.4 – 0.5
West Indian Ocean	1.2	1.4	1.8	0	2	5	0.5 – 0.6

Table 29-2: Summary of projected percentage changes in tropical Pacific tuna catches by 2036 and 2100 relative to 1980-2000 and the estimated resulting percentage change to government revenue (after Bell *et al.*, 2011).

Tuna Fishery		**Year and SRES Scenario**		
		2035	**2100**	
		B1/A2	**B1**	**A2**
Skipjack tuna	**Western fishery**	+ 11%	-0.2%	-21%
	Eastern fishery	+37%	+43%	+27%
Bigeye tuna	**Western fishery**	-2%	-12%	-24%
	Eastern fishery	+3%	-4%	-18%
Skipjack tuna	**Total**	+19%	+12%	-7%
Bigeye tuna	**Total**	+0.3%	-9%	-27%
Total Change to Government Revenue (%)	**Federated States of Micronesia**	0.8 to 1.7%	-0.9 to -1.9%	
	Solomon Islands	0.01 to 0.16%	-0.03 to 0.77%	
	Kiribati	+11 to 18.4%	+7.2 to 12.0%	
	Tuvalu	+3.7 to 9.2%	+2.5 to 6.2%	

Table 29-3: Type of island in the Pacific region and implications for hydro-meteorological hazards (after Campbell, 2009).

Island type and size	**Island elevation, slope, rainfall**	**Implications for hazard**
Continental - Large - High biodiversity - Well developed soils	- High elevations - River flood plains - Orographic rainfall	River flooding more likely to be a problem than in other island types. In Papua New Guinea high elevations expose areas to frost (extreme during El Nino).
Volcanic High Islands - Relatively small land area - Barrier reefs - Different stages of erosion	- Steep slopes - Less well developed river systems - Orographic rainfall	Because of size few areas are not exposed to tropical cyclones. Streams and rivers subject to flash flooding. Barrier reefs may ameliorate storm surge.
Atolls - Very small land area - Small islets surround a lagoon - Larger islets on windward side - Shore platform on windward side - No or minimal soil	- Very low elevations - Convectional rainfall - No surface (fresh) water - Ghyben-Herzberg (freshwater) lens	Exposed to storm surge, 'king' tides and high waves. Narrow resource base. Exposed to fresh water shortages and drought. Water problems may lead to health hazards.
Raised Limestone Islands - Concave inner basin - Narrow coastal plains - No or minimal soil	- Steep outer slopes - Sharp karst topography - No surface water	Depending on height may be exposed to storm surge. Exposed to fresh water shortages and drought. Water problems may lead to health hazards.

Table 29-4: Selected key risks and potential for adaptation for small islands from the present-day to the long-term.

Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
Loss of livelihoods, coastal settlements and infrastructure in small islands (*high confidence*)	Significant potential exists for adaptation in islands but will require additional external resources and technologies. It is unlikely that traditional community coping strategies will be effective in the future.		Figure 29-4	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Decline and possible loss of coral reef ecosystems in small islands through thermal stress (*high confidence*)	Limited coral reef adaptation responses, however, minimising the negative impact of anthrogopenic stresses (ie: water quality change, destructive fishing practices) may increase resilience.		29.3.1.2	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	The interaction of rising global mean sea levels in the 21st century with high water level events will threaten low-lying coastal areas in small islands (*high confidence*)	High ratio of coastal area to land mass will make adaptation a significant financial and resource challenge for islands. Adaptation strategies could include: maintenance and restoration of coastal landforms and ecosystems, improved management of soils and freshwater resources, appropriate building codes and settlement patterns.		29.4.3, Table 29-1, WGI 13.5.1, Table 13.5	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	

Table 29-5: Top ten countries in the Asia-Pacific region based on absolute and relative physical exposure to storms and impact on GDP (between 1998 and 2009) (after ESCAP and UNISDR, 2010).

Rank	Absolute exposure (millions affected)	Relative exposure (% of the population affected)	Absolute GDP loss ($billions)	Loss (as a % of GDP)
1	Japan (30.9)	**North Mariana Islands (58.2)**	Japan (1,226.7)	**North Mariana Islands (59.4)**
2	Philippines (12.1)	**Niue (25.4)**	Rep. of Korea (35.6)	**Vanuatu (27.1)**
3	China (11.1)	Japan (24.2)	China (28.5)	**Niue (24.9)**
4	India (10.7)	Philippines (23.6)	Philippines (24.3)	**Fiji (24.1)**
5	Bangladesh (7.5)	**Fiji (23.1)**	Hong Kong (13.3)	Japan (23.9)
6	Rep. of Korea (2.4)	**Samoa (21.4)**	India (8.0)	Philippines (23.9)
7	Myanmar (1.2)	**New Caledonia (20.7)**	Bangladesh (3.9)	**New Caledonia (22.4)**
8	Viet Nam (0.8)	**Vanuatu (18.3)**	**North Mariana Islands (1.5)**	**Samoa (19.2)**
9	Hong Kong (0.4)	**Tonga (18.1)**	Australia (0.8)	**Tonga (17.4)**
10	Pakistan (0.3)	**Cook Islands (10.5)**	**New Caledonia (0.7)**	Bangladesh (5.9)

Note: Small islands are highlighted in **bold**

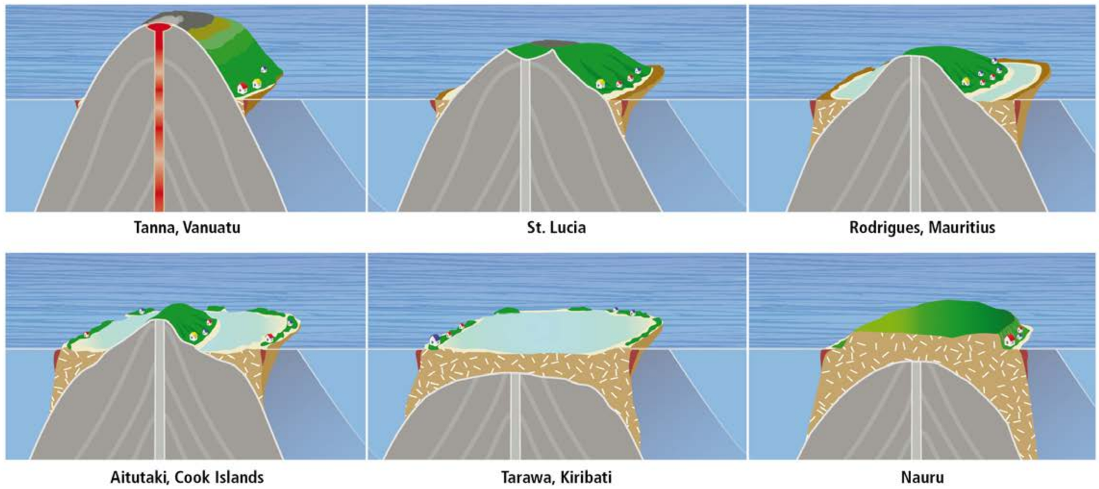

Figure 29-1: Representative tropical island typologies. From top-left: a young, active volcanic island (with altitudinal zones) and limited living perimeter reefs (purple zone at outer reef edge), through to an atoll (centre bottom) and raised limestone island (bottom right) dominated by ancient reef deposits (brown + white fleck). Atolls have limited, low-lying land areas but well developed reef/lagoon systems. Islands composed of 'continental rocks' are not included in this figure, but see Table 29-3]

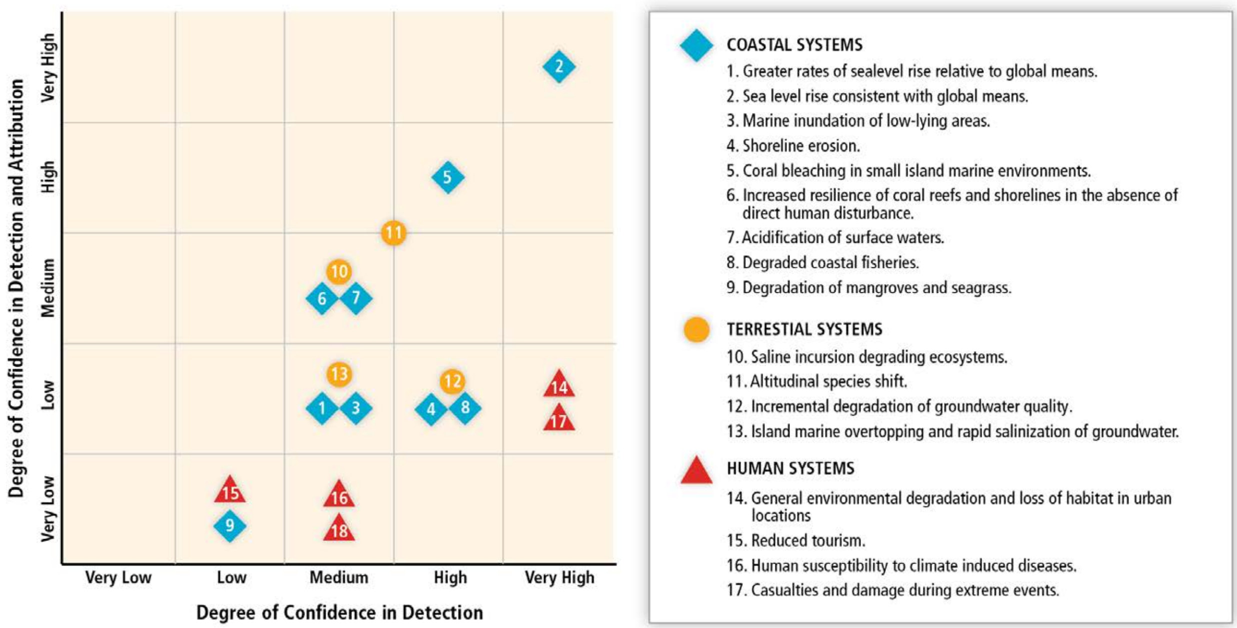

Figure 29-2: A comparison of the degree of confidence in the detection of observed impacts of climate change on tropical small islands with the degree of confidence in attribution to climate change drivers at this time. For example, the blue symbol No. 2 (Coastal Systems), indicates there is *very high confidence* in both the detection of 'sea-level rise consistent with global means' and its attribution to climate change drivers; whereas the red symbol No. 17 (Human Systems) indicates whilst detection of 'casualties and damage during extreme events' is *very high*, there is presently *low confidence* in the attribution to climate change. It is important to note that *low confidence* in attribution frequently arises due to the limited research available on small island environments.

Figure 29-3: Time series of RCP scenarios annual projected temperature and precipitation change relative to 1986-2005 for six small islands regions (using regions defined in AR5 WG1, Annex 1: Atlas of Global and Regional Climate Projections).] Thin lines denote one ensemble member per model, thick lines the CMIP5 multi-model mean. On the right-hand side the 5th, 25th, 50th (median), 75th and 95th percentiles of the distribution of 20-yr mean changes are given for 2081–2100 in the four RCP scenarios. Note that the model ensemble averages in the figure are for grid points over wide areas and encompass many different climate change signals. To get projections for a specific location and time period use the maps in the Atlas or the online interactive version at but please note that in regions with small islands the models basically simulate the climate of the surrounding ocean and local conditions on land may differ. **[Illustration to be redrawn to conform to IPCC publication specifications.]**

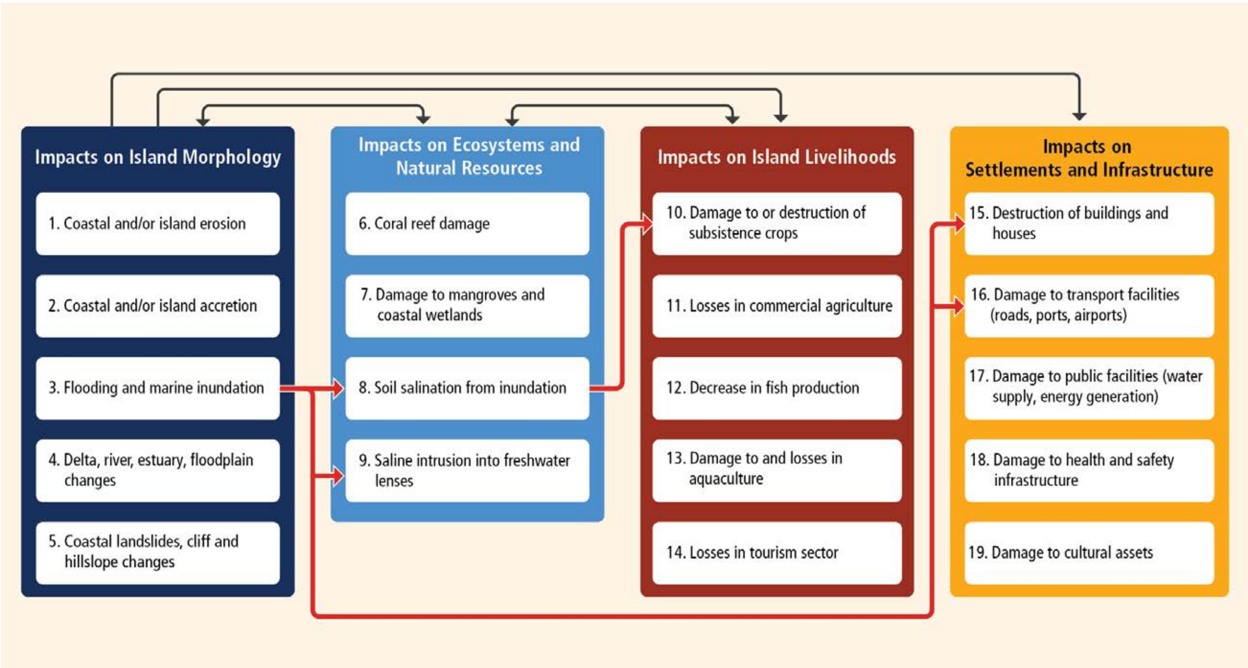

Figure 29-4: Tropical and extra-tropical cyclone impacts on the coasts of small islands. Four types of impacts are distinguished here, black arrows showing the connections between them, based on the existing literature. An example of the chain of impacts associated with two extra-tropical cyclones centred to the east of Japan is illustrated by the red arrows. Swell waves generated by these events in December 2008 reached islands in the southwest Pacific and caused extensive flooding (3) that impacted soil quality (8), freshwater resources (9), and damaged crops (10), buildings (15), and transport facilities (16) in the region (Example based on Hoeke *et al.*, 2013).

Executive Summary

The Ocean plays a central role in Earth's climate and has absorbed 93% of the extra energy from the enhanced greenhouse effect and approximately 30% of anthropogenic CO_2 from the atmosphere. Regional responses are addressed here by dividing the Ocean into seven sub-regions: High Latitude Spring Bloom Systems (HLSBS), Eastern Boundary Upwelling Ecosystems (EBUE), Coastal Boundary Systems (CBS), Equatorial Upwelling Systems (EUS), Sub-Tropical Gyres (STG), Semi-Enclosed Seas (SES), and the Deep Sea (DS; >1000 m). The eighth region, Polar Seas, is dealt with by Chapter 28 [Figure 30-1; WGI 3.2.5, Box 3.1, 3.8].

Global average sea surface temperatures have increased since both the beginning of the 20th Century and the 1950s (*virtually certain*). The average sea surface temperature (SST) of the Indian, Atlantic and Pacific Oceans has increased by 0.65, 0.41 and 0.31°C respectively over the period 1950–2009 (*very likely*, p-value$\leq$0.05). Changes in the surface temperatures of the ocean basins are consistent with temperature trends simulated by ocean-atmosphere models with anthropogenic greenhouse gas forcing over the past century (*high confidence*). Sub-regions within the Ocean also show *robust evidence* of change, with the influence of long-term patterns of variability (e.g., Pacific Decadal Oscillation, PDO; Atlantic Multi-decadal Oscillation, AMO) contributing to variability at regional scales, and making changes due to climate change harder to distinguish and attribute [30.3.1, Figure 30-2e–g, Table 30-1; WGI 2.4.2-3, 3.2–3.8, 10.3.4, 14].

Uptake of CO_2 has decreased ocean pH (approximately 0.1 unit over 100 years), fundamentally changing ocean carbonate chemistry in all ocean sub-regions, particularly at high latitudes (*high confidence*). The current rate of ocean acidification is unprecedented within the last 65 Ma (*high confidence*) if not the last 300 Ma (*medium confidence*). Warming temperatures, declining pH and carbonate ion concentrations represent risks to the productivity of fisheries and aquaculture, and the security of regional livelihoods given the direct and indirect effects of these variables on physiological processes (e.g., skeleton formation, gas exchange, reproduction, growth, and neural function) and ecosystem processes (e.g., primary productivity, reef building, and erosion) (*high confidence*) [6.2, 6.3, 30.3.1, 30.3.2; 6.1.2; WGI 3.8.2, Box 3.2, 5.3.1].

Regional changes observed in winds, surface salinity, stratification, ocean currents, nutrient availability, and oxygen depth profile in many regions may be a result of anthropogenic greenhouse gas emissions (*low* to *medium confidences*). Marine organisms and ecosystems are *likely* to change in response to these regional changes, although evidence is limited and responses uncertain [30.3, 30.5; 6.2, 6.3; WGI 2.5, 2.7 3.3–3.8, 10.4.2, 10.4.4].

Most, if not all, of the Ocean will continue to warm and acidify, although the rates will vary regionally (*high confidence*). Differences between Representative Concentration Pathways (RCPs) are *very likely* to be minimal until 2040 (*high confidence*). Projected temperatures of the surface layers of the Ocean, however, diverge as the 21st Century unfolds and will be 1–3°C higher by 2100 under RCP8.5 than RCP2.6 across most ocean sub-regions. The projected changes in ocean temperature pose serious risks and vulnerabilities to ocean ecosystems and dependent human communities (*robust evidence*, *high agreement*, *high confidence*) [6.5, 30.3.1, 30.3.2, 30.7.1 Figure 30-2e–g, Table 30-3].

Rapid changes in physical and chemical conditions within ocean sub-regions have already affected the distribution and abundance of marine organisms and ecosystems. Responses of species and ecosystems to climate change have been observed from every ocean sub-region (*high confidence*). Marine organisms are moving to higher latitudes consistent with warming trends (*high confidence*), with fish and zooplankton migrating at the fastest rates, particularly in HLSBS regions. Changes to sea temperature have also altered the phenology or timing of key life-history events such as plankton blooms, and migratory patterns and spawning in fish and invertebrates over recent decades (*medium confidence*). There is *medium* to *high agreement* that these changes pose significant uncertainties and risks to fisheries, aquaculture and other coastal activities. Ocean acidification maybe driving similar changes (*low confidence*), although there is *limited evidence* and *low agreement* at present. The associated risks will intensify as ocean warming and acidification continue [Box CC-MB, 30.4, 30.5, 6.3, 6.4].

Regional risks and vulnerabilities to ocean warming and acidification can be compounded by non-climate related stressors such as pollution, nutrient runoff from land, and over-exploitation of marine resources, as well as natural climate variability (*high confidence*). These influences confound the detection and attribution of the impacts of climate change and ocean acidification on ecosystems yet may also represent opportunities for reducing risks through management strategies aimed at reducing their influence, especially in CBS, SES, and HLSBS [30.1.2, 30.5, 5.3.4, 18.3.3–4].

Recent changes to wind and ocean mixing within the highly productive HLSBS, EBUE, and EUS are *likely* to influence energy transfer to higher trophic levels and microbial processes. There is, however, *limited evidence* and *low agreement* on the direction and magnitude of these changes and their relationship to ocean warming and acidification (*low confidence*). In cases where NPP increases or is not consumed (e.g., Benguela EBUE, *low confidence*), the increased transfer of organic carbon to deep regions can stimulate microbial respiration and reduce O_2 levels (*medium confidence*). Oxygen concentrations are also declining in the tropical Pacific, Atlantic, and Indian Oceans (particularly EUS) due to reduced O_2 solubility at higher temperatures, and changes in ocean ventilation and circulation [Box CC-PP, 30.3.1, 30.3.2, 30.5.5–6, 6.3.3; WGI 3.8.3].

Global warming will result in more frequent extreme events and greater associated risks to ocean ecosystems (*high confidence*). In some cases (e.g., mass coral bleaching and mortality), projected increases will eliminate ecosystems, and increase risks and vulnerabilities to coastal livelihoods and food security (e.g., CBS in SE Asia; SES, CBS, and STG in the Indo-Pacific) (*medium* to *high confidence*). Reducing stressors not related to climate change represents an opportunity to strengthen the ecological resilience within these regions, which may help them survive some projected changes in ocean temperature and chemistry [5.4, 30.6.1, 30.5.3–4, 30.5.6, Figure 30-4, Box CC-CR, IPCC 2012].

The highly productive HLSBS in the North-eastern Atlantic has changed in response to warming oceans (*medium evidence*, *high agreement*), with a range of consequences for fisheries. These ecosystems are responding to recent warming, with the greatest changes being observed since the late 1970s in the phenology, distribution and abundance of plankton assemblages, and the reorganization of fish assemblages (*high confidence*). There is *medium confidence* that these changes will have both positive and negative implications depending on the particular HLSBS fishery and the time frame [Box CC-MB, Box 6-1, 6.4.1.2, 30.5.1, 30.6.2.1].

EUS, which support highly productive fisheries off equatorial Africa and South America, have warmed over the past 60 years (Pacific EUS: 0.43^{o}C, Atlantic EUS: 0.54^{o}C; *very likely*, p-value$\leq$0.05). While warming is consistent with changes in upwelling intensity, there is *low confidence* in our understanding of how EUS will change, especially in how El Niño-Southern Oscillation (ENSO) and other patterns of variability will interact in a warmer world. The risk, however, of changes to upwelling increases with average global temperature, posing significant uncertainties for dependent ecosystems, communities, and fisheries [30.5.2; WGI 14.4,].

The surface waters of the SES show significant warming from 1982 and most CBS show significant warming since 1950. Warming of the Mediterranean has led to the recent spread of tropical species invading from the Atlantic and Indian Oceans. Projected warming increases the risk of greater thermal stratification in some regions, which can lead to reduced O_2 ventilation and the formation of hypoxic zones, especially in the Baltic and Black Seas (*medium confidence*). In some CBS, such as the East China Sea and Gulf of Mexico, these changes are further influenced by the contribution of nutrients from coastal pollution contributing to the expansion of hypoxic (low O_2) zones. These changes are *likely* to influence regional ecosystems as well as dependent industries such as fisheries and tourism, although there is *low confidence* in the understanding of potential changes and impacts [Table 30-1, 30.5.3, 5.3.4.3].

Coral reefs within CBS, SES, and STG are rapidly declining as result of local (i.e., coastal pollution, overexploitation), and climate change (*high confidence*). Elevated sea temperatures drive impacts such as mass coral bleaching and mortality (*very high confidence*), with an analysis of the CMIP5 ensemble projecting the loss of coral reefs from most sites globally by 2050 under mid to high rates of ocean warming (*very likely*) [Figure 30-10, 30.5.3–4, 30.5.6, Box CC-CR].

The productive EBUE and EUS involve upwelling waters that are naturally high in CO_2 concentrations and low in pH, and hence are potentially vulnerable to ocean warming and acidification (*medium confidence*). There is *limited evidence* and *low agreement*, as to how upwelling systems are *likely* to change (*low confidence*). Declining O_2 and shoaling of the aragonite saturation horizon through ocean acidification increases the risk of upwelling water being low in pH and O_2 with impacts on coastal ecosystems and fisheries, as has been seen already (e.g., California Current EBUE). These risks and uncertainties are *likely* to involve significant challenges for fisheries and livelihoods along the west coasts of South America, Africa, and North America (*low* to *medium confidence*) [30.3.2.2, 30.5.2, 30.5.5, Box CC-UP, Box CC-PP].

Chlorophyll concentrations measured by satellites have decreased in the STG of the North Pacific, Indian and North Atlantic Oceans by 9%, 12% and 11%, respectively, over and above the inherent seasonal and interannual variability from 1998–2010 (*high confidence*; p-value$\leq$0.05). Significant warming over this period has resulted in increased water column stratification, reduced mixed layer depth and possibly declines in nutrient availability and ecosystem productivity (*limited evidence*, *medium agreement*). The short timeframe of these studies against well-established patterns of long-term variability lead to the conclusion that these changes are *about as likely as not* due to climate change [30.5.6, Table 30-1, Box CC-UP, 6.3.4].

The world's most abundant yet difficult to access habitat, the DS, is changing (*limited evidence*, *medium agreement*), with warming between 700–2000 m from 1957–2010 *likely* to involve a significant anthropogenic signal (*medium confidence*). Decreased primary productivity of surface waters (e.g., STG) is *likely* to reduce the availability of organic carbon to DS ecosystems. Understanding of the risks of climate change and ocean acidification to the DS is important given the size of the DS region but is limited (*low confidence*) [30.5.7, Figure 30-2; WGI 3.2.4, Figure 3.2, 3.9].

Changes to surface wind and waves, sea level, and storm intensity will increase the vulnerability of ocean-based industries such as shipping, energy and mineral extraction (*medium confidence*). Risks to equipment and people may be reduced through the design and use of ocean-based infrastructure, together with the evolution of policy (*medium agreement*). Risks and uncertainties will increase with further climate change. New opportunities as well as risks for shipping, energy and mineral extraction, and international issues over access and vulnerability, may accompany warming waters, particularly at high latitudes [30.3.1, 30.6.2, 28.2.2, 28.2.5, 28.3.4, 10.2.2, 10.4.4, IPCC 2012].

Changes to ocean temperature, chemistry and other factors are generating new challenges for fisheries, as well as benefits (*high agreement*). Climate change is a risk to the sustainability of capture fisheries and aquaculture development, adding to the threats of over-fishing and other non-climate stressors. In EUS and STG, shifts in the distribution and abundance of large pelagic fish stocks will have the potential to create 'winners' and 'losers' among island nations and economies. There has been a boost in fish stocks of high latitude fisheries in the HLSBS of the North Pacific and North Atlantic, partly as a result of 30 years of increase in temperature. This is *very likely* to continue, although some fish stocks will eventually decline. A number of practical adaptation options and supporting international policies can minimize the risks and maximize the opportunities [30.6, 30.7, 7.4.2, 29.4].

Adaptation strategies for ocean regions beyond coastal waters are generally poorly developed but will benefit from international legislation and expert networks, as well as marine spatial planning (*high agreement*). Fisheries and aquaculture industries with high-technology and/or large investments, as well as marine shipping and oil and gas industries, have high capacities for adaptation due to greater development of environmental monitoring, modeling and resource assessments. For smaller-scale fisheries and developing nations, building social resilience, alternative livelihoods, and occupational flexibility represent important strategies for reducing the vulnerability of ocean-dependent human communities. Building strategies that include climate forecasting and early-warning systems can reduce impacts of warming and ocean acidification in the short term. Overall, there is a strong need to develop ecosystem-based monitoring and adaptation strategies to mitigate rapidly growing risks and uncertainties to the coastal and oceanic industries, communities and nations (*high agreement*) [30.6, 7.3.2.4].

Significant opportunity exists within the Ocean and its sub-regions for reducing the CO_2 flux to the atmosphere (*limited evidence, medium agreement*). Ecosystems such as mangroves, seagrass and salt marsh offer important carbon storage and sequestration opportunities (e.g., Blue Carbon*; limited evidence*, *medium agreement*). Blue Carbon strategies can also be justified in terms of the ecosystem services provide by coastal vegetated habitats such as protection against coastal erosion and storm damage, and maintenance of habitats for fisheries species. Sequestration of anthropogenic CO_2 into deep ocean areas still faces considerable hurdles with respect to the expense, legality and vulnerability of storage sites and infrastructure. There are also significant opportunities with the Ocean for the development of offshore renewable energy such as wind and tidal power [30.6.1, 30.6.4].

International frameworks for collaboration and decision-making are critically important for coordinating policy that will enable mitigation and adaptation by the Ocean sectors to global climate change (e.g., United Nations Convention on the Law of the Sea, UNCLOS). These international frameworks offer an opportunity to solve problems collectively, including improving fisheries management across national borders (e.g., reducing illegal, unreported and unregulated fishing, IUU), responding to extreme events, and strengthening international food security. Given the importance of the Ocean to all countries, there is a need for the international community to progress rapidly to a 'whole of ocean' strategy for responding to the risks and challenges posed by anthropogenic ocean warming and acidification [30.7.2].

30.1. Introduction

The Ocean exerts a profound influence as part of the Earth, interacting with its atmosphere, cryosphere, land, and biosphere to produce planetary conditions. It also directly influences human welfare through the provision and transport of food and resources, as well as by providing cultural and economic benefits, and indirectly through the regulation of atmospheric gas content and the distribution of heat and water across the planet. Chapter 30 examines the extent to which regional changes to the Ocean can be accurately detected and attributed to anthropogenic climate change and ocean acidification, building on the conclusions of Chapter 6, which focuses on the marine physiological and ecological responses to climate change and ocean acidification. Detailed assessment of the role of recent physical and chemical changes within the Ocean to anthropogenic climate change is provided in WGI (particularly Chapters 2, 3, 13, and 14). In Chapter 30, impacts, risks, and vulnerabilities associated with climate change and ocean acidification are assessed for seven ocean sub-regions, and the expected consequences and adaptation options for key ocean-based sectors are discussed. Polar oceans (defined by the presence of sea ice in the north and by the Polar Front in the south) are considered in Chapter 28.

While climate change affects coastal and low-lying sub-regions of multiple nations, detailed discussion of potential risks and consequences for these regions occurs in the relevant chapters of this report (e.g., WGII Chapters 5 and 29 as well as other regional sections).

30.1.1. Major Sub-Regions within the Ocean

The Ocean represents a vast region that stretches from the high tide mark to the deepest oceanic trench (11,030 m) and occupies 71% of the earth's surface. The total volume of the Ocean is approximately 1.3 billion km^3, with approximately 72% of this volume being below 1000 m (Deep Sea (DS), 30.5.7). There are considerable challenges in assessing the regional impacts of climate change on the Ocean. Devising an appropriate structure in order to explore the influence of climate change across the entire Ocean region and the broad diversity of life forms and habitats is challenging. [*Longhurst*, 1998] identified over 50 distinct ecological provinces in the Ocean, defined by physical characteristics and the structure and function of phytoplankton communities. Longhurst's scheme, however, yields far more sub-regions than could be sensibly discussed in the space allocated within AR5. Consequently, we have used comparable principles but have divided the non-polar ocean into seven larger sub-regions similar to *Barber* [1988]. We recognize that these sub-regions do not always match physical-chemical patterns or specific geographies, and that they interact strongly with terrestrial regions through weather systems and the exchange of materials. Different ocean sub-regions may also have substantially different primary productivities and fishery catch. Notably, over 80% of fishery catch is associated with three ocean sub-regions: Northern Hemisphere High Latitude Spring Bloom Systems (HLSBS), Coastal Boundary Systems (CBS), and Eastern Boundary Upwelling Ecosystems

(EBUE; Table SM30-1, Figure 30-1). The DS (>1000m) is included as a separate category that overlaps with the six other ocean sub-regions dealt with in Chapter 30.

[INSERT FIGURE 30-1 HERE
Figure 30-1: (a) Separation of the world's non-polar oceans into seven major sub-regions (excluding the polar oceans, which are considered in Chapter 28). The chlorophyll-*a* signal measured by SeaWiFS and averaged over the period from Sep 4, 1997 to 30 Nov 2010 (NASA) is provides a proxy for differences in marine productivity (with the caveats provided in Box CC-PP). Ecosystem structure and functioning, as well as key oceanographic features provided the basis for separating the Ocean into the sub-regions shown. The map insert shows the distribution of Deep Sea (DS) habitat (>1000 m; Bathypelagic and Abyssopelagic habitats combined). Numbers refer to: 1 = High Latitude Spring Bloom Systems (HLSBS); 2 = Equatorial Upwelling Systems (EUS); 3 = Semi-Enclosed Seas (SES); 4 = Coastal Boundary Systems (CBS); 5 = Eastern Boundary Upwelling Ecosystems (EBUE); 6 = Sub-Tropical Gyres (STG); and 7 = DS (>1000 m). (b) Relationship between fish catch and area for each ocean sub-region is shown in (a). Red columns: average fish catch (as millions tons yr^{-1}) for the period 1970–2006. Blue columns: area (millions km^2). The four left-hand columns (sub-regions HLSBS-North, CBS, EBUE, and SES) cover 20 % of the world oceans' area and deliver 80% of the world's fish catches. The values for the percent area of the Ocean, primary productivity, and fishery catch for the major sub-regions are listed in Table SM30-1.].

30.1.2. Detection and Attribution of Climate Change and Ocean Acidification in Ocean Sub-Regions

The central goal of Chapter 30 is to assess the recent literature on the Ocean as a region for changes that can be attributed to climate change and/or ocean acidification. Detailed assessments of recent physical and chemical changes in the Ocean are outlined in WGI Chapters 2, 3, 6, 10, 13, and 14 (AR5). The detection and attribution of climate change and ocean acidification on marine organisms and ecosystems is addressed in Chapter 6. Chapter 30 draws on these chapters to investigate regional changes in the physical, chemical, ecological, and socio-economic aspects of the Ocean and the extent to which they can be attributed to climate change and ocean acidification.

Generally, successful attribution to climate change occurs when the full range of possible forcing factors is considered and those related to climate change are found to be the most probable explanation for the detected change in question [18.2.1.1]. Comparing detected changes with the expectations of well-established scientific evidence also plays a central role in the successful attribution of detected changes. We attempt to do this for seven sub-regions of the Ocean. There are a number of general limitations to the detection and attribution of impacts to climate change and ocean acidification that are discussed elsewhere [18.2.1] along with challenges [18.2.2]. Different approaches and 'best practice' guidelines are discussed in WGI Chapters 10 and 18 as well as in several other places [*Hegerl et al.*, 2007; *Hegerl et al.*, 2010; *Stott et al.*, 2010]. The fragmentary nature of ocean observing, structural uncertainty in model simulations, the influence of long-term variability, and confounding factors unrelated to climate change (e.g., pollution, introduced species, overexploitation of fisheries) represent major challenges [*Halpern et al.*, 2008; *Hoegh-Guldberg et al.*, 2011b; *Parmesan et al.*, 2011]. Different factors may also interact synergistically or antagonistically with each other and climate change, further challenging the process of detection and attribution [*Hegerl et al.*, 2007; *Hegerl et al.*, 2010].

30.2. Major Conclusions from Previous Assessments

An integrated assessment of the impacts of climate change and ocean acidification on the Ocean as a region was not included in recent IPCC assessments, although a chapter devoted to the Ocean in the Second Assessment Report (SAR) did "attempt to assess the impacts of projected regional and global climate changes on the oceans" [*Ittekkot et al.*, 1996]. The fact that assessments for ocean and coastal systems are spread throughout previous IPCC assessment reports reduces the opportunity for synthesizing the detection and attribution of climate change and ocean acidification across the physical, chemical, ecological, and socio-economic components of the Ocean and its sub-regions. The IPCC Fourth Assessment Report (AR4) concluded, however, that while terrestrial sub-regions are warming faster than the oceans, "Observations since 1961 show that the average temperature of the global ocean has increased to depths of at least 3000 m and that the ocean has been taking up over 80% of the heat being added to the

climate system." AR4 also concluded that sea levels had risen due to the thermal expansion of the Ocean but recognized that our understanding of the dynamics of glaciers and ice sheets was "too limited to assess their likelihood or provide a best estimate or an upper boundary for sea level rise" (AR4, SPM). Changes to ocean temperature and density have been identified as having the potential to alter large-scale ocean circulation. AR4 concluded that with respect to the Meridional Overturning Circulation (MOC) "it is *very likely* that up to the end of the 20th Century the MOC was changing significantly at interannual to decadal time scales" (AR4, WGI Chapter 5, Box 5.1), despite limited evidence of a slowing MOC.
According to AR4, "sea-level rise over the last 100–150 years is probably contributing to coastal erosion in many places", including the east coast of the United States and the United Kingdom (AR4, WGII Chapter 1). The AR4 assessment was *virtually certain* that rising atmospheric CO_2 had changed carbonate chemistry of the ocean (i.e., buffering capacity, carbonate and bicarbonate concentrations), and that a decrease in surface pH of 0.1 had occurred over the global ocean (calculated from the uptake of anthropogenic CO_2 between 1750 and 1994 ([*Sabine et al.*, 2004; *Raven et al.*, 2005]; AR4, 5.4.2.3, WGI Table 7.3). Large-scale changes in ocean salinity were also observed from 1955–1998 and were "characterized by a global freshening in sub-polar latitudes and salinification of shallower parts of the tropical and subtropical oceans". In this case, freshening was observed in the Pacific, with increased salinity being observed in the Atlantic and Indian Oceans (AR4, WGI 5.3.2–5.3.5). These changes in surface salinity were qualitatively consistent with expected changes to surface freshwater flux. Freshening of mid and high latitude waters together with increased salinity at low latitudes were seen as evidence "of changes in precipitation and evaporation over the oceans".

Substantial evidence indicated that changing ocean conditions have extensively influenced marine ecosystems (AR4, WGII Table 1.5). AR4 noted that there is an "accumulating body of evidence to suggest that many marine ecosystems, including managed fisheries, are responding to changes in regional climate caused predominately by warming of air and sea surface temperatures (SST) and to a lesser extent by modification of precipitation regimes and wind patterns" (AR4, WGII 1.3.4.2). Observed changes in marine ecosystems and managed fisheries reported within AR4 included: changes to plankton community structure and productivity, the phenology and biogeography of coastal species, intertidal communities on rocky shores and kelp forests, and the distribution of pathogens and invasive species. Changes were also observed in coral reefs (primarily increased mass coral bleaching and mortality), migratory patterns and trophic interactions of marine birds, reptiles, and mammals, as well as of a range of other marine organisms and ecosystems (AR4, WGII Table 1.5), although a separate exercise in detection and attribution of changes to climate change (as done for terrestrial studies) was not done as part of AR4.

30.3. Recent Changes and Projections of Future Ocean Conditions

Evidence that increasing concentrations of atmospheric CO_2 have resulted in the warming and acidification of the upper layers of the Ocean has strengthened since AR4. Understanding the full suite of physical and chemical changes to the Ocean is critical to the interpretation of the past and future responses of marine organisms and ecosystems, especially with respect to the implications for coastal and low-lying areas.

30.3.1. Physical Changes

30.3.1.1. Heat Content and Temperature

The Ocean has absorbed 93% of the extra heat arising from the enhanced greenhouse effect (1971–2010), with most of the warming (64%) occurring in the upper (0–700 m) ocean (1971–2010; WGI Section 3.2.3, Figure 3.2, Box 3.1). It is *virtually certain* that global average sea surface temperatures (SST) have increased since the beginning of the 20th Century, with improvements and growth of data sets and archives, and the understanding of errors and biases since AR4 (WGI 2.4.2). It is *virtually certain* that the upper ocean (0–700m depth) has warmed from 1971–2010 (Figure 30-2a), while it is *likely* that the surface layers of the Ocean have warmed from the 1870s to 1971. Rates of increase in temperature are highest near the surface of the Ocean (>0.1°C decade^{-1} in the upper 75 m from 1971 to 2010) decreasing with depth (0.015°C decade^{-1} at 700 m; Figure 30-2b, c). It is *very likely* that the intensification of this warming near the surface has increased thermal stratification of the upper ocean by about 4%

between 0–200 m depth from 1971–2010 in all oceans north of 40°S. It is *likely* that the Ocean has warmed between 700–2000 m from 1957–2010, with the warming signal becoming less apparent or non-existent at deeper depths (WGI 3.2.1–3.2.3, Figures 3.1–3.2, Figure 3.9). These changes include a significant anthropogenic signal (*virtually certain*) [*Gleckler et al.*, 2012; *Pierce et al.*, 2012], with the surface waters of all three ocean basins warming at different rates, that all exceed those expected if there were no changes to greenhouse gas forcing over the past century (Figure 30-2e-g). In this respect, the observed record also falls within the range of historical model outputs that include observed increases in the concentration of greenhouse gases as opposed to models that do not (Figure 30-2 e-g).

Data archives such as HadISST1.1 contain sea surface temperatures (SST) reconstructed from a range of sources, allowing an opportunity to explore mean monthly, gridded, global SST from 1870 to the present [*Rayner et al.*, 2003]. We used the published HadISST1.1 data set (higher temporal and spatial resolution than HadSST3) to explore trends in historic SST within our sub-regions (Figure 30-1a; see definition of regions in Figure SM30-1 and Table SM30-2, column 1). The median SST for 1871–1995 from the Comprehensive Ocean-Atmosphere Data Set (COADS) were merged with data from the UK Met Office Marine Data Bank (MDB) to produce monthly globally-complete fields of SST on a 1° latitude-longitude SST grid from 1870 to date.

The surface layers of the three ocean basins have warmed (p-value$\leq$0.05, *very likely*), with the Indian Ocean (0.11℃ decade^{-1}) warming faster than the Atlantic (0.07℃ decade^{-1}) and Pacific (0.05℃ decade^{-1}) Oceans *(high confidence)* (Table 30-1). This is consistent with the depth-averaged (0–700 m) temperature trend observed from 1971–2010 (Figure 30-2a).

While some regions (e.g., North Pacific) did not show a clear warming trend, most regions showed either significant warming in the average temperature, or significant warming in either/or the warmest and coolest months of the year, over the period 1950–2009 (HadISST1.1 data, Table 30-1). Trends in SST show considerable sub-regional variability (Table 30-1, Figure 30-2a). Notably, the average temperature of most HLSBS did not increase significantly from 1950–2009 (except in the Indian Ocean; Table 30-1) yet the temperatures of the warmest month (North and South Atlantic, and South-eastern Pacific) and of the coolest month (North and South Atlantic, and South Pacific) showed significant upward trends over this period (p-value$\leq$0.05; Table 30-1).

The two EUS warmed from 1950–2009 (Pacific EUS, 0.07℃ decade^{-1} and Atlantic EUS, 0.09℃ decade^{-1}; Table 30-1). The average monthly SST of the SES did not warm significantly, although the temperature of the coolest month increased significantly within the Baltic Sea (0.35°C decade^{-1} or 2.11°C from 1950–2009), as did the temperatures of the warmest months in the Black (0.14°C decade^{-1} or 0.83°C from 1950–2009), Mediterranean (0.11°C decade^{-1} or 0.66°C from 1950–2009) and Red (0.05°C decade^{-1} or 0.28°C from 1950–2009) Seas over the period 1950–2009 (*very likely*) (Table 30-1). Studies over shorter periods (e.g., 1982–2006, [*Belkin*, 2009]) report significant increases in average SST of the Baltic (1.35°C), Black (0.96°C), Red (0.74°C), and Mediterranean (0.71°C) Seas. Such studies are complicated by the influence of patterns of long-term variability and by the small size and land-locked nature of SES. Coastal Boundary Systems (except the Caribbean and Gulf of Mexico) all showed highly significant (p-value$\leq$0.05) warming (0.09°C–0.13°C.decade^{-1}, Table 30-1). Among the EBUE, the Canary and Californian current regions exhibited a significant rate of change in the average SST (0.09°C decade^{-1} and 0.12°C decade^{-1}, respectively; p-value$\leq$0.05), while the Benguela and Humboldt currents did not show significant temperature changes from 1950–2009 (p-value>0.05; Table 30-1). There was some variability between current systems in terms of the behavior of the coolest and warmest months. The temperature of the coolest month increased significantly from 1950–2009 in the case of the Benguela and California currents (0.06°C decade^{-1} and 0.12°C decade^{-1} respectively, p-value$\leq$0.05), while there was a significant increase in the temperature of the warmest month in the case of the Canary and Humboldt currents (0.11°C decade^{-1} and 0.10°C decade^{-1}, respectively, Table 30-1).

The average temperature of STG showed complex patterns with increasing temperatures (1950–2009) in the Indian, South Atlantic, and South Pacific Oceans (*very likely*) (0.11, 0.08, and 0.06°C decade^{-1}, respectively; p-value$\leq$0.05), but not in the North Atlantic or North Pacific Ocean (p-value>0.05). These rates are half the value reported over shorter periods (e.g., 1998–2010, Table 1 in [*Signorini and McClain*, 2012] and based on NOAA_OI_SST_V2 data). Given the sensitivity of coral reefs to temperature ([*Eakin et al.*, 2010; *Strong et al.*, 2011; *Lough*, 2012]; Box CC-CR), trends in key coral reef regions were also examined using the World Resources Institute's *Reefs at Risk* report (www.wri.org) to identify HadISST1.1 grid cells containing coral reefs (Figure 30-4b). Grouping the results into six major coral reef regions, we found that coral reef waters (with the notable exception of the Gulf of Mexico and Caribbean) have shown strong increases in average temperature (0.07–0.13°C decade^{-1}) as well as the temperature of the coolest (0.07–0.14°C decade^{-1}) and warmest months (*very likely*) (0.07–0.12°C decade^{-1}; Table 30-1). These trends in temperature have resulted in an absolute increase in sea temperature of 0.44–0.79°C from 1950–2009.

[INSERT FIGURE 30-2 HERE
Figure 30-2: (a) Depth-averaged 0–700 m temperature trend for 1971–2010 (longitudinal versus latitude, colors and gray contours in °C per decade). (b) Zonally averaged temperature trends (latitude versus depth, colors and gray contours in °C per decade) for 1971–2010, with zonally averaged mean temperature over plotted (black contours in °C). (c) Globally-averaged temperature anomaly (Time versus depth, colors and grey contours in °C) relative to the 1971–2010 mean. (d) Globally-averaged temperature difference between the Ocean surface and 200 m depth (Black: annual values; red: five year running mean). Panels (a)–(d) from WGI Figure 3.1. (e)–(g) Observed and simulated variations in past and projected future annual average SST over three ocean basins (excluding regions within 300 km of the coast). The black line shows estimates from HadISST1.1 observational measurements. Shading denotes the 5–95 percentile range of climate model simulations driven with 'historical' changes in anthropogenic and natural drivers (62 simulations), historical changes in 'natural' drivers only (25), and the Representative Concentration Pathways: Dark Blue: RCP2.6; Light Blue: RCP4.5; Green: RCP6.0, and Red: RCP8.5). Data are anomalies from the 1986–2006 average of the HadISST1.1 data (for the HadISST1.1 time series) or of the corresponding historical all-forcing simulations. Further details are given in Box 21-2.]

[INSERT FIGURE 30-3 HERE
Figure 30-3: Velocity at which sea surface temperature (SST) isotherms shifted (km decade^{-1}) over the period 1960–2009 calculated using HaDISST1.1, with arrows indicating the direction and magnitude of shifts. Velocity of climate change is obtained by dividing the temperature trend in °C decade^{-1} by the local spatial gradient °C km^{-1}. The direction of movement of SST is denoted by the direction of the spatial gradient and the sign of the temperature trend: towards locally cooler areas with a local warming trend or towards locally warmer areas where temperatures are cooling. Adapted from [*Burrows et al.*, 2011].]

[INSERT TABLE 30-1 HERE
Table 30-1: Regional changes in sea surface temperature (SST) over the period 1950–2009 using the Ocean regionalization specified in Figure 30-1a (for further detail of regions defined for analysis, see Figure SM30-1 and Table 30-2, column 1). A linear regression was fitted to the average of all 1×1 degree monthly SST data extracted from the HadISST1.1 data set [*Rayner et al.*, 2003] for each sub-region over the period 1950–2009. All SST values less than -1.8°C, together with all SST pixels that were flagged as being sea ice, were reset to the freezing point of seawater (-1.8°C) to reflect the sea temperature under the ice. Separate analyses were also done to explore trends in the temperatures extracted from the coldest-ranked and the warmest-ranked month of each year (Table SM30-2). The table includes the slope of the regression (°C decade^{-1}), the p-value for the slope being different from zero and the total change over 60 years (i.e., the slope of linear regression multiplied by 6 decades) for each category. The p-values that exceed 0.05 plus the associated slope and change values have a gray background, denoting the lower statistical confidence in the slope being different from zero (no slope). Note, changes with higher p-values may still describe informative trends although the level of confidence is lower that the slope is different from zero.]

Given the essential role that temperature plays in the biology and ecology of marine organisms (Box CC-MB, 6.2, 6.3, [*Pörtner*, 2002; *Poloczanska et al.*, 2013]), the speed of isotherm migration ultimately determines the speed at which populations must either move, adapt or acclimate to changing sea temperatures [*Pörtner*, 2002; *Burrows et al.*, 2011; *Hoegh-Guldberg*, 2012]. *Burrows et al.* [2011] calculated the rate at which isotherms are migrating as the ratio of the rate of SST change (°C yr^{-1}) to the spatial gradient of temperature (°C km^{-1}) over the period 1960–2009 (Figure 30-3). While many of these temperature trajectories are towards the polar regions, some are not and are influenced by features such as coastlines. This analysis and others (e.g., North Atlantic, *González-Taboada and Anadón* [2012]) reveals that isotherms in the Ocean are moving at high velocities (up to 200 km decade^{-1}), especially at low latitudes (*high confidence*) (Figure 30-3). Other sub-regions showed smaller velocities with contracting isotherms (cooling) in some areas (e.g., the Central and North Pacific, and Atlantic Oceans, Figure 30-3). There are also changes in the timing of seasonal temperatures in both spring and fall/autumn [*Burrows et al.*, 2011; *Poloczanska et al.*, 2013] which, together with other variables (e.g., light, food availability, geography), are *likely* to affect biological processes such as the migration of species to higher latitudes, and the timing and synchrony of reproductive and other seasonal behaviors.

Significant excursions of sea temperature above long-term summer temperature maxima (or below long-term temperature minima) significantly affect marine organisms and ecosystems [*Hoegh-Guldberg*, 1999; *Bensoussan et al.*, 2010; *Crisci et al.*, 2011; *Harley*, 2011]. Consequently, calculating heat stress as a function of exposure time and size of a particular temperature anomaly has proven useful in understanding recent changes to organisms and ecosystems (e.g., coral reefs and thermal anomalies, [*Strong et al.*, 2011]). The total heat stress accumulated over the period 1981–2010 was calculated using the methodology of [*Donner et al.*, 2007] and a reference climatology based on 1985–2000 in which the highest monthly SST was used to define the thermal threshold, above which accumulated thermal stress was calculated as 'exposure time multiplied by stress' or Degree Heating Months (DHM) as the running total over four consecutive months. While most sub-regions of the Ocean experienced an accumulation of heat stress (relative to a climatology based on the period 1985–2000), equatorial and high latitude sub-regions in the Pacific and Atlantic Oceans have the greatest levels of the accumulated heat stress (Figure 30-4a). These are areas rich in thermally-sensitive coral reefs (Figure 30-4b, [*Strong et al.*, 2011]). There was also a higher proportion of years that have had at least one stress event (DHM>1) in the last 30 years (1981–2010, Figure 30-4c) than in the preceding 30 years (1951–1980, Figure 30-4c, d.

[INSERT FIGURE 30-4 HERE
Figure 30-4: Recent changes in thermal stress calculated using HadISST1.1 data. A monthly climatology was created by averaging the HadISST monthly SST values over the period 1985–2000 to create twelve averages, one for each month of the year. The Maximum Monthly Mean (MMM) climatology was created by selecting the hottest month for each pixel. Anomalies were then created by subtracting this value from each SST value, but only allowing values to be recorded if they were greater than zero [*Donner et al.*, 2007]. Two measures of the change in thermal stress were calculated as a result: (a) The total thermal stress for the period 1981–2010, calculated by summing all monthly thermal anomalies for each grid cell. (b) The location of coral reef grid cells used in Table 30-1 and for comparison to regional heat stress here. Each dot is positioned over a 1×1 degree grid cell within which lies at least one carbonate coral reef. The latitude and longitude of each reef is derived from data provided by the World Resources Institute's *Reefs at Risk* report (http://www.wri.org). The six regions are as follows: Red – Western Pacific Ocean; Yellow – Eastern Pacific Ocean; Dark Blue – Caribbean & Gulf of Mexico; Green – Western Indian Ocean; Pink – Eastern Indian Ocean; and Light Blue – Coral Triangle & SE Asia. (c) Proportion of years with thermal stress, which is defined as any year that has a thermal anomaly, for the periods 1951–1980 and (d) 1981–2010.]

The three ocean basins will continue warming under moderate (RCP4.5) to high (RCP8.5) emission trajectories (*high confidence*) and will only stabilize over the second half of the century in the case of low range scenarios such as RCP2.6 (Figure 30-2 e-g; WGI, AI.4–AI.8). Projected changes were also examined for specific ocean sub-regions using ensemble averages from AOGCM simulations available in the CMIP5 archive (Table SM30-3) for the four scenarios of the future (Representative Concentration Pathways: RCP2.6, RCP4.5, RCP6.0 and RCP8.5; [*van Vuuren et al.*, 2011]). Ensemble averages for each RCP are based on simulations from 10–16 individual models (Table SM30-3). The subset of CMIP5 models were chosen because each has historic runs enabling the derivation of the MMM climatology from 1985–2000, ensuring that all anomalies were comparable across time periods and across RCPs (Figure 30-10). Model hind-cast changes matched those observed for ocean sub-regions for the period 1980–2009 (HadISST1.1; Figure 30-2), with the model ensemble slightly overestimating the extent of change across the different ocean sub-regions (slope of observed/model = 0.81, $r^2 = 0.76$, p-value$\leq$0.001). In this way, the absolute amount of change projected to occur in the ocean sub-regions was calculated for near-term (2010–2039) and long-term (2070–2099) periods (Table SM30-4). In the near-term, changes in the temperature projected for the surface layers of the Ocean are largely indistinguishable between the different RCP pathways due to the similarity in forcing until 2040. By the end of the century, however, SST across the ocean sub-regions were 1.8–3.3°C higher under RCP8.5 than those projected to occur under RCP2.6 (Table SM30-4; Figure 30-2 e–g). The implications of these projected changes on the structure and function of oceanic systems are discussed below.

30.3.1.2. Sea Level

The rate of sea level rise since the mid-19th Century has been larger than the mean rate during the previous two millennia (*high confidence*). Over the period 1901–2010, Global Mean Sea Level (GMSL) rose by 0.19 (0.17–0.21) m (WGI Figure SPM, 3.7, 5.6, 13.2). It is *very likely* that the mean rate of global averaged sea level rise was 1.7 [1.5–1.9] mm yr^{-1} between 1901 and 2010, 2.0 [1.7–2.3] mm yr^{-1} between 1971 and 2010 and 3.2 [2.8–3.6] mm yr^{-1} between 1993 and 2010 (WGI SPM, 3.7). These observations are consistent with thermal expansion of the Ocean due to warming plus the addition of water from loss of mass by melting glaciers and ice sheets. Current rates of sea level rise vary geographically, and can be higher or lower than the GMSL for several decades at time due to fluctuations in natural variability and ocean circulation (Figure 30-5). For example, rates of sea level rise are up to three times higher than the GMSL in the Western Pacific and South-east Asian region, and decreasing in many parts of the Eastern Pacific for the period 1993–2012 as measured by satellite altimetry (Figure 30-5; WGI 13.6.5).

Sea level rise under increasing atmospheric greenhouse gas concentrations will continue for hundreds of years, with the extent and rate of the increase in GMSL being dependent on the emission scenario followed. Central to this analysis is the millennial-scale commitment to further sea level rise that is *likely* to arise from the loss of mass of the Greenland and Antarctic ice sheets (WGI 13.5.4, Figure 13.13). Sea level rise is *very likely* to increase during the 21st Century relative to the period 1971–2010 due to increased ocean warming and the continued contribution of water from loss of mass from glaciers and ice sheets. There is *medium confidence* that median sea level rise by 2081–2100 relative to 1986-2005 will be (5–95% range of process-based models): 0.44 m for RCP2.6, 0.53 m for RCP4.5, 0.55 m for RCP6.0, and 0.74 m for RCP8.5. Higher values of sea level rise are possible but are not backed by sufficient evidence to enable reliable estimates of the probability of specific outcomes. Many semi-empirical model projections of GMSL rise are higher than process-based model projections (up to about twice as large), but there is no consensus in the scientific community about their reliability and there is thus *low confidence* in their projections (WGI 13.5.2–3; Table 13.6, Figure 13.12).

It is considered *very likely* that increases in sea level will result in greater levels of coastal flooding and more frequent extremes by 2050 (WGI 13.7.2; [*IPCC*, 2012]). It is *about as likely as not* that the frequency of the most intense storms will increase in some ocean basins, although there is *medium agreement* that the global frequency of tropical cyclones is *likely* to decrease or remain constant (WGI 14.6, 14.8). While understanding of associated risks is relatively undeveloped, coastal and low-lying areas, particularly in the southern Asia, Pacific Ocean and North Atlantic regions, face increased flood risk (5.3.3.2, 8.2.3.4, 9.3.4.4. Future impacts of sea level rise include increasing penetration of storm surges into coastal areas and changing patterns of shoreline erosion (5.3), as well as the inundation of coastal aquifers by saltwater (5.4.2.5, 29.3.2). Regionally, some natural ecosystems may reduce in extent (e.g., mangroves), although examples of habitat expansion have been reported [*Brown et al.*, 2011]. Overall, changes to sea level are *very likely* to modify coastal ecosystems such as beaches, salt marshes, coral reefs and mangroves (5.4.2, Box CC-CR), especially where rates of sea level rise are highest (e.g., South-east Asia and the Western Pacific).

[INSERT FIGURE 30-5 HERE
Figure 30-5. Map of the rate of change in sea surface height (geocentric sea level) for the period 1993–2012 derived from satellite altimetry. Also shown are relative sea level changes (gray lines) from selected tide gauge stations for the period 1950–2012. For comparison, an estimate of global mean sea level change is shown (red lines) with each tide gauge time series. The relatively large short-term oscillations in local sea level (gray lines) are due to the natural climate variability and ocean circulation. For example, the large regular deviations at Pago Pago are associated with the El Niño-Southern Oscillation. Figure originally presented in WGI (FAQ 13.1, Figure 1).

30.3.1.3. Ocean Circulation, Surface Wind, and Waves

Circulation of atmosphere and ocean (and their interactions) drives much of the chemical, physical, and biological characteristics of the Ocean, shaping phenomena such as ocean ventilation, coastal upwelling, primary production, and biogeochemical cycling. Critical factors for transporting nutrients from deep waters to the marine primary producers in the upper layers of the ocean include wind-driven mixing and upwelling.

There has been a poleward movement of circulation features, including a widening of the tropical belt, contraction of the northern polar vortex, and a shift of storm tracks and jet streams to higher latitudes (*medium confidence*, WGI 2.7.5, 2.7.6, 2.7.8, Box 2.5). Long-term patterns of variability (years to decades) continue to prevent robust conclusions regarding long-term changes in atmospheric circulation and winds in many cases (WGI 2.7.5). There is *high confidence*, however, that the increase in northern mid-latitude westerly winds from the 1950s to the 1990s, and the weakening of the Pacific Walker circulation from the late 19th Century to the 1990s have been largely offset by recent changes (WGI 2.7.5, 2.7.8, Box 2.5). Wind stress has increased since the early 1980s over the Southern Ocean (*medium confidence*) (WGI 3.4.4), and tropical Pacific since 1990 (*medium confidence*), while zonal mean wind stress may have declined by 7% in the equatorial Pacific from 1862–1990 due to weakening of the tropical Walker circulation (*medium confidence*) (WGI 3.4.4; [*Vecchi et al.*, 2006]). For example, it is *very likely* that the sub-tropical gyres of the major ocean basins have expanded and strengthened since 1993. However, the short-term nature of observing means that these changes are *as likely as not* to be due to decadal variability and/or due to longer term trends in wind forcing associated with climate change (WGI 3.6). Other evidence of changes in ocean circulation is limited to relatively short-term records that suffer from low temporal and spatial coverage. Therefore, there is *very low confidence* that multi-decadal trends in ocean circulation can be separated from decadal variability (WGI 3.6.6). There is no evidence of a long-term trend in large-scale currents such as the Atlantic Meridional Overturning Circulation (AMOC), Indonesian Throughflow (ITF), the Antarctic Circumpolar Current (ACC), or the transport of water between the Atlantic Ocean and Nordic Seas [WGI 3.6, Figures 3.10, 3.11].

Winds speed may have increased within the regions of EBUE (*low confidence* in attribution to climate; e.g. California Current, WGI 2.7.2). Changing wind regimes have the potential to influence mixed layer depth (MLD) and upwelling intensity in highly productive sub-regions of the world's oceans, although there is *low agreement* as to whether or not upwelling will intensify or not under rapid climate change ([*Bakun*, 1990; *Bakun et al.*, 2010]; Box CC-UP). Surface waves are influenced by wind stress, although understanding trends remains a challenge due to limited data. There is *medium confidence* that Significant Wave Height (SWH) has increased since the mid-1950s over much of the North Atlantic north of 45°N, with typical winter season trends of up to 20 cm per decade (WGI 3.4.5). There is *low confidence* in the current understanding of how SWH will change over the coming decades and century for most of the Ocean. It remains an important knowledge gap (WGI 3.4).

30.3.1.4. Solar Insolation and Clouds

Solar insolation plays a crucially important role in the biology of many marine organisms, not only as a source of energy for photosynthesis but also as a potential co-stressor in the photic zone (with temperature), as is seen during mass coral bleaching and mortality events (e.g., [*Hoegh-Guldberg*, 1999]). Global surface solar insolation (from the NCEP/NCAR Reanalysis Project, *Kalnay et al.* [1996]) decreased by 4.3 W m^{-2} $decade^{-1}$ from the 1950s until 1991, after when it increased at 3.3 W m^{-2} $decade^{-1}$ until 1999 [*Ohmura*, 2009; *Wild*, 2009], matching a broad suite of evidence from many land-based sites (WGI, 2.3.3). While there is consistency between independent data sets for particular regions, there is substantial ambiguity and therefore *low confidence* in observations of global-scale cloud variability and trends (WGI 2.5.7). There is also *low confidence* in projections of how cloudiness, solar insolation and precipitation will change as the planet warms due to the large interannual and decadal variability (ENSO, PDO), short observation time series and uneven spatial sampling, particularly in the early record (before 1950; WGI 2.5.8).

30.3.1.5. Storm Systems

As agents of water column mixing, storms (from small atmospheric disturbances to intense tropical cyclones) can remix nutrients from deeper areas into the photic zone of the Ocean, stimulating productivity. Storms can also reduce local sea temperatures and associated stress by remixing heat into the deeper layers of the Ocean [*Carrigan and Puotinen*, 2011]. Large storms can destroy coastal infrastructure and coastal habitats such as coral reefs and mangrove forests, which can take decades to recover [*Lotze et al.*, 2011; *De'ath et al.*, 2012]. While there is *low* *confidence* for long-term trends in tropical cyclone activity globally (largely due to the lack of reliable long-term data sets), it is *virtually certain* that the frequency and intensity of the strongest tropical cyclones in the North Atlantic have increased since the 1970s (WGI 2.6.3). There is *medium agreement* that the frequency of the most intense cyclones in the Atlantic has increased since 1987 (WGI 2.6.3) and *robust evidence* of interdecadal changes in the storm track activity within the North Pacific and North Atlantic [*Lee et al.*, 2012]. It is also *very likely* that there has been a decrease in the number of land-falling tropical cyclones along the East Australian coast since the 19th Century (WGI 2.6.3, [*Callaghan and Power*, 2011]). It is *likely* that these patterns are influenced by interannual variability such as ENSO, with land-falling tropical cyclones being twice as common in La Niña versus El Niño years (*high confidence*) [*Callaghan and Power*, 2011]. There has been an increase in the number of intense wintertime extra-tropical cyclone systems since the 1950s in the North Pacific. Similar trends have been reported for the Asian region, although analyzes are limited in terms of the spatial and temporal coverage of reliable records (WGI 2.6.4). There is *low confidence*, however, in large-scale trends in storminess or storminess proxies over the last century due to the lack of long-term data and inconsistencies between studies (WGI 2.6.4).

30.3.1.6. Thermal Stratification

As heat has accumulated in the Ocean there has been a 4% increase in thermal stratification of the upper layers in most ocean regions (0–200 m, 40-year record) north of 40°S (WGI 3.2.2). Increasing thermal stratification has reduced ocean ventilation and the depth of mixing in many ocean sub-regions (*medium confidence*) WGI 3.8.3). This in turn reduces the availability of inorganic nutrients and consequently primary productivity (*medium confidence*) (6.3.4). In the STG, which dominate the three major ocean basins (30.5.6), satellite-derived estimates of surface chlorophyll and primary production decreased between 1999 and 2007 (Box CC-PP). In contrast, however, *in situ* observations at fixed stations in the North Pacific and North Atlantic Oceans (Hawaii Ocean Time-series or HOT, and Bermuda Atlantic Time-series Study, BATS), showed increases in nutrient and chlorophyll levels and primary production over the same period, suggesting that other processes (e.g., ENSO, PDO, NAO, winds, eddies, advection) can counteract broad-scale trends at local scales (Box CC-PP). The continued warming of the surface layers of the Ocean will *very likely* further enhance stratification and potentially limit the nutrient supply to the euphotic zone in some areas. The response of upwelling to global warming is *likely* to vary between regions and represents a complex interplay between local and global variables and processes (Box CC-UW).

30.3.2. Chemical Changes

30.3.2.1. Surface Salinity

The global water cycle is dominated by evaporation and precipitation occurring over ocean regions, with surface ocean salinity varying with temperature, solar radiation, cloud cover, and ocean circulation [*Deser et al.*, 2004]. Changes in salinity influence stratification of water masses and circulation. Ocean salinity varies regionally (Figure 30-6a) and is an outcome of the balance between evaporation and precipitation ([*Durack and Wijffels*, 2010]; WGI 3.3). Evaporation-dominated regions (Figure 30-6b) such as the STG, and Atlantic and Western Indian Oceans (WGI 3.3.3) have elevated salinity, while areas of high precipitation such as the North Pacific, North-eastern Indian Ocean, South-east Asia, and the eastern Pacific have relatively low salinities (WGI 3.3.3, Figure 30-6a). It is *very likely* that large-scale trends in salinity have also occurred in the Ocean interior, deriving from changes to salinity at the surface and subsequent subduction (WGI 3.3.2–3.3.4).

Salinity trends are consistent with the amplification of the global hydrological cycle [*Durack et al.*, 2012; *Pierce et al.*, 2012], a consequence of a warmer atmosphere *very likely* producing the observed trend in greater precipitation, evaporation, atmospheric moisture (Figure 30-6b), and extreme events (WGI 2.6.2.1, 3.3.4; [*IPCC*, 2012]). Spatial patterns in salinity and evaporation-precipitation are similar, providing indirect evidence that these processes have been enhanced since the 1950s [WGI 3.3.2–3.3.4, Figures 3.4, 3.5 and 3.20d, FAQ 3.3]. These trends in salinity are *very likely* to have a discernible contribution from anthropogenic climate change (WGI 10.4.2). The combined changes in surface salinity and temperature are consistent with changes expected due to anthropogenic forcing of the climate system and are inconsistent with the effects of natural climate variability, either internal to the climate system (e.g., ENSO, PDO; Figure 30-6c, d) or external to it (e.g., solar forcing or volcanic eruptions; [*Pierce et al.*, 2012]). There is *high confidence* between climate models that the observed trends in ocean salinity will continue as average global temperature increases [*Durack and Wijffels*, 2010; *Terray et al.*, 2012]. Ramifications of these changes are largely unknown but are of interest given the role of ocean salinity and temperature in fundamental processes such as the Atlantic Meridional Overturning Circulation (AMOC).

[INSERT FIGURE 30-6 HERE
Figure 30-6: (a) The 1955–2005 climatological-mean sea surface salinity [*Antonov et al.*, 2010] color contoured at 0.5 PSS78 intervals (black lines). (b) Annual mean evaporation-precipitation averaged over the period 1950–2000 (NCEP) color contoured at 0.5 m yr–1 intervals (black lines). (c) The 58-year (2008 minus 1950) sea surface salinity change derived from the linear trend (PSS78), with seasonal and ENSO signals removed [*Durack and Wijffels*, 2010] color contoured at 0.116 PSS78 intervals (black lines). (d) The 30-year (2003–2007 average centered at 2005, minus the 1960–1989 average centered at 1975) sea surface salinity difference (PSS78) color contoured at 0.06 PSS78 intervals (black lines). Contour intervals in (c) and (d) are chosen so that the trends can be easily compared, given the different time intervals in the two analyzes. White areas in (c) and (d) are marginal seas where the calculations are not carried out. Regions where the change is not significant at the 99% confidence level are stippled in gray. Figure originally presented as WGI Figure 3.4 in WGI.]

30.3.2.2. Ocean Acidification

The Ocean has absorbed approximately 30% of atmospheric CO_2 from human activities resulting in decreased ocean pH and carbonate ion concentrations, and increased bicarbonate ion concentrations (Box CC-OA, WG1 Box 3.2; Figure SM30-2). The chemical response to increased CO_2 dissolving into the Ocean from the atmosphere is known with *very high confidence* (WGI 6.4.4). Factors such as temperature, biological processes, and sea ice (WGI 6.4) play significant roles in determining the saturation state of seawater for polymorphs (i.e. different crystalline forms) of calcium carbonate. Consequently, pH and the solubility of aragonite and calcite are naturally lower at high latitudes and in upwelling areas (e.g., eastern Pacific upwelling, Californian Current'), where organisms and ecosystems may be relatively more exposed to ocean acidification as a result ([*Feely et al.*, 2012; *Gruber et al.*, 2012]; Figure 30-7a, b; Figure SM30-2). Aragonite and calcite concentrations vary with depth, with under-saturation occurring at deeper depths in the Atlantic (calcite: 3500–4500 m, aragonite: 400–3000 m) as opposed to the Pacific and Indian Oceans (calcite: 100–3000 m, aragonite: 100–1200 m; [*Feely et al.*, 2004; *Orr et al.*, 2005; *Feely et al.*, 2009]; Figure 30-8).

[INSERT FIGURE 30-7 HERE
Figure 30-7: Projected ocean acidification from 11 CMIP5 Earth System models under RCP8.5 (other RCP scenarios have also been run with the CMIP5 models): (a) Time series of surface pH shown as the mean (solid line) and range of models (filled), given as area-weighted averages over the Arctic Ocean (green), the tropical oceans (red) and the Southern Ocean (blue). (b) Maps of the median model's change in surface pH from 1850–2100. Panel (a) also includes mean model results from RCP2.6 (dashed lines). Over most of the Ocean, gridded data products of carbonate system variables are used to correct each model for its present-day bias by subtracting the model-data difference at each grid cell following [*Orr et al.*, 2005]. Where gridded data products are unavailable (Arctic Ocean, all marginal seas and the Ocean near Indonesia), the results are shown without bias correction. The bias correction reduces the range of model projections by up to a factor of 4, e.g., in panel (a) compare the large range of model projections for the Arctic (without bias correction) to the smaller range in the Southern Ocean (with bias correction). Figure originally presented in WGI Figure 6.28 in WGI.]

[INSERT FIGURE 30-8 HERE
Figure 30-8: Projected aragonite saturation state from 11 CMIP5 Earth System models under RCP8.5 scenario: (a) time series of surface carbonate ion concentration shown as the mean (solid line) and range of models (filled), given as area weighted averages over the Arctic Ocean (green), the tropical oceans (red), and the Southern Ocean (blue); maps of the median model's surface ΩA in (b) 2010, (d) 2050, and (f) 2100; and zonal mean sections (latitude versus depth) of ΩA in 2100 over (c) the Atlantic Ocean and (e) the Pacific Ocean, while the ASH (Aragonite Saturation Horizon) is shown for 2010 (dotted line) and 2100 (solid line). Panel (a) also includes mean model results from

RCP2.6 (dashed lines). As for Figure 30-7, gridded data products of carbonate system variables [*Key et al.*, 2004] are used to correct each model for its present-day bias by subtracting the model-data difference at each grid cell following [*Orr et al.*, 2005]. Where gridded data products are unavailable (Arctic Ocean, all marginal seas and the Ocean near Indonesia), results are shown without bias correction. Reprinted from Figure 6.29 in WGI.]

Surface ocean pH has decreased by approximately 0.1 pH units since the beginning of the Industrial Revolution (*high confidence*) (Figure 30-7a; WGI 3.8.2, Box 3.2), with pH decreasing at the rate of -0.0013 and -0.0024 pH units yr^{-1} (WGI 3.8.2, Table 3.2). The presence of anthropogenic CO_2 diminishes with depth. The saturation horizons of both polymorphs of calcium carbonate, however, are shoaling rapidly (1–2 m yr^{-1}, and up to 5 m yr^{-1} in regions such as the California Current [*Orr et al.*, 2005; *Feely et al.*, 2012]. Further increases in atmospheric CO_2 are *virtually certain* to further acidify the Ocean and change its carbonate chemistry (Figures S30.2, 30.7 and 30.8). Doubling atmospheric CO_2 (~RCP4.5; [*Rogelj et al.*, 2012]) will decrease ocean pH by another 0.1 units and decrease carbonate ion concentrations by approximately 100 µmol kg^{-1} in tropical oceans (Figure 30-8a) from the present day average of 250 µmol kg^{-1} (*high confidence*). Projected changes for the open Ocean by 2100 (Figures 30.7, 30.8) range from a pH change of -0.14 unit with RCP2.6 (421 ppm CO_2, +1ºC, 22% reduction of carbonate ion concentration) to a pH change of -0.43 unit with RCP8.5 (936 ppm CO_2, +3.7ºC, 56% reduction of carbonate ion concentration). The saturation horizons will also become significantly shallower in all oceans (with the aragonite saturation horizon between 0 and 1500 m in the Atlantic Ocean and 0 and 600 m (poles versus equator) in the Pacific Ocean ([*Sabine et al.*, 2004; *Orr et al.*, 2005]; WGI 6.4, Figure 6.28). Trends towards under-saturation of aragonite and calcite will also partly depend on ocean temperature, with surface polar waters expected to become seasonally under-saturated with respect to aragonite and calcite within a couple of decades (Figure 30-8c–f, Box CC-OA[*McNeil and Matear*, 2008]).

Overall, observations from a wide range of laboratory, mesocosm and field studies reveal that marine macro-organisms and ocean processes are sensitive to the levels of ocean acidification projected under elevated atmospheric CO_2 (*high confidence*) (Box CC-OA, 6.3.2, [*Munday et al.*, 2009; *Kroeker et al.*, 2013]). Ecosystems that are characterized by high rates of calcium carbonate deposition (e.g., coral reefs, calcareous plankton communities) are sensitive to decreases in the saturation states of aragonite and calcite (*high confidence*). These changes are *very likely* to have broad consequences such as the loss of three-dimensional coral reef frameworks [*Hoegh-Guldberg et al.*, 2007; *Manzello et al.*, 2008; *Fabricius et al.*, 2011; *Andersson and Gledhill*, 2013; *Dove et al.*, 2013] and restructuring of food webs at relatively small (~50 ppm) additional increases in atmospheric CO_2. Projected shoaling of the aragonite and calcite saturation horizons are *likely* to impact deep water (100–2000 m) communities of scleractinian corals and other benthic organisms as atmospheric CO_2 increases ([*Orr et al.*, 2005; *Guinotte et al.*, 2006]; WGI 6.4), although studies from the Mediterranean and of seamounts off SW Australia report that some deep water corals may be less sensitive [*Thresher et al.*, 2011; *Maier et al.*, 2013]. Organisms are also sensitive to changes in pH with respect to physiological processes such as respiration and neural functions (6.3.2). Due to the relatively short history, yet growing effort, to understand the implications of rapid changes in pH and ocean carbonate chemistry, there are a growing number of organisms and processes reported to be sensitive. The impacts of ocean acidification on marine organisms and ecosystems continues to raise serious scientific concern, especially given that the current rate of ocean acidification (at least 10–100 faster than the recent glacial transitions [*Caldeira and Wickett*, 2003; *Hoegh-Guldberg et al.*, 2007]) is unprecedented within the last 65 Ma (*high confidence*) [*Ridgwell and Schmidt*, 2010] and possibly 300 Ma of Earth history (*medium confidence*) ([*Hönisch et al.*, 2012]; 6.1.2).

30.3.2.3. Oxygen Concentration

Dissolved O_2 is a major determinant of the distribution and abundance of marine organisms (6.3.3). Oxygen concentrations vary across ocean basins and are lower in the eastern Pacific and Atlantic basins, and northern Indian Ocean (Figure 30-9b, 6.1.1.3). In contrast, some of the highest concentrations of O_2 are associated with cooler high latitude waters (Figure 30-9b). There is *high agreement* among analyzes providing *medium confidence* that O_2 concentrations have decreased in the upper layers of the Ocean since the 1960s, particularly in the equatorial Pacific and Atlantic Oceans (WGI Figure 3.20, 3.8.3). A formal fingerprint analysis undertaken by *Andrews et al.* [2013] concluded that recent decreases in oceanic O_2 are due to external influences (*very likely*). Conversely, O_2 has increased in the North and South Pacific, North Atlantic and Indian Oceans, consistent with greater mixing and ventilation due to strengthening wind systems (WGI 3.8.3). The reduction in O_2 concentration in some areas of the Ocean is consistent with that expected from higher ocean temperatures and a reduction in mixing (increasing stratification) (WGI 3.8.3). Analysis of ocean O_2 trends over time [*Helm et al.*, 2011b] reveals that the decline in O_2 solubility with increased temperature is responsible for no more than 15% of the observed change. The remaining 85%, consequently, is associated with increased deep-sea microbial respiration and reduced O_2 supply due to increased ocean stratification (WGI Box 6.5 Figure 1). In coastal areas, eutrophication can lead to increased transport of organic carbon into adjacent ocean habitats where microbial metabolism is stimulated, resulting in a rapid drawdown of O_2 [*Weeks et al.*, 2002; *Rabalais et al.*, 2009; *Bakun et al.*, 2010].

The development of hypoxic conditions (generally defined as O_2 concentrations below ~60 μmol kg^{-1}) over recent decades has been documented across a wide array of ocean sub-regions including some SES (e.g., Black and Baltic Seas), the Arabian Sea, and the California, Humboldt, and Benguela Current systems, where eruptions of hypoxic, sulfide-laden water have also occurred in some cases [*Weeks et al.*, 2002]. Localized, seasonal hypoxic 'dead zones' have emerged in economically valuable coastal areas such as the Gulf of Mexico [*Turner et al.*, 2008; *Rabalais et al.*, 2010], the Baltic Sea [*Conley et al.*, 2009] and the Black Sea [*Kideys*, 2002; *Ukrainskii and Popov*, 2009] in connection with nutrient fluxes from land. Over a vast region of the eastern Pacific stretching from southern Chile to the Aleutian Islands, the minimum O_2 threshold (less than 2 mg l^{-1} or ~60 $mmol^{-1}$) is found at 300 m depth and upwelling of increasingly hypoxic waters is well documented [*Karstensen et al.*, 2008]. Hypoxic waters in the northern Arabian Sea and Bay of Bengal are located close to continental shelf areas. Long-term measurements reveal that O_2 concentrations are declining in these waters, with *medium evidence* that economically significant mesopelagic fish populations are being threatened by a reduction in suitable habitat as respiratory stress increases [*Koslow et al.*, 2011]. It should be noted that hypoxia profiles based on a critical threshold of 60 μmol kg^{-1} can convey an overly simplistic message given that critical concentrations of O_2 in this regard are very much species, size, temperature, and life history stage specific. This variability in sensitivity is, however, a critical determinant for any attempt to understand how ecosystems will respond to changing future O_2 levels (6.3.3).

There is *high agreement* among modeling studies that O_2 concentrations will continue to decrease in most parts of the Ocean due to the effect of temperature on O_2 solubility, microbial respiration rates, ocean ventilation, and ocean stratification (Figure 30-9c, d; WGI Table 6.14 [*Andrews et al.*, 2013]), with implications for nutrient and carbon cycling, ocean productivity, marine habitats, and ecosystem structure (6.3.5). The outcomes of these global changes are *very likely* to be influenced by regional differences such as wind stress, coastal processes, and the supply of organic matter.

[INSERT FIGURE 30-9 HERE
Figure 30-9: (a) Simulated changes in dissolved O_2 (mean and model range as shading) relative to 1990s for RCP2.6, RCP4.5, RCP6.0, and RCP8.5. (b) Multi-model mean dissolved O_2 (mmol m^{-3}) in the main thermocline (200–600 m depth average) for the 1990s, and changes in the 2090s relative to 1990s for RCP2.6 (c) and RCP8.5 (d). To indicate consistency in the sign of change, regions are stippled when at least 80% of models agree on the sign of the mean change. These diagnostics are detailed in [*Cocco et al.*, 2013] in a previous model inter-comparison using the SRES-A2 scenario and have been applied to CMIP5 models here. Models used: CESM1-BGC, GFDL-ESM2G, GFDL-ESM2M, HadGEM2-ES, IPSL-CM5A-LR, IPSL-CM5A-MR, MPI-ESM-LR, MPI-ESM-MR, NorESM1. Figure originally presented in WGI Figure 6.30 in WGI.]

30.4. Global Patterns in the Response of Marine Organisms to Climate Change and Ocean Acidification

Given the close relationship between organisms and ecosystems with the physical and chemical elements of the environment, changes are expected in the distribution and abundance of marine organisms in response to ocean warming and acidification (6.3, Box CC-MB, Box CC-OA). Our understanding of the relationship between ocean warming and acidification reveals that relatively small changes in temperature and other variables can result in often large biological responses that range from simple linear trends to more complex non-linear outcomes. There has been a rapid increase in studies that focus on the influence and consequences of climate change for marine ecosystems since AR4 ([*Hoegh-Guldberg and Bruno*, 2010; *Poloczanska et al.*, 2013], representing an opportunity to examine, and potentially attribute, detected changes within the Ocean to climate change. Evidence of global and regional responses of marine organisms to recent climate change have been shown through assessments of multiple studies focused on single-species, populations, and ecosystems [*Tasker*, 2008; *Thackeray et al.*, 2010; *Przeslawski et al.*, 2012; *Poloczanska et al.*, 2013]. The most comprehensive assessment, in terms of geographic spread and number of observed responses, is that of *Poloczanska et al.* [2013]. This study reveals a coherent pattern in observed responses of ocean life to recent climate change across regions and taxonomic groups, with 81% of responses by organisms and ecosystems being consistent with expected changes to recent climate change (*high confidence*) (Box CC-MB). On average, spring events in the Ocean have advanced by 4.4 ± 0.7 days decade^{-1} (mean ± SE) and the leading edges of species' distributions have extended (generally poleward) by 72.0 ± 0.35 km decade^{-1}. Values were calculated from data series ranging from the 1920s to 2010, although all series included data after 1990. The fastest range shifts generally occurred in regions of high thermal velocity (the speed and direction at which isotherms move [*Burrows et al.*, 2011], 30.3.1.1). Subsequently, [*Pinsky et al.*, 2013], using a database of 360 fish and invertebrate species and species groups from coastal waters around North America, showed differences in the speed and directions that species shift can be explained by differences in local climate velocities (Box CC-MB).

30.5. Regional Impacts, Risks, and Vulnerabilities: Present and Future

This section explores the impacts, risks, and vulnerabilities of climate change for the seven sub-regions within the Ocean. There is considerable variability from region to region, especially in the extent and interaction of climate change and non-climate change stressors. While the latter may complicate attribution attempts in many sub-regions, interactions between the two groups of stressors may also represent opportunities to reduce the overall effects on marine organisms and processes by environmental changes being driven by climate change (including ocean acidification) [*Crain et al.*, 2008; *Griffith et al.*, 2012].

30.5.1. High Latitude Spring Bloom Systems

High Latitude Spring Bloom Systems (HLSBS) stretch from 35ºN to the edge of the winter sea ice (and from 35ºS to the polar front) and provide 36% of world's fish catch (Figure 30-1b). Although much of the North Pacific is iron limited [*Martin and Fitzwater*, 1988] and lacks a classical spring bloom [*McAllister et al.*, 1960], strong seasonal variability of primary productivity is pronounced at all high latitudes because of seasonally varying photoperiod and water column stability [*Racault et al.*, 2012]. Efficient transfer of marine primary and secondary production to higher trophic levels, including commercial fish species, is influenced by both the magnitude and the spatial and temporal synchrony between successive trophic production peaks [*Hjort*, 1914; *Cushing*, 1990; *Beaugrand et al.*, 2003; *Beaugrand and Reid*, 2003].

30.5.1.1. Observed Changes and Potential Impacts

30.5.1.1.1. North Atlantic

The average temperature of the surface waters of the North Atlantic HLSBS has warmed by 0.07°C decade^{-1}, resulting in an increase in sea temperature of 0.44°C between 1950 and 2009 (*likely*) (p-value = 0.15; Table 30-1). Over the same period, both winter and summer temperatures have increased significantly (0.05°C decade^{-1} and 0.12°C decade^{-1} respectively, p-value$\leq$0.05). Since the 1970s, the Atlantic Ocean has warmed more than any other ocean basin (0.3ºC decade^{-1}; Figure 30-2a, WGI 3.2.2), with greatest warming rates over European continental shelf areas such as the southern North Sea, the Gulf Stream front, the sub-polar gyres and the Labrador Sea [*MacKenzie and Schiedek*, 2007b; a; *Levitus et al.*, 2009; *Lee et al.*, 2011; *González-Taboada and Anadón*, 2012]. Basin-wide warming in the North Atlantic since the mid-1990s has been driven by global warming and the current warm phase of the Atlantic Multidecadal Oscillation (AMO) ([*Wang and Dong*, 2010]; WGI 14.7.6).

The North Atlantic is one of the most intensively fished ocean sub-regions. The major areas for harvesting marine living resources span the eastern North American, European and Icelandic shelves [*Livingston and Tjelmeland*, 2000]. In addition, the deep regions of the Nordic Seas and the Irminger Sea contain large populations of pelagic fish such as herring, blue whiting and mackerel, and mesopelagic fish such as pearlsides and redfish. The region covers a wide latitudinal range from 35º–80ºN and, hence, a large span in thermal habitats. This is reflected in the latitudinal gradient from subtropical/temperate species along the southern fringe to boreal/arctic species along the northern fringe.

Climate change is *virtually certain* to drive major changes to the northern fringes of the Atlantic HLSBS by 2100. For the Barents Sea region, which borders the HLSBS and Arctic regions, modeling projections from 1995–2060 (SRES B2 scenario) gave an increase in phytoplankton production of 8%, an increase in Atlantic zooplankton production of 20%, and a decrease of Arctic zooplankton production of 50% [*Ellingsen et al.*, 2008]. These changes result in a total increase in zooplankton production in the HLSBS section of the Barents Sea and a decrease in the Arctic section. Together with poleward shifts of fish species, a substantial increase in fish biomass and catch is also *very likely* at the northern fringes of the HLSBS [*Cheung et al.*, 2011]. However, for some species like capelin, which feeds in summer at the ice edge and spawns in spring at the southern Atlantic Norwegian/Murman coast of the Barents Sea, the continuous temperature increase is *very likely* to cause discontinuous changes in conditions. The limited migration potential for this small pelagic fish is also *likely* to drive an eastwards shift in spawning areas to new spawning grounds along the Novaja Semlja coast[*Huse and Ellingsen*, 2008].

Observations of fish and other species moving to higher latitudes [*Beare et al.*, 2005; *Perry et al.*, 2005; *Collie et al.*, 2008; *Lucey and Nye*, 2010] within the North Atlantic HLSBS are consistent with results of modeling exercises [*Stenevik and Sundby*, 2007; *Cheung et al.*, 2011]. Examples from the Barents (28.2.2.1, Nordic, and North Seas (Box 6-1; 23.4.6) show how warming from the early 1980s influenced North Atlantic ecosystems, where substantial biological impacts such as large-scale modification of the phenology, abundance and distribution of plankton assemblages and reorganization of fish assemblages have been observed [*Beaugrand et al.*, 2002; *Edwards*, 2004; *Edwards and Richardson*, 2004; *Tasker*, 2008; *Nye et al.*, 2009; *Head and Pepin*, 2010; *Simpson et al.*, 2011]. The ranges of some cold-water zooplankton assemblages in the North-east Atlantic have contracted towards the Arctic since 1958, and were replaced by warm-water zooplankton assemblages (specifically copepods) (*high confidence*), which moved up to 1000 km northward [*Beaugrand et al.*, 2002; *Beaugrand*, 2009]. Although changes to surface circulation may have played a role [*Reid et al.*, 2001], the primary driver of the shift was shown to be regional warming [*Beaugrand et al.*, 2002; *Beaugrand*, 2004]. Reorganization of zooplankton communities and an observed decline in mean size has implications for energy transfer to higher trophic levels including commercial fish stocks ([*Beaugrand et al.*, 2003; *Kirby and Beaugrand*, 2009; *Lindley et al.*, 2010], 23.4.6). Warm-water species of fish have increased in abundance on both sides of the North Atlantic (*medium confidence*) [*Beare et al.*, 2005; *Collie et al.*, 2008; *Genner et al.*, 2010; *Hermant et al.*, 2010; *Lucey and Nye*, 2010; *Simpson et al.*, 2011]. Diversity of zooplankton and fish has increased as more diverse warm-water assemblages extend northward in response to changing environmental conditions (*high confidence*) ([*Kane*, 2007; *Hiddink and ter Hofstede*, 2008; *Beaugrand*, 2009; *Mountain and Kane*, 2010; *ter Hofstede et al.*, 2010], Box 6-1, 23.6.5).

The past decade has been the warmest decade ever recorded in the Barents Sea, resulting in large populations of krill shrimp, and pelagic and demersal fish stocks linked to the Atlantic and boreal ecosystem of the Barents Sea (*high confidence*) ([*Johannesen et al.*, 2012]; 28.2.2.1). Recruitment to boreal fish stocks such as cod, haddock, and herring has increased [*Eriksen et al.*, 2012]. The relatively warm Atlantic waters have advanced northward and eastward [*Årthun et al.*, 2012] and sea-ice has retreated along with the Arctic water masses. As a result, boreal euphausiids, which are mainly confined to Atlantic water, have increased in biomass and distribution [*Dalpadado et al.*, 2012] enhancing growth of young cod *Gadus morhua* (boreal) as well as the more Arctic (arcto-boreal) capelin (*Mallotus villosus*). The abundance of amphipods of more Arctic origin has decreased, resulting in poorer feeding conditions for polar zooplankton predators such as polar cod (*Boreogadus saida).* Blue whiting (*Micromesistius poutassou*), which spawns west of the British Isles and feeds on zooplankton in the Norwegian Sea during the summer, extended their summer feeding distribution into the Barents Sea during the recent warm period.

The Norwegian Sea is one of the two core regions for the herbivore copepod *Calanus finmarchicus,* an important prey species for pelagic fish and early life-stages of all fish around the rim of this high latitude sea including the North Sea and the Barents Sea [*Sundby*, 2000]. *C. finmarchicus* is the main food item for some of the world's largest fish stocks such as the Norwegian spring-spawning herring (*Clupea harengus*), blue whiting (*M. poutassou*), and northeast Atlantic mackerel (*Scomber scombrus*). These stocks have increased considerably during the recent warming that started in the early 1980s [*Huse et al.*, 2012]. The individual size of herring has also increased, enabling longer feeding migrations to utilize boreal zooplankton occurring closer to distant Arctic water masses. Mackerel (*Scomber scombrus*) has advanced northward and westward into Icelandic waters [*Astthorsson et al.*, 2012] and was even observed in East Greenland water in summer 2013 [*Nøttestad et al.*, 2013]. Since 2004, the sum of spawning stock biomass of the three pelagic fish species (herring, blue whiting, and mackerel) leveled out at around 16 million tons.

Observed changes in the phenology of plankton groups in the North Sea over the past 50 years are driven by climate forcing, in particular regional warming (*high confidence)* [*Edwards and Richardson*, 2004; *Wiltshire and Manly*, 2004; *Wiltshire et al.*, 2008; *Lindley et al.*, 2010; *Lindley and Kirby*, 2010; *Schluter et al.*, 2010], although responses are species-specific with substantial variation within functional groups ([*Edwards and Richardson*, 2004]; Box 6-1). For example, the peak maximum abundance of the copepod *C. finmarchicus* advanced by 10 days from the 1960s to the 2000s, but its warm-water equivalent, *C. helgolandicus*, did not advance [*Bonnet et al.*, 2005]. In the North Sea, bottom temperatures in winter have warmed by 1.6°C (1980–2004; [*Dulvy et al.*, 2008]). The whole demersal fish community shifted deeper by 3.6 m decade^{-1} over the period 1980–2004, although mean latitude of the whole community did not show net displacement [*Dulvy et al.*, 2008]. Within the community, cool-water specialists generally shifted northward while abundant warm-water species shifted southward, reflecting winter warming of the southern North Sea. The cold winter temperatures of the shallow regions of the southern North Sea have acted to exclude species with warm-water affinities. Trawl survey data from the rapidly-warming southern North Sea suggests waves of immigration by southern species such as red mullet (*Mullus surmuletus*), anchovy (*Engraulis encrasicholus*), and sardines (*Sardina pilchardus*), linked to increasing population sizes and warming temperatures [*Beare et al.*, 2004; *Beare et al.*, 2005].

In the North-east Atlantic, range expansions and contractions linked to changing climate have also been observed in benthic crustaceans, bivalves, gastropods, and polychaetes (*medium confidence*) [*Mieszkowska et al.*, 2007; *Beukema et al.*, 2009; *Berke et al.*, 2010]. For example, the southern range limit of the common intertidal barnacle *Semibalanus balanoides* contracted northward along European coastlines at a rate of 15–50 km decade^{-1} since 1872, and its retreat is attributed to reproductive failure as winter temperatures warm [*Southward et al.*, 2005; *Wethey and Woodin*, 2008]. *Chthamalus montagui*, its warm-water competitor, increased in abundance to occupy the niche vacated by *S. balanoides (high confidence)* [*Southward et al.*, 1995; *Poloczanska et al.*, 2008].

Many of the longest and most comprehensive time series used to investigate the ecological consequences of climate fluctuations and fishing, that span periods of cooling and warming over the past century, are from the North-east Atlantic [*Toresen and Østvedt*, 2000; *Southward et al.*, 2005; *Sundby and Nakken*, 2008; *Edwards et al.*, 2010; *Poloczanska et al.*, 2013]. Meta-analysis of 288 long-term datasets (spanning up to 90 years) of zooplankton, benthic invertebrates, fish, and seabirds from the OSPAR Commission Maritime Area in the North-east Atlantic showed widespread changes in distribution, abundance, and seasonality that were consistent (77%) with expectations from enhanced greenhouse warming [*Tasker*, 2008]. The study bought together evidence of changes in ocean climate and ecological responses across a range of species that encompassed both exploited and unexploited species from a variety of information types including peer-reviewed reports from International Council for the Exploration of the Sea (ICES) Working Groups. In particular, observations indicated poleward shifts in zooplankton communities, increasing abundance of fish species in the northern part of their ranges and decreases in southern parts, and the expansion of benthic species into more northerly or less coastal areas (*high confidence*).

The major portion of the literature on the influence of climate change on the North Atlantic region covers time spans that are longer than for most other sub-regions of the Ocean. Even here, however, the bulk of the literature is limited to the last 30–50 years. The few publications covering the first half of the 20th Century represent an important longer-term perspective on the influence of climate change [*Toresen and Østvedt*, 2000; *Drinkwater*, 2006; *Sundby and Nakken*, 2008; *Bañón*, 2009; *Astthorsson et al.*, 2012]. For example, distinct changes in fauna were associated with a pronounced warming period over 1920–1940 [*Wood and Overland*, 2010], when fish and other fauna shifted northward [*Iversen*, 1934; *Southward et al.*, 2005; *Drinkwater*, 2006; *Hátún et al.*, 2009]. The major lesson from these reports is that a rapid large-scale temperature increase occurred in the high latitude North Atlantic between the 1920s and 1940s, with basin-scale consequences for marine ecosystems that are comparable to warming and observed impacts over the last 30 years. The former event was of great concern within the scientific community, particularly during the late 1940s and early 1950s [*Iversen*, 1934; *Tåning*, 1949; *Tåning*, 1953; *Southward*, 1980]. However, with the subsequent long-term cooling in the 1970s, discussion around climate responses was discontinued [*Southward*, 1980]. The centennial-long perspective indicates that multi-decadal variability has played a major role in changes observed over the past 30 years. The 150-yr instrumental record shows distinct warm phases of the Atlantic Multidecadal Oscillation (AMO) during approximately 1930–1965 and from 1995, and cool phases between approximately 1900–1930 and 1960–1995 (WGI 14.7.6). However, it is *virtually certain* that the enhanced warming in recent decades cannot be explained without external forcing (WGI 10.3.1.1.3). Understanding the changes in interdecadal variability over the next century is particularly important. The current warm phase of the AMO is *likely* to terminate in the next few decades, leading to a cooling influence in the North Atlantic and potentially offsetting some of the effects of global warming (WGI 14.7.6, 11.3.2.4.1). Over the transition period, the climate of the North Atlantic is *likely* to change more rapidly than during previous transitions since 1900.

30.5.1.1.2. North Pacific

Sub-decadal variability in the North Pacific HLSBS is dominated by ENSO ([*Trenberth*, 1990]; WGI 14.4). Unlike the North Atlantic HLSBS, the North Pacific HLSBS does not show any significant trends in temperature over time, *very likely* as a consequence of climate variability influences on long-term warming patterns (1950–2009; Table 30-1). Decadal and longer periods of variability in the North Pacific are reflected in the principal mode, the Pacific Decadal Oscillation (PDO; WGI 14.7.3), with periodicities in SST of both 15–25 y and 50–70 y [*Minobe*, 1997; *Mantua and Hare*, 2002]. Further modes of climate variability include the North Pacific Gyre Oscillation (NPGO; [*Di Lorenzo et al.*, 2008; *Chhak et al.*, 2009]. The PDO exhibits SST anomalies of one sign along the eastern boundary and the opposite sign in western and central Pacific. The PDO has been reported to have an anthropogenic component [*Bonfils and Santer,* 2011] but confidence in this is *very low* (*limited evidence, low agreement*) (WGI 10.3.3). The interplay of the phases of these modes of variability has strong influence on high latitude Pacific ecosystems (*very high confidence*). In the space of three years, the eastern North Pacific fluctuated from one of the warmest years in the past century (2005) to one of the coldest (2008) [*McKinnell et al.*, 2010; *McKinnell and Dagg*, 2010]. This rapid change was accompanied by large changes in primary productivity, zooplankton communities, and fish and seabird populations [*McKinnell et al.*, 2010; *McKinnell and Dagg*, 2010; *Batten and Walne*, 2011; *Bi et al.*, 2011; *Keister et al.*, 2011].

Climate transitions among phases of variability tend to be characterized by abrupt reorganization of the ecosystems as dynamic trophic relationships among species alter [*Hunt et al.*, 2002; *Peterson and Schwing*, 2003; *Litzow and Ciannelli*, 2007; *Litzow et al.*, 2008; *Alheit*, 2009]. Periods of broad-scale environmental change were observed across high latitude ecosystems in the North Pacific HLSBS (eastern Bering Sea and Gulf of Alaska) during 1976–78, 1987–89 and 1998–99. These periods were associated with regime shifts in foraging fish that occurred in 1979–82, 1988–92 and 1998–2001. The changes indicate how basin-scale variability such as the PDO can manifest across distinct ecosystems [*Overland et al.*, 2008; *Link et al.*, 2009a; *Link et al.*, 2009b]. Phenological shifts observed in the zooplankton communities of the North Pacific were *very likely* in response to decadal climate variability, with distinct changes noted after the climate shifts of the 1970s and 1990s [*Mackas et al.*, 1998; *Peterson and Schwing*, 2003; *Chiba et al.*, 2006]. Modeling evidence suggests a weak shift in PDO towards more occurrences of the negative phase but credibility of projections remains uncertain (WGI 14.7.3). It is *about as likely as not* that the PDO will change its form or behavior in the future (WGI 14.7.3).

The Kuroshio-Oyashio Extension (KOE) in the North-west Pacific displays pronounced decadal-scale variability [*Yatsu et al.*, 2008; *Sugisaki et al.*, 2010]. 'Warm periods' in the mid-1970s and late-1980s were accompanied by dramatic changes in pelagic ecosystems and sardine and anchovy stocks [*Chiba et al.*, 2008; *Yatsu et al.*, 2008]. Observations and climate model simulations indicate that global warming is *likely* to further alter the dynamics of the Kuroshio Current and the KOE over the coming century [*McPhaden and Zhang*, 2002; *Sakamoto et al.*, 2005; *Wu et al.*, 2012; *Zhang et al.*, 2013]. Alteration of the KOE will alter the timing, magnitude, and structure of spring blooms in the western Pacific and have implications for pelagic fish recruitment, production, and biogeochemical cycles [*Ito et al.*, 2004; *Hashioka et al.*, 2009; *Yatsu et al.*, 2013].

Commercial catches of salmon species in the North Pacific HLSBS follow decadal fluctuations in climate [*Hare and Mantua*, 2000; *Mantua and Hare*, 2002]. Catches peaked in the warm periods of the 1930s–1940s and 1990s–2000s, with 2009 yielding the highest catch to date, and warming trends are *about as likely as not* to have contributed to recent peaks in some sub-regions [*Morita et al.*, 2006; *Irvine and Fukuwaka*, 2011]. Poleward range shifts of some large pelagic fish in the western North Pacific, such as yellowtail *Seriola quinqueradiata* and Spanish mackerel *Scomberomorus niphonius*, were attributed, in part, to regional warming (*high confidence*) and these two species are projected to shift 39–71 km poleward from the 2000s to 2030s under SRES A1B [*Tian et al.*, 2012; *Jung et al.*, 2013]. Anticipating ecological responses to future anthropogenic climate change also requires evaluation of the role of changes to climate beyond warming *per se*. For example, declining sea level pressure (SLP) in the North Pacific is *likely* influenced by anthropogenic forcing [*Gillett et al.*, 2003; *Gillett and Stott*, 2009] (WGI 10.3.3.4) and SLP in turn is related to atmospheric climate parameters (e.g., turbulent mixing via wind stress) that regulate commercially significant fish populations [*Wilderbuer et al.*, 2002].

The northern fringe of the Bering Sea is among the most productive of marine sub-regions and includes the world's largest single-species fishery, walleye pollock *Theragra chalcogramma* [*Hunt et al.*, 2010]. This region underwent major changes in recent decades as a result of climate variability, climate change, and fishing impacts ([*Litzow et al.*, 2008; *Mueter and Litzow*, 2008; *Jin et al.*, 2009; *Hunt et al.*, 2010]; 28.2.2.1). Seasonal sea ice cover declined since the 1990s (to 2006), although there is no linear trend between 1953 and 2006, and the initiation of spring ice retreat over the south-eastern Bering Sea shelf became earlier [*Wang et al.*, 2007a; *Wang et al.*, 2007b]. Concurrent with the retreat of the 'cold pool', an area of reduced water temperature (<2°C) on the northern Bering Sea shelf that is formed as a consequence of sea ice and is maintained over summer [*Hunt et al.*, 2010], bottom trawl surveys of fish and invertebrates show a significant community-wide northward distribution shift and a colonization of the former cold pool areas by sub-arctic fauna (*high confidence*) [*Wang et al.*, 2006a; *Mueter and Litzow*, 2008].

Over a vast region of the eastern Pacific stretching from southern Chile to the Aleutian Islands, waters low in dissolved O_2 (Oxygen Minimum Zone, OMZ) are found at 300 m depth [*Karstensen et al.*, 2008]. Sporadic upwelling of these low-O_2 waters along the continental shelf is well documented, where biological respiration can further reduce dissolved O_2 levels and result in hypoxic or anoxic conditions that lead to mortality of coastal fishes and invertebrates [*Grantham et al.*, 2004; *Chan et al.*, 2008]. The magnitude and severity of seasonal hypoxic conditions in shallow-shelf waters of the eastern North Pacific HLSBS increased in recent decades [*Bograd et al.*, 2008; *Chan et al.*, 2008]. In addition, minimum pH values in the water column usually occur near the depths of the OMZ (WGI Box 3.2). A shoaling of the aragonite saturation horizon has *likely* resulted in low-aragonite conditions within the density layers being upwelled on the shelf of the west coast of the USA, increasing the risk of seasonally-upwelled water being relatively acidified [*Feely et al.*, 2008] with observed impacts on Pacific oyster (*Crassostrea gigas*) hatcheries [*Barton et al.*, 2012]. In the time period 1991–2006, reductions in pH in the North Pacific between 800 m and ~100 m were attributed in approximately equal measure to anthropogenic and natural variations ([*Byrne et al.*, 2010]; WGI 3.8.2, Figure 3.19).

30.5.1.1.3. Southern Hemisphere

The seasonal peaks in phytoplankton productivity in the southern hemisphere are much less pronounced and of smaller magnitude than those at northern hemisphere high latitudes [*Yoder et al.*, 1993]. The southern hemisphere HLSBS is broadly bounded by the sub-tropical front (STF) and the sub-Antarctic front. Associated with the STF is intense biological activity of bloom-forming coccolithophores (phytoplankton) [*Brown and Yoder*, 1994]. The calcifying plankton assemblages play a key role in carbon cycles in the region and the transport of carbon to deep ocean sediments. The coccolithophore *Emiliania huxleyi* extended its range south of 60° in the South-west Pacific (141–145°E) over the two decades since 1983 [*Cubillos et al.*, 2007]. Although the drivers for this range extension are not clear, it was proposed that the extension is facilitated by surface warming or changes in the abundance of grazing zooplankton.

Large regions of the sub-Antarctic and Arctic surface waters are *likely* to become undersaturated with respect to aragonite during winter by 2030, which will impact calcifying plankton and Southern Ocean ecosystems ([*McNeil and Matear*, 2008; *Bednaršek et al.*, 2012]; 28.2.2.2). Shell weights of the modern foraminifer *Globigerina bulloides* in the sediments of the sub-Antarctic region of the HLSBS south of Australia were observed to be 30–35% lower than those from sediment cores representing pre-industrial periods, consistent with a recent decline in pH [*Moy et al.*, 2009]. Examination of the pteropod *Limacina helicina antarctica* captured from polar waters further south, show severe levels of shell dissolution consistent with the shoaling of the aragonite saturation horizon and indicate that the impact of ocean acidification is already occurring [*Bednaršek et al.*, 2012].

While the South Pacific HLSBS has not shown warming overall, both the warmest and coolest months show a slight, but significant, increase over time (both 0.05°C decade^{-1} from 1950–2009, p-value $\leq$ 0.05, Table 30-1), although some areas within this sub-region have warmed. For example, the western Tasman Sea has shown enhanced warming since 1900 as compared to average global trends (*high confidence*). This has been driven by changes in large-scale wind-forcing leading to a southward expansion of the South Pacific STG and intensification of the southward-flowing East Australian Current (EAC; [*Cai*, 2006; *Hill et al.*, 2008; *Wu et al.*, 2012]; WG1 3.6.2). Model simulations suggest both stratospheric ozone depletion and greenhouse forcing contribute to the observed trend in wind stress [*Cai and Cowan*, 2007]. Coinciding with this warming and intensified EAC is the observation that a number of benthic invertebrates, fish, and zooplankton are now found further south than they were in the mid-20th Century [*Ling*, 2008; *Pitt et al.*, 2010; *Last et al.*, 2011]. Warming facilitated the establishment of the grazing urchin *Centrostephanus rodgersii* in eastern Tasmania during the late 1970s (*high confidence*), which has resulted in deleterious effects on macroalgal beds [*Ling*, 2008; *Ling et al.*, 2008; *Ling et al.*, 2009; *Banks et al.*, 2010].

30.5.1.2. Key Risks and Vulnerabilities

Projected changes to the temperature of surface waters match those of the past 50 years, with average sea temperatures in the HLSBS regions projected to increase by 0.35–1.17°C in the near-term (2010–2039) and by 1.70–4.84°C over the long-term (2010–2099) under the 'Business as usual' (BAU) RCP8.5 scenario (Table SM30-4). Under the lower-case scenario considered here (RCP2.6), projected rates of regional warming are much lower (0.12-0.79°C) in the near-term, with slight cooling for some regions in the long-term (-0.16–1.46°C). Risks to HLSBS from warming of surface waters include changes to primary production and carbon cycling, and the reorganization of ecosystems in response to warmer and more acidified oceans. Both primary production and the timing of the spring bloom in HLSBS are very sensitive to environmental change. Latitudinal shifts in the distribution of phyto- and zooplankton communities will alter seasonality, community composition, and bloom dynamics [*Beaugrand*, 2009; *Ito et al.*, 2010; *Shoji et al.*, 2011]. Alteration of the structure and composition of plankton communities can propagate through high latitude food webs due to tight trophic linkages [*Edwards and Richardson*, 2004; *Beaugrand et al.*, 2010; *Beaugrand and Kirby*, 2010]. Mechanisms are complex, and tend to be non-linear, with impacts on ecosystems, fisheries, and biogeochemical cycles being hard to project with any certainty (Box CC-PP). A reorganization of commercial fish stocks, with attendant social and economic disruption, is a key risk of ongoing climate change in HLSBS sub-regions. AR4 reported that the productivity of some marine fisheries is *likely* to increase in the North Atlantic (AR4 WGII 10.4.1, 12.4.7). A large number of publications since then has substantially extended such documentation and begun to elucidate the nuances in how marine ecosystems and organisms respond [*Sumaila et al.*, 2011].

An additional risk exists for sub-polar areas from the loss of seasonal sea ice. Decreases in seasonal sea ice are *very likely* to lead to increases in the length of the growth season and the intensity of the light available to fuel phytoplankton growth and, hence, enhance primary production and attending modifications of ecosystem structure [*Arrigo et al.*, 2008]. In the long-term, however, primary production may decrease due to the reduced supply of nutrients to the surface layers (Box CC-PP). The decline in Arctic sea ice will open ecological dispersal pathways, as well as new shipping routes (30.6.2.3), between the North Atlantic and the North Pacific; large numbers of the Pacific diatom *Neodenticula seminae* were found in the North Atlantic in 1999 [*Reid et al.*, 2007].

HLSBS are also vulnerable to rapid changes in the carbonate chemistry of ocean waters. Ocean acidification will produce additional and large-scale challenges. There is *medium agreement* that calcifying organisms in these regions will be negatively affected by ocean acidification with substantial impacts on higher trophic levels, although there is *limited evidence* at this point.

30.5.2. Equatorial Upwelling Systems

The largest upwelling systems are found in the equatorial regions of the eastern Pacific and Atlantic Oceans (Figure 30-1a). Equatorial Upwelling Systems (EUS) produce highly productive 'cold tongues' that stretch westward across equatorial areas, which is different to other upwelling systems (e.g., EBUE; 30.5.5). The associated upwelling is a consequence of the Earth's rotation and easterly (westward) winds and currents, which drive water northwards and southwards at the northern and southern edges of these sub-regions. As result, cold, nutrient-rich, and high CO_2/low pH waters are transported from the deeper layers of the Ocean to the surface, driving high levels of primary productivity that support 4.7% of total global fisheries productivity (Table SM30-1, Figure 30-1b). Interannual modes of variability (e.g., ENSO; WGI 14.4) dominate EUS, particularly in the Pacific [*Barber et al.*, 1994; *McCarthy et al.*, 1996; *Signorini et al.*, 1999; *Le Borgne et al.*, 2002; *Christian and Murtugudde*, 2003; *Mestas-Nuñez and Miller*, 2006; *Pennington et al.*, 2006; *Wang et al.*, 2006b]. Upwelling of the Pacific EUS declines during El Niño events, when the trade winds weaken, or even reverse, and is strengthened during La Niña events. ENSO periodicity controls primary productivity and consequently has a strong influence over associated fisheries production [*Mestas-Nuñez and Miller*, 2006]. The Intertropical Convergence Zone (ITCZ; WGI 14.3.1.1), an important determinant of regional ocean temperature, is located at the edges of the Indian and Pacific equatorial upwelling zone and influences a range of variables including productivity, fisheries, and precipitation. The EUS are also affected by interdecadal variability (e.g., Interdecadal Pacific Oscillation (IPO); [*Power et al.*, 1999]; WGI 11.2.2, 14.3).

30.5.2.1. Observed Changes and Potential Impacts

The average sea temperature associated with the EUS has increased significantly (p-value$\leq$0.05) by 0.43°C and 0.54°C from 1950–2009 in the Pacific and Atlantic EUS, respectively [Table 30-1). In the Pacific, regional variability in SST trends is driven by the temporal patterns in El Niño-Southern Oscillation and the more frequent El Niño Modoki or Central Pacific El Niño events in recent decades (*high confidence*) ([*Ashok et al.*, 2007; *Yu and Kao*, 2007; *Lee and McPhaden*, 2010]; WGI 14.2.4.4). The faster warming of the Atlantic EUS is *likely* to be associated with a weakening of upwelling [*Tokinaga and Xie*, 2011]. Sea level rise in the eastern equatorial Pacific has been decreasing by up to –10 mm yr^{-1} since 1993 ([*Church et al.*, 2006]; Figure 30-5).
Coral reefs in the EUS of the eastern Pacific (e.g., Galápagos and Cocos islands) have relatively low species diversity and poorly developed carbonate reef frameworks, due to the low pH and aragonite saturation of upwelling waters (*high confidence*) [*Glynn*, 2001; *Manzello et al.*, 2008; *Manzello*, 2010]. Prolonged periods of elevated temperature associated with El Niño have negatively affected corals, kelps and associated organisms, and induced several possible local extinctions (*high confidence*) [*Glynn*, 2011]. Since 1985, coral reefs from west of South America to the Gilbert Islands of Kiribati have experienced the highest levels of thermal stress relative to other areas [*Donner et al.*, 2010]. In 1982/1983, mass coral bleaching and mortality affected most of the reef systems within the eastern equatorial Pacific [*Glynn*, 1984; *Baker et al.*, 2008]. Subsequent canonical El Niño and Central Pacific El Niño events in 1997/8, 2002/3, 2004/5, and 2009/10 (WGI 14.4.2, Figure 14.13) triggered mass coral bleaching by adding to the background increases in sea temperatures (*high confidence*) [*Donner et al.*, 2010; *Obura and Mangubhai*, 2011; *Vargas-Ángel et al.*, 2011]. In some locations, impacts of El Niño have also interacted with other anthropogenic changes, such as those arising from changes to fishing pressure [*Edgar et al.*, 2010], further complicating the attribution of recent ecological changes to climate change.

30.5.2.2. Key Risks and Vulnerabilities

Climate models indicate that ENSO is *virtually certain* to continue to be a major driver of oceanic variability over the coming century, although not all models can accurately replicate its behavior (WGI 9.5.3). Superposition of a warming ocean on future ENSO activity (possibly modified in frequency and intensity) is *likely* to result in oceanic conditions that are different from those experienced during past El Niño and La Niña events [*Power and Smith*, 2007]. Temperatures within EUS sub-regions are projected to continue to warm significantly (p-value$\leq$0.05). Under RCP8.5, SST of the Atlantic EUS is projected to increase by 0.81°C over 2010–2039 and 2.56°C over 2010–2099, with similar increases projected for the Pacific EUS (Table SM30-4). Differences between RCPs for the two EUS become clear beyond mid-century, with warming of SST over 2010–2099 being 0.43°C and 0.46°C under RCP2.6 and 3.01°C and 3.03°C under RCP8.5, for Pacific and Atlantic EUS respectively (Table SM30-4). These projected increases in sea temperature will increase heat stress and ultimately irreversibly degrade marine ecosystems such as coral reefs (*very likely*). Further increases in atmospheric CO_2 will cause additional decrease in pH and aragonite saturation of surface waters (adding to the low pH and aragonite saturation of upwelling conditions), with significant differences between emission trajectories by the middle of the century. These changes in ocean carbonate chemistry are *very likely* to negatively affecting some marine calcifiers, although many of the species from this region are adapted to the low aragonite and calcite saturation states that result from equatorial upwelling, albeit with much lower rates of calcification [*Manzello*, 2010; *Friedrich et al.*, 2012]. A substantial risk exists with respect to the synergistic interactions between sea temperature and declining pH, especially as to how they influence a large number of key biological processes (Box CC-OA).

There is *low confidence* in the current understanding of how (or if) climate change will influence the behavior of ENSO and other long-term climate patterns ([*Collins et al.*, 2010]; WGI 12.4.4.2). There is also *low agreement* between different CMIP5 GCMs on how ocean warming will affect ENSO, with no significant change to ENSO amplitude in half the models examined, and both increasing and decreasing activity in others [*Guilyardi et al.*, 2012]. These differences appear to be a consequence of the delicate balance within ENSO between dampening and amplifying feedbacks, and the different emphasis given to these processes within the different GCMs [*Collins et al.*, 2010]. Other studies have looked at the interaction between the STG and EUS, and warming of surface waters in the Pacific, with at least one study projecting the possible expansion of the STG at the expense of the EUS [*Polovina et al.*, 2011]. In the latter case, the area of equatorial upwelling within the North Pacific would decrease by 28%, and primary production and fish catch by 15%, by 2100. Many of the projected changes imply additional consequences for pelagic fisheries due to the migration of fish stocks deriving from changing distribution of particular sea temperatures [*Lehodey et al.*, 2006; *Lehodey et al.*, 2008; *Cheung et al.*, 2010; *Lehodey et al.*, 2011; *Sumaila et al.*, 2011; *Bell et al.*, 2013b]. These projections suggest that fisheries within EUS will experience increased vulnerability due to elevated variability in space and time as a result of climate change (*low confidence*).

30.5.3. Semi-Enclosed Seas

Semi-Enclosed Seas (SES) represent a subset of ocean sub-regions that are largely land-locked and consequently heavily influenced by surrounding landscapes and climates [*Healy and Harada*, 1991]. In most cases, they support small but regionally significant fisheries (3.3% of global production; Table SM30-1, Figure 30-1b) and opportunities for other industries such as tourism. Five SES (all over 200,000 km² with single entrances ≤120 km wide) are considered here. This particular geography results in reduced circulation and exchange with ocean waters, and jurisdictions for these water bodies are shared by two or more neighboring states. In many cases, the small volume and disconnected nature of SES (relative to coastal and oceanic environments) makes them highly vulnerable to both local and global stressors, especially with respect to the much reduced options for the migration of organisms as conditions change.

30.5.3.1. Observed Changes and Potential Impacts

30.5.3.1.1. Arabian Gulf

The Arabian Gulf (also referred to as the Persian Gulf), along with Red Sea, is the world's warmest sea, with both extreme negative and positive temperature excursions (annual temperature range of 12–35°C). Like other SES, the Arabian Gulf is particularly vulnerable to changing environmental conditions as a result of its landlocked nature. Trends in SST were not significant over the period 1950–2009 (Table 30-1), which is probably due to long-term variability, and a consequence of regional and abrupt changes that occurred in the late 1980s [*Conversi et al.*, 2010]. In keeping with this, recent (1985–2002) localized analyses (e.g., Kuwait Bay) show strong and significant warming trends (based in this case on AVHRR (NOAA) satellite data) of 0.6°C $decade^{-1}$ [*Al-Rashidi et al.*, 2009]. There is *limited evidence* and *low agreement* as to how this variability influences marine ecosystems and human activities within the Arabian Gulf, although impacts on some ecosystem components (e.g., coral reefs) have been defined to some extent. The mass coral bleaching and mortality that occurred in 1996 and 1998 were a direct result of the sensitivity of reef-building corals to elevated sea temperatures (*high confidence*) ([*Riegl*, 2002; 2003]; Box CC-CR). These changes to coral reefs have resulted in a loss of fish species that feed on coral-associated invertebrates while herbivores and planktivorous fish abundances have increased (*medium confidence*) [*Riegl*, 2002]. Despite coral ecosystems in this sub-region being adapted to some of the highest temperatures in shallow seas on earth, anthropogenic climate change is driving higher frequencies and intensities of mass coral bleaching and mortality [*Riegl et al.*, 2011]. Other biological changes (e.g., harmful algal blooms and fish kills, [*Heil et al.*, 2001]) have been associated with the increasing sea temperatures of the Arabian Gulf, although attribution to increasing temperatures as opposed to other factors (e.g., water quality) is limited [*Bauman et al.*, 2010].

30.5.3.1.2. Red Sea

Few studies have focused on attributing recent changes in the Red Sea ecosystems to climate change (including ocean acidification). The Red Sea warmed by 0.74°C from 1982–2006 [*Belkin*, 2009], although trends in the average SST, however, are not significant from 1950–2009 (p-value>0.05, Table 30-1) due to a high degree of variability when longer periods were examined (supplementary material in [*Belkin*, 2009]). The temperature of the warmest month of the year, however, showed a significant increase over the 60-year period (0.05°C decade^{-1}; Table 30-1). Regional trends within the Red Sea may also differ, with at least one other study reporting higher rates of warming for the central Red Sea (1.46°C, relative to 1950–1997 NOAA Extended Reconstructed SST (ERSST) v3b climatology [*Cantin et al.*, 2010]).

Long-term monitoring of coral community structure and size over 20 years shows that average colony size of corals has declined (*high confidence*) and species' latitudinal limits may have changed (*medium confidence*). The decline in average colony size is ascribed to heat-mediated bleaching as well as increases in coral diseases and Crown of Thorns Starfish (*Acanthaster* sp.) predation [*Riegl et al.*, 2012]. The patterns of this decline correlate well with the pattern of recent heating in the Red Sea [*Raitsos et al.*, 2011] with the biggest changes being seen in the southern part of the Red Sea. Skeletal growth of the long-lived massive coral *Diploastrea heliopora* has declined significantly, *very likely* due to warming temperatures (*medium confidence*) (p-value≤0.05; [*Cantin et al.*, 2010].

Cantin et al. [2010] proposed that the massive coral *Diploastrea helipora* will cease to grow in the central Red Sea by 2070 under SRES A1B and A2 (*medium confidence*), although this may not hold for other coral species. For example, an increase in linear extension of *Porites* corals, beginning in the 1980s, was recorded in the northern Red Sea [*Heiss*, 1996], where temperatures have increased by 0.74ºC from 1982-2006 [*Belkin*, 2009] suggesting that these corals were living in sub-optimal conditions (cooler waters). They may therefore benefit from elevated temperature before reaching their thermal threshold, at which point growth rates would be predicted to decline, as they are doing in other oceans. *Riegl and Piller* [2003] concluded that coral habitats at moderate depths in the Red Sea might provide important refugia from some aspects of climate change in the future (*limited evidence*). *Silverman et al.* [2007] quantified the sensitivity of net coral reef ecosystem calcification to changes in carbonate chemistry (pH, aragonite saturation). Their results demonstrate a strong negative effect of ocean acidification on ecosystem-scale calcification and decalcification, and show that small changes in carbonate dissolution could have large-scale implications for the long-term persistence of carbonate coral reef systems within the Red Sea [*Silverman et al.*, 2007; *Silverman et al.*, 2009].

30.5.3.1.3. Black Sea

The temperature of the surface waters of the Black Sea increased by 0.96ºC from 1982–2006 [*Belkin*, 2009], which is consistent with other studies (*high confidence*) [*Buongiorno Nardelli et al.*, 2010; *Bozkurt and Sen*, 2011]. As with other SES (i.e., Arabian Gulf and Baltic, Mediterranean, and Red Seas), longer data sets do not reveal a significant trend due to large-scale variability prior to 1982, which may be due to the influence of AMO, NAO, and other long-term sources of variability (Table 30-1; supplementary material in *Belkin, 2009*). *Buongiorno Nardelli et al.* [2010] observed that short-term SST variability (week-month) is strongly influenced by interactions with the overlying atmosphere, which itself is strongly influenced by the surrounding land temperatures. As with the Mediterranean and Red Seas, however, a significant upward trend in the temperature is recorded in the warmest month of the year over the period 1950–2009 (Table 30-1). Freshwater discharge from rivers draining into the Black Sea has remained more or less constant since the early 1960s [*Ludwig et al.*, 2009]. Increasing water temperature has steadily eliminated the Cold Intermediate Layer (CIL; temperatures below 8°C) throughout the Black Sea basin over 1991–2003 (*high confidence*)[*Oguz et al.*, 2003]. Reduced water column mixing and upwelling during warmer winter periods has reduced the supply of nutrients to the upper layers of the Black Sea [*Oguz et al.*, 2003] and expanded areas of low O_2 in the deeper parts of the Black Sea, which is the world's largest anoxic marine basin (*high confidence*) [*Murray et al.*, 1989]. These changes coincided with the collapse of fish stocks and the invasion by the ctenophore *Mnemiopsis leidyi* in the 1980s [*Oguz et al.*, 2008], while inputs of nutrients such as phosphate from the Danube River decreased strongly since 1992–1993 [*Oguz and Velikova*, 2010]. Environmental perturbations explain the declining levels of primary productivity, phytoplankton, bacterioplankton, and fish stocks in the Black Sea from the mid-1990s [*Yunev et al.*, 2007; *Oguz and Velikova*, 2010]. The Black Sea system is very dynamic and is strongly affected by non-climate stressors in addition to climate change, making attribution of detected trends to climate change difficult.

30.5.3.1.4. Baltic Sea

Temperatures in the highly dynamic Baltic Sea increased substantially since the early 1980s [*Aleksandrov et al.*, 2009; *Belkin*, 2009], with increases of 1.35°C (1982–2006) being among the highest for any SES [*Belkin*, 2009]. Increases of this magnitude are not seen in longer records throughout the Baltic Sea (1861–2001, [*MacKenzie et al.*, 2007; *MacKenzie and Schiedek*, 2007b; a]; 1900–1998, [*Madsen and Højerslev*, 2009]). The salinity of the surface and near bottom waters of the Baltic Sea (e.g., Gdansk Basin, [*Aleksandrov et al.*, 2009]; central Baltic [*Fonselius and Valderrama*, 2003; *Möllmann et al.*, 2003] decreased from 1975–2000, due to changing rainfall and river run-off, and a reduction in the pulses of sea water (vital for oxygenation and related chemical changes) from the North Sea through its opening via the Kattegat (*high confidence*) [*Samuelsson*, 1996; *Conley et al.*, 2009; *Hänninen and Vuorinen*, 2011]. There is a strong vertical zonation within the Baltic Sea in terms of the availability of O_2. The shallow sub-regions of the Baltic are relatively well oxygenated. However, O_2 levels are low in the deeper basins, producing conditions where organisms and ecosystems are exposed to prolonged hypoxia.

The annual biomass of phytoplankton has declined almost threefold in the Baltic Transition Zone (Kattegat, Belt Sea) and Western Baltic Sea since 1979 [*Henriksen*, 2009], reputedly due to changing nitrogen loads in the Danish Straits (*medium confidence)* in addition to increasing sea temperature (*very likely*) [*Madsen and Højerslev*, 2009]. Reduced phytoplankton production may have reduced the productivity of fisheries in the western Baltic Sea and the Transition Zone (*low to medium confidence*) [*Chassot et al.*, 2007]. Decreasing salinity in the Baltic deep basins may also affect zooplankton reproduction, especially that of the copepod *Pseudocalanus acuspes,* contributing to density-dependent decrease in growth of the commercially important herring and sprat stocks (*high confidence*) [*Möllmann et al.*, 2003; *Möllmann et al.*, 2005; *Casini et al.*, 2011]. The strong relationship between phytoplankton and fish production, and increasing sea temperature, decreasing salinity and other environmental factors, suggests that major changes in fisheries production will occur as sea temperatures increase and the hydrological cycle in the Baltic region changes (*high confidence*) [*MacKenzie et al.*, 2012]. A combination of climate change-induced oceanographic changes (i.e., decreased salinity and increased temperatures), eutrophication, and overfishing have resulted in major changes in trophic structure in the deep basins of the Baltic Sea [*Möllmann et al.*, 2009]. This had important implications for cod, a commercially important top-predator (*medium confidence*)[*Lindegren et al.*, 2010].

30.5.3.1.5. Mediterranean Sea

The Mediterranean Sea is strongly linked to the climates of North Africa and Central Europe. SST within the Mediterranean increased by 0.43℃ from 1957–2008 (supplementary material, *[Belkin, 2009]*), although analysis of data from 1950–2009 only detected a significant trend in summer temperature (0.11℃ decade^{-1}, p-value$\leq$0.05, Table 30-1) due to large fluctuations in SST prior to the 1980s. Surface temperatures increased in the Mediterranean Sea consistent with significant increases in SST at a number of monitoring sites (*high agreement*, *robust evidence*) (e.g.

[*Coma et al.*, 2009; *Conversi et al.*, 2010; *Calvo et al.*, 2011]). It is *likely* that temperatures, along with salinity, have also increased at depth (400 m or more) in the western Mediterranean Sea over the past 30-40 years which, when analyzed in the context of heat budget and water flux of the Mediterranean, is consistent with anthropogenic greenhouse warming [*Bethoux et al.*, 1990; *Rixen et al.*, 2005; *Vargas-Yáñez et al.*, 2010]. Large scale variability such as the AMO and NAO can obscure or accentuate the overall warming trend ([*Marullo et al.*, 2011]; WGI 14.5.1, 14.7.6). Relatively warm episodes in the 1870s, 1930–1970s and since the mid-1990s, for example, exhibit an influence of the AMO [*Kerr*, 2000; *Moron*, 2003]. Reported temperature anomalies in the Mediterranean, often locally manifesting themselves as periods of low wind, increased water column stratification, and a deepening thermocline, are associated with positive phases of the NAO index [*Molinero et al.*, 2005; *Lejeusne et al.*, 2010].

Sea levels have increased rapidly in some areas over recent decades and are also strongly influenced by NAO phases. The rate has been approximately 3.4 mm yr^{-1} (1990–2009) in the North-west Mediterranean (*high confidence*) [*Calvo et al.*, 2011]. These influences are reduced when measurements are pooled over longer time-scales, resulting in a lower rate of sea level rise [*Massuti et al.*, 2008]. If the positive phase of the NAO is more frequent in the future ([*Terray et al.*, 2004; *Kuzmina et al.*, 2005]; WGI 14.4.2), then future sea level rise may be slightly suppressed due to atmospheric influences (*medium confidence*) [*Jordà et al.*, 2012]. As temperatures have increased, the Mediterranean has become more saline (+0.035–0.040 psu from 1950–2000, [*Rixen et al.*, 2005]) and the length of the thermal stratification period persisted twice as long in 2006 as it did in 1974 [*Coma et al.*, 2009].

Conditions within the Mediterranean Sea changed abruptly and synchronously with similar changes across the North, Baltic, and Black Seas in the late 1980s [*Conversi et al.*, 2010], which possibly explains the lack of trend in SES SST when examined from 1950–2009 (Table 30-1). These changes in physical conditions (increased temperature, higher sea level pressure, positive NAO index) also coincided with step-changes in the diversity and abundance of zooplankton, decreases in stock abundance of anchovies, decreases in the frequency of “red tides”, and increases in mucilage outbreaks [*Conversi et al.*, 2010]. Mucilage outbreaks are strongly associated with warmer and more stratified water columns (*high confidence*), and lead to a greater abundance and diversity of marine microbes and potentially disease-causing organisms (*likely*) [*Danovaro et al.*, 2009]. Increasing temperatures are also driving the northward spread of warm-water species (*medium confidence*) such as the sardine *Sardinella aurita* [*Sabatés et al.*, 2006; *Tsikliras*, 2008], and have contributed to the fast spread of the invading Atlantic coral *Oculina patagonia* [*Serrano et al.*, 2013]. The recent spread of warm-water species that have invaded through the Straits of Gibraltar and the Suez Canal into cooler northern areas is leading to the ‘tropicalisation’ of Mediterranean fauna (*high confidence*) [*Bianchi*, 2007; *Ben Rais Lasram and Mouillot*, 2008; *CIESM*, 2008; *Galil*, 2008; 2011]. Warming since the end of the 1990s has accelerated the spread of tropical invasive species from the eastern Mediterranean basin ([*Raitsos et al.*, 2010]; 23.6.5).

In addition to general patterns of warming, periods of extreme temperatures have had large-scale and negative consequences for Mediterranean marine ecosystems. Unprecedented mass mortality events, that affected at least 25 prominent invertebrate species, occurred during the summers of 1999, 2003, and 2006 across hundreds of kilometers of coastline in the North-west Mediterranean Sea (*very high confidence*) [*Cerrano et al.*, 2000; *Garrabou et al.*, 2009; *Calvo et al.*, 2011; *Crisci et al.*, 2011]. Events coincided with either short periods (2–5 days: 2003, 2006) of high sea temperatures (27°C) or longer periods (30–40 days) of modestly high temperatures (24°C: 1999; [*Bensoussan et al.*, 2010; *Crisci et al.*, 2011]). Impacts on marine organisms have been reported in response to the extreme conditions during these events (e.g., gorgonian coral mortality [*Coma et al.*, 2009], shoot mortality, and anomalous flowering of seagrasses (*high confidence*) [*Diaz-Almela et al.*, 2007; *Marbà and Duarte*, 2010]. The frequency and intensity of these types of heat stress events are expected to increase as sea temperatures increase (*high confidence*).

Longer-term data series (over several decades) of changes in relative acidity of the Mediterranean Sea are scarce [*Calvo et al.*, 2011; *MerMex-Group*, 2011]. Recent re-analysis, however, has concluded that the pH of Mediterranean waters has decreased by 0.05–0.14 pH units since the pre-industrial period (*medium confidence*) [*Luchetta et al.*, 2010; *Touratier and Goyet*, 2011]. Anthropogenic CO_2 has penetrated the entire Mediterranean water column, with the western basin being more contaminated than the eastern basin [*Touratier and Goyet*, 2011]. Studies that have explored the consequences of ocean acidification for the biology and ecology of the Mediterranean Sea are rare [*Martin and Gatusso*, 2009; *Rodolfo-Metalpa et al.*, 2010; *Movilla et al.*, 2012], although insights have been gained by studying natural CO_2 seeps at Mediterranean sites such as Ischia in Italy, where biodiversity decreases with decreasing pH towards the vents, with a notable decline in calcifiers. [*Hall-Spencer et al.*, 2008]. Transplants of corals, mollusks, and bryozoans along the acidification gradients around seeps reveal a low level of vulnerability to CO_2 levels expected over the next 100 years *(low confidence*) [*Rodolfo-Metalpa et al.*, 2010 ; *Rodolfo-Metalpa et al.*, 2011]. However, periods of high temperature can increase vulnerability to ocean acidification, thereby increasing the long-term risk posed to Mediterranean organisms and ecosystems as temperatures warm. Significantly, some organisms such as seagrasses and some macroalgae appeared to benefit from local ocean acidification [*Hall-Spencer et al.*, 2008].

30.5.3.2. Key Risks and Vulnerabilities

SES are highly vulnerable to changes in global temperature on account of their small volume and landlocked nature. Consequently, SES will respond faster than most other parts of the Ocean (*high confidence*). Risks to ecosystems within SES are *likely* to increase as water columns become further stratified under increased warming, promoting hypoxia at depth and reducing nutrient supply to the upper water column (*medium evidence*, *high agreement*). The impact of rising temperatures on SES is exacerbated by their vulnerability to other human influences such as overexploitation, pollution, and enhanced run-off from modified coastlines. Due to a mixture of global and local human stressors, key fisheries have undergone fundamental changes in their abundance and distribution over the past 50 years (*medium confidence*). A major risk exists for SES from projected increases in the frequency of temperature extremes that drive mass mortality events, increasing water column stabilization leading to reduced mixing, and changes to the distribution and abundance of marine organisms. The vulnerability of marine ecosystems, fisheries, and human communities associated with the SES will continue to increase as global temperatures increase.

Sea temperatures are *very likely* to increase in the five SES under moderate (RCP6.0) to high (RCP8.5) future scenarios. Under BAU (RCP8.5; Table SM30-3), sea temperatures in the SES are projected to increase by 0.93–1.24°C over 2010–2039 (Table SM30-4). Increases of 3.45–4.37°C are projected over 2010–2099, with the greatest increases projected for the surface waters of the Baltic Sea (4.37°C) and Arabian Gulf (4.26°C), and lower yet substantial amounts of warming in the Red Sea (3.45°C) (Table SM30-4). The heat content added to these small ocean regions is *very likely* to increase stratification, which will reduce the nutrient supply to the upper layers of the water column, reducing primary productivity and driving major changes to the structure and productivity of fisheries. Reduced mixing and ventilation, along with increased microbial metabolism, will *very likely* increase hypoxia and expand the number and extent of ‘dead zones’. Changing rainfall intensity (23.3, WGI 12.4.) can exert a strong influence on the physical and chemical conditions within SES, and in some cases will combine with other climatic changes to transform these areas. These changes are *likely* to increase the risk of reduced bottom-water O_2 levels to Baltic and Black Sea ecosystems (due to reduced solubility, increased stratification, and microbial respiration), which is *very likely* to affect fisheries. These changes will increase the frequency and intensity of impacts arising from heat stress, based on responses to temperature extremes seen over the past 30 years, such as the mass mortality of benthic organisms that occurred in the Mediterranean Sea during the summers of 1999, 2003, and 2006, and the Arabian Gulf in 1996 and 1998. Extreme temperature events such as heat waves are projected to increase (*high confidence*) (23.2, [*IPCC*, 2012]). Similar projections to those outlined in 30.5.4.2 can be applied to the coral reefs of the Arabian Gulf and the Red Sea, where temperatures are *very likely* to increase above established thresholds for mass coral bleaching and mortality (*very high confidence*) (Figure 30-10).

30.5.4. Coastal Boundary Systems

The Coastal Boundary Systems (CBS) are highly productive regions, comprising 10.6% of primary production and 28.0% of global fisheries production (Table SM30-1, Figure 30-1b). The CBS include the marginal seas of the North-west Pacific, Indian, and Atlantic Oceans, encompassing: the Bohai/Yellow Sea, East China Sea, South China Sea, and South-east Asian Seas (e.g., the Timor, Arafura, and Sulu Seas, and the northern coast of Australia) in the Pacific; the Arabian Sea, Somali Current system, East Africa coast, Mozambique Channel, and Madagascar in the Indian Ocean; and the Caribbean Sea and Gulf of Mexico in the Atlantic Ocean). Some CBS are dominated by powerful currents such as the Kuroshio (Pacific), or are strongly influenced by monsoons (e.g., Asian-Australian and African monsoons).

30.5.4.1. Observed Changes and Potential Impacts

Many ecosystems within the CBS are strongly affected by the local activities of often-dense coastal human populations. Activities such as the overexploitation of fisheries, unsustainable coastal development, and pollution have resulted in the wide-spread degradation of CBS ecosystems [*Burke et al.*, 2002; *Burke et al.*, 2011]. These influences have combined with steadily increasing ocean temperature and acidification to drive major changes to a range of important ecosystems over the past 50 years. Understanding the interactions between climate change and non-climate change drivers is a central part of the detection and attribution process within the CBS.

Overall, the CBS warmed by 0.14–0.80°C from 1950–2009 (Table 30-1), although changes within the Gulf of Mexico/Caribbean Sea sub-region were not significant (p-value>0.05) over this period. Key sub-regions within the CBS such as the Coral Triangle and Western Indian Ocean warmed by 0.79 and 0.60°C, respectively, from 1950–2009 (Table 30-1). Rates of sea level rise vary from decreasing sea levels (-5 to -10 mm yr^{-1}) to low (2–3 mm yr^{-1}, Caribbean) to very high (10 mm yr^{-1}, South-east Asia; Figure 30-5) rates of increase. Ocean acidification also varies from region to region (Figure SM30-2), and is influenced by oceanographic and coastal processes, which often have a large human component.

30.4.4.1.1. Bohai/Yellow Sea/East China Sea

The Bohai Sea, Yellow Sea and the East China Sea (ECS) are shallow marginal seas along the edge of the North-west Pacific that are strongly influenced by the Kuroshio Current [*Matsuno et al.*, 2009], the East Asian Monsoon (EAM), and major rivers such as the Yellow (Huang He) River and Yangtze (Changjiang) River. Upwelling of the Kuroshio sub-surface waters provides abundant nutrients that support high levels of primary productivity [*Wong et al.*, 2000; *Wong et al.*, 2001]. The ecosystems of the ECS are heavily affected by human activities (e.g., overfishing and pollution), which tend to compound the influence and consequences of climate change.

SST within the ECS has increased rapidly since the early 1980s (*high confidence*) [*Lin et al.*, 2005; *Jung*, 2008; *Cai et al.*, 2011; *Tian et al.*, 2012]. The largest increases in SST have occurred in the ECS in winter (1.96℃, 1955–2005) and in the Yellow Sea in summer (1.10℃, 1971–2006, [*Cai et al.*, 2011]). These changes in SST are closely linked to a weakening of the EAM (e.g., [*Cai et al.*, 2006; *Tang et al.*, 2009; *Cai et al.*, 2011]) and increasing warmth of the Kuroshio Current [*Qi et al.*, 2010; *Zhang et al.*, 2011; *Wu et al.*, 2012]. At the same time, dissolved O_2 has decreased [*Lin et al.*, 2005; *Jung*, 2008; *Qi et al.*, 2010], with an associated increase in the extent of the hypoxic areas in coastal areas of the Yellow Sea/ECS [*Jung*, 2008; *Tang*, 2009; *Ning et al.*, 2011].

Primary productivity, biomass yields, and fish capture rates have experienced large changes within the ECS over the past decades (*limited evidence*, *medium agreement*, *low confidence)* [*Tang et al.*, 2003; *Lin et al.*, 2005; *Tang*, 2009]. Fluctuations in herring abundance appear to closely track SST shifts within the Yellow Sea [*Tang*, 2009]. For plankton and fish species, the proportions of warm-water species relative to warm-temperate species in the Changjiang River Estuary (extending to the southern Taiwan Strait) have changed in past decades [*Zhang et al.*, 2005; *Ma et al.*, 2009; *Lin and Yang*, 2011]. Northward shifts in catch distribution for some pelagic fish species in Korean waters were driven, in part, by warming SST (*medium confidence*, [*Jung et al.*, 2013]. The frequency of harmful algal blooms (HAB) and blooms of the giant jellyfish *Nemopilema nomurai* in the offshore area of the ECS have increased and have been associated with ocean warming and other factors such as eutrophication [*Ye and Huang*, 2003; *Tang*, 2009; *Cai and Tan*, 2010]. While attribution of these changes to anthropogenic climate change is complicated by the increasing influence of non-climate related human activities, many of these changes are consistent with those expected as SST increases.

30.5.4.1.2. South China Sea

The South China Sea (SCS) is surrounded by continental areas and a large number of islands, and is connected to the Pacific, ECS, and Sulu Sea by straits such as the Luzon and Taiwan Strait. The region is greatly influenced by cyclones/typhoons, and by the Pearl, Red, and Mekong Rivers. The region has a distinct seasonal circulation and is greatly influenced by the southwest monsoon (in summer), the Kuroshio Current and northeast monsoon (in winter). The SCS includes significant commercial fisheries areas and includes coral reefs, mangroves, and seagrasses.

The surface waters of the SCS have been warming steadily from 1945–1999 with the annual mean SST in the central SCS increasing by 0.92℃ (1950–2006, [*Cai et al.*, 2009]), a rate similar to that observed for the entire Indo-Pacific/SE Asian CBS from 1950–2009 (0.80°C, Table 30-1). Significant freshening in the SCS intermediate layer since the 1960s has been observed [*Liu et al.*, 2007]. The temperature change of the upper layers of the SCS has made a significant contribution to sea level variation, which is spatially non-homogeneous and varies in time [*Li et al.*, 2002; *Cheng and Qi*, 2007; *Liu et al.*, 2007].

Identifying the extent to which climate change is influencing the SCS is difficult due to confounding non-climate change factors and their interactions (e.g., local human pollution, over-exploitation together with 'natural' climate variability such as EAM, ENSO, and PDO). Changing sea temperatures have influenced the abundance of phytoplankton, benthic biomass, cephalopod fisheries, and the size of demersal trawl catches in the northern SCS observed over the period 1976–2004 (*limited evidence, medium agreement*) [*Ning et al.*, 2009]. Coral reefs and mangroves are degrading rapidly as a result of both climate change and non-climate change related factors (*very likely*) (Box CC-CR, [*Chen et al.*, 2009; *China-SNAP*, 2011; *Zhao et al.*, 2012]). Mass coral bleaching and mortality of coral reefs within the SCS were triggered by elevated temperatures in 1998 and 2007 [*Yu et al.*, 2006; *Li et al.*, 2011]. Conversely, warming enabled the establishment of a high latitude, non-carbonate, coral community in Daya Bay in the northern SCS, although this community has recently degraded due to increasing anthropogenic stresses [*Chen et al.*, 2009; *Qiu et al.*, 2010].

30.5.4.1.3. South-east Asian Seas

The South-east Asian Seas (SAS) include an archipelago of diverse islands that interact with the westward flow of the North Equatorial Current and the Indonesian Throughflow (Figure 30-1a). A large part of this region is referred to as the 'Coral Triangle' [*Veron et al.*, 2009]. The world's most biologically diverse marine area, it includes parts of Malaysia, Indonesia, the Philippines, Timor Leste, the Solomon Islands, and Papua New Guinea. SST increased significantly from 1985–2006 [*Peñaflor et al.*, 2009; *McLeod et al.*, 2010], although with considerable spatial variation. Trends examined over longer periods (1950–2009) show significant warming (+0.80°C, p-value$\leq$0.05, Table 30-1). The sea level is rising by up to 10 mm yr^{-1} in much of this region [*Church et al.*, 2004; *Church et al.*, 2006; *Green et al.*, 2010]. Like other tropical areas in the world, coral reefs within SAS have experienced periods of elevated temperature, which has driven several mass coral bleaching and mortality events since the early 1980s (*high confidence*) [*Hoegh-Guldberg et al.*, 2009; *McLeod et al.*, 2010] (Figure 30-10a). The most recent occurred during warm conditions in 2010 [*Krishnan et al.*, 2011]. These changes are the result of increasing ocean temperatures and are *very likely* to be a consequence of anthropogenic climate change (*high confidence*) (Box CC-CR, WGI 10.4.1). Although calcification rates of some key organisms (e.g., reef-building corals; [*Tanzil et al.*, 2009]) have slowed over the past two decades, it is not possible to conclude that the changes are due to ocean acidification. While a large part of the decline in coral reefs has been due to increasing local stresses (principally destructive fishing, declining water quality, and overexploitation of key reef species), projected increases in SST represent a major challenge for these valuable ecosystems (*high agreement*) [*Burke et al.*, 2002; *Burke and Maidens*, 2004].

30.5.4.1.4. Arabian Sea and Somali Current

The Arabian Sea and Somali Current are relatively productive ocean areas, being strongly influenced by upwelling and the monsoonal system. Wind-generated upwelling enhances primary production in the western Arabian Sea

[*Prakash and Ramesh*, 2007]. Several key fisheries within this region are under escalating pressure from both fishing and climate change. Sea surface temperature increased by 0.18℃ and 0.26℃ in the Arabian Sea and Somali Current, respectively, from 1982–2006 (HadSST2, [*Rayner et al.*, 2003; *Belkin*, 2009]), which is consistent with the overall warming of the Western Indian Ocean portion of the CBS from 1950–2009 (0.60℃, Table 30-1). Salinity of surface waters in the Arabian Sea increased by 0.5–1.0% over the past 60 years (Figure 30-6c), due to increased evaporation from warming seas and contributions from the outflows of the saline Red Sea and Arabian Gulf. As in other tropical sub-regions, increasing sea temperatures have increased the frequency of mass coral bleaching and mortality within this region [*Wilkinson and Hodgson*, 1999; *Goreau et al.*, 2000; *Wilkinson*, 2004].

The aragonite saturation horizon in both the Arabian Sea and Bay of Bengal is now 100–200 m shallower than in pre-industrial times as a result of ocean acidification (*medium confidence*) [*Feely et al.*, 2004]. Shoaling of the aragonite saturation horizon is *likely* to affect a range of organisms and processes, such as the depth distribution of pteropods (zooplankton) in the western Arabian Sea (*medium confidence*) [*Hitchcock et al.*, 2002; *Mohan et al.*, 2006]. More than 50% of the area of oxygen minimum zones (OMZs) in the world's oceans occur in the Arabian Sea and Bay of Bengal and long-term measurements reveal that O_2 concentrations are declining in this region (*high confidence*) [*Helly and Levin*, 2004; *Karstensen et al.*, 2008; *Stramma et al.*, 2010] (30.3.2.3). The information regarding the consequences of climate change within this region is undeveloped and suggests that important physical, chemical, and biological responses to climate change need to be the focus of further investigation.

30.5.4.1.5. East Africa coast and Madagascar

The Western Indian Ocean strongly influences the coastal conditions associated with Kenya, Mozambique, Tanzania, Madagascar, La Réunion, Mayotte, and three archipelagos (Comoros, Mauritius, and the Seychelles). Sea temperatures in the Western Indian Ocean have increased by 0.60℃ over 1950–2009 (*high confidence*) (p-value$\leq$0.05; Table 30-1), increasing the frequency of positive thermal anomalies which have triggered mass coral bleaching and mortality events across the region over the past two decades (*high confidence*,[*Baker et al.*, 2008; *Nakamura et al.*, 2011](CC-HS). Trends in changes in SST and surface salinity vary with location along the East African coastline, with faster rates at higher latitudes (Figure 30-2). Periods of heat stress over the past 20 years have triggered mass coral bleaching and mortality on coral reef ecosystems within this region [*McClanahan et al.*, 2007; *McClanahan et al.*, 2009a; *McClanahan et al.*, 2009c; *McClanahan et al.*, 2009b; *Ateweberhan and McClanahan*, 2010; *Ateweberhan et al.*, 2011]. Steadily increasing sea temperatures have also produced anomalous growth rates in long-lived corals such as *Porites* (*high confidence*) [*McClanahan et al.*, 2009b]. Differences in the susceptibility of reef-building corals to stress from rising sea temperatures has also resulted in changes to the composition of coral (*high confidence*) (p-value$\leq$0.05; [*McClanahan et al.*, 2007]) and benthic fish communities (*high confidence*) (p-value$\leq$0.05; [*Graham et al.*, 2008; *Pratchett et al.*, 2011a]). These changes are *very likely* to alter species composition and potentially the productivity of coastal fisheries (*robust evidence, high agreement, high confidence*) [*Jury et al.*, 2010], although there may be a significant lag between the loss of coral communities and the subsequent changes in the abundance and community structure of fish (p-value$\leq$0.05, [*Graham et al.*, 2007]). Some of these potential changes can be adverted or reduced by interventions such as the establishment of marine protected areas and changes to fishing management [*McClanahan et al.*, 2008; *Cinner et al.*, 2009; *Jury et al.*, 2010; *MacNeil et al.*, 2010].

30.5.4.1.6. Gulf of Mexico and Caribbean Sea

The Gulf of Mexico and Caribbean Sea form a semi-contained maritime province within the Western Atlantic. These areas are dominated by a range of activities including mineral extraction, fishing, and tourism, which provide employment and opportunity for almost 75 million people who live in coastal areas of the US, Mexico, and a range of other Caribbean nations [*Adams et al.*, 2004]. The Gulf of Mexico and Caribbean Sea have warmed by 0.31°C and 0.50°C and respectively from 1982–2006 (*very likely*) [*Belkin*, 2009]. Warming trends are not significant from 1950–2009 (Table 30-1), which may be partly due to spatial variability in warming patterns (30.5.3.1). The Caribbean region has experienced a sustained decrease in aragonite saturation state from 1996–2006 (*very likely*)

[*Gledhill et al.*, 2008]. Sea levels within the Gulf of Mexico and Caribbean Sea have increased at the rate of 2–3 mm y^{-1} from 1950–2000 [*Church et al.*, 2004; *Zervas*, 2009].

Understanding influences of climate change on ocean ecosystems in this region is complicated by the confounding influence of growing human populations and activities. The recent expansion of the seasonal hypoxic zone, and the associated 'dead zone', in the Gulf of Mexico has been attributed to nitrogen inputs driven by land management [*Turner and Rabalais*, 1994; *Donner et al.*, 2004] and changes to river flows, wind patterns, and thermal stratification of Gulf waters (*high confidence*) [*Justić et al.*, 1996; *Justić et al.*, 2007; *Levin et al.*, 2009; *Rabalais et al.*, 2009; *Rabalais et al.*, 2010]. The increases in coastal pollution and fishing have potentially interacted with climate change to exacerbate impacts on marine ecosystems within this region (5.3.4, 29.3). These changes have often been abrupt and non-linear [*Taylor et al.*, 2012].

A combination of local and global disturbances has driven a large-scale loss of reef-building corals across the Caribbean Sea since the late 1970s (*high confidence*) [*Hughes*, 1994; *Gardner et al.*, 2003]. Record thermal stress in 2005 triggered the largest mass coral bleaching and mortality event on record for the region, damaging coral reefs across hundreds of km^2 in the eastern Caribbean Sea (*high confidence*) [*Donner et al.*, 2007; *Eakin et al.*, 2010]. Although conditions in 2010 were milder than 2005, elevated temperatures still occurred in some parts of the Caribbean [*Smith et al.*, 2013]. Increasing temperatures in the Caribbean have also been implicated in the spread of marine diseases [*Harvell et al.*, 1999; *Harvell et al.*, 2002; *Harvell et al.*, 2004] and some introduced species (*likely*) [*Firth et al.*, 2011]. As in other sub-regions, pelagic fish species are sensitive to changes in sea temperature and modify their distribution and abundance [*Muhling et al.*, 2011]. Fish and invertebrate assemblages in the Gulf of Mexico have shifted deeper in response to SST warming over 1970s-2011 (*medium confidence*) [*Pinsky et al.*, 2013].

Coral ecosystems in the Caribbean Sea are at risk from ocean acidification (*very likely*) [*Albright et al.*, 2010; *Albright and Langdon*, 2011], although impacts are yet to be observed under field conditions. Ocean acidification may also be altering patterns of fish recruitment to coral reefs, although direct evidence for how this has affected Caribbean species is lacking (*low confidence*) [*Dixson et al.*, 2008; *Munday et al.*, 2009; *Dixson et al.*, 2010].

30.5.4.2. Key Risks and Vulnerabilities

Worldwide, 850 million people live within 100 km of tropical coastal ecosystems such as coral reefs and mangroves deriving multiple benefits including food, coastal protection, cultural services, and income from industries such as fishing and tourism [*Burke et al.*, 2011]. Marine ecosystems within the CBS are sensitive to increasing sea temperatures (Figure 30-10), although detection and attribution is complicated by the significant influence and interaction with non-climate change stressors (water quality, over-exploitation of fisheries, coastal degradation; Box CC-CR). Warming is *likely* to have changed the primary productivity of ocean waters, placing valuable ecosystems and fisheries within the ECS at risk (*low to medium confidence*). Other risks include the expansion of hypoxic conditions and associated dead zones in many parts of the CBS. Given the consequences for coastal ecosystems and fisheries, these changes are *very likely* to increase the vulnerability of coastal communities throughout the CBS.

Sea temperatures are increasing within many parts of the CBS ecosystems (1950–2009, Table 30-1), and will continue to do so over the next few decades and century. Sea temperatures are projected to change by 0.34–0.50°C over the near-term (2010–2039) and by 0.23–0.74°C over the long-term (2010–2099) under the lowest RCP scenario (RCP2.6). Under BAU (RCP8.5), CBS sea temperatures are projected to increase by 0.62–0.85°C over tne near-term and 2.44–3.32°C over the long-term (Table SM30-4). Given the large-scale impacts (e.g., mass coral bleaching and mortality events) that have occurred in response to much smaller changes in the past over the CBS regions (0.14–0.80°C from 1950–2009, Table 30-1), the projected changes of 2.44–3.32°C over 2010-2099 are *very likely* to have large-scale and negative consequences for the structure and function of many CBS ecosystems (*virtually certain*), especially given the sensitivity of coral reefs to relatively small increases in temperature over the past three decades [*Hoegh-Guldberg*, 1999; *Eakin et al.*, 2010; *Lough*, 2012].

It is *very likely* that coral-dominated reef ecosystems within the CBS (and elsewhere) will continue to decline and will consequently provide significantly less ecosystem goods and services for coastal communities if sea temperatures increase by more than 1°C above current temperatures (Box CC-CR, Figure 30-10). Combining the known sensitivity of coral reefs within the Caribbean and Coral Triangle sub-regions [*Strong et al.*, 1997; *Hoegh-Guldberg*, 1999; *Strong et al.*, 2011], with the exposure to higher temperatures that are projected under medium (RCP4.5) to high (RCP8.5) scenarios, reveals that both coral reef-rich regions are *virtually certain* to experience levels of thermal stress (DHM≥1) that cause coral bleaching every 1–2 years by the mid to late part of this century (*robust evidence, high levels of agreement, very high confidence*) (Figure 30-4b, c; Figure 30-10, Figure 30-12, Figure SM30-3; [*van Hooidonk et al.*, 2013]). The frequency of mass mortality events (DHM≥5, Figure 30-10a-c) also climbs towards events that occur every 1–2 years by the mid to late part of this century under low to high climate change scenarios (*robust evidence, high agreement, very high confidence*) [*Hoegh-Guldberg*, 1999; *Donner et al.*, 2005; *Frieler et al.*, 2012]. Mass mortality events that affect coral reefs will result in changes to community composition in the near-term (2010–2039) [*Berumen and Pratchett*, 2006; *Adjeroud et al.*, 2009] and a continuing downward trend in reef-building coral stocks in the longer term [*Gardner et al.*, 2003; *Bruno and Selig*, 2007; *Baker et al.*, 2008].

It is *virtually certain* that composition of fisheries catches [*Graham et al.*, 2007; *Pratchett et al.*, 2011a] [*Pratchett et al.*, 2008; *Pratchett et al.*, 2011b] will change. The productivity of many fisheries will decrease (*limited evidence, medium agreement*) as waters warm, acidify, and stratify, and as crucial habitat such as coral reefs degrades (*low confidence*). These changes are *very likely* to increase the vulnerability of millions of people who live in coastal communities and depend directly on fisheries and other ecological goods and services [*Hoegh-Guldberg et al.*, 2009; *McLeod et al.*, 2010].

[INSERT FIGURE 30-10 HERE
Figure 30-10: Annual maximum proportions of reef pixels with Degree Heating Months [*Donner et al.*, 2007]; DHM)≥1 (used for projecting coral bleaching; [*Strong et al.*, 1997; *Strong et al.*, 2011]) and DHM≥5 (associated with bleaching across 100% of affected areas with significant mortality, [*Eakin et al.*, 2010] for the period 1870–2009 for each of the six coral regions (Figure 30-4d) using the HadISST1.1 data set. The black line on each graph is the maximum annual area value for each decade over the period 1870–2009. This value is continued through 2010–2099 using CMIP5 data and splits into the four Representative Concentration Pathways (RCP2.6, 4.5, 6.0, and 8.5). DHM were produced for each of the four RCPs using the ensembles of CMIP models. From these global maps of DHM, the annual percentage of grid cells with DHM≥1 and DHM≥5 were calculated for each coral region. These data were then grouped into decades from which the maximum annual proportions were derived. The plotted lines for 2010–2099 are the average of these maximum proportion values for each RCP. Monthly SST anomalies were derived using a 1985–2000 maximum monthly mean (MMM) climatology derived in the calculations for Figure 30-4. This was done separately for HadISST1.1, the CMIP5 models, and each of the four RCPs, at each grid cell for every region. DHMs were then derived by adding up the monthly anomalies using a 4-month rolling sum. Figure SM30-3 presents past and future sea temperatures for the six major coral reef provinces under historic, un-forced, RCP4.5 and RCP8.5 scenarios.]

30.5.5. Eastern Boundary Upwelling Ecosystems

The Eastern Boundary Upwelling Ecosystems (EBUE) include the California, Peru/Humboldt, Canary/North-west Africa, and Benguela Currents. They are highly productive sub-regions with rates of primary productivity that may exceed 1000 g C m^{-2} yr^{-1}. Although these provinces comprise less than 2% of the Ocean area, they contribute nearly 7% of marine primary production (Figure 30-1b) and more than 20% of the world's marine capture fisheries [*Pauly and Christensen*, 1995]. Catches in the EBUE are dominated by planktivorous sardine, anchovy, and horse/jack mackerel, and piscivorous benthic fish such as hake. Nutrient input from upwelling of cooler waters stimulates primary production that is transferred to mid and upper trophic levels, resulting in substantial fish, seabird, and marine mammal populations. As a result, the EBUE are considered 'hotspots' of productivity and biodiversity [*Block et al.*, 2011]. The high level of productivity is a result of large-scale atmospheric pressure gradients and wind systems that advect surface waters offshore leading to the upwelling of cold, nutrient-rich waters from depth (Box CC-UP) [*Chavez and Messie*, 2009; *Chavez et al.*, 2011]. Upwelling waters are typically low in pH and high in CO_2, and are *likely* to continue to enhance changes in pH and CO_2 resulting from rising atmospheric CO_2 [*Feely et al.*, 2008; *Gruber*, 2011].

30.5.5.1. Observed Changes and Potential Impacts

There are extensive studies of the coupled climate-ecosystem dynamics of individual EBUE (e.g., California Current). Decadal variability poses challenges to the detection and attribution of changes within the EBUE to climate change, although there are a number of long-term studies that have been able to provide insight into the patterns of change and their causes. Like other ocean sub-regions, EBUE are projected to warm under climate change, with increased stratification and intensified winds as westerly winds shift poleward (*likely*). However, cooling has also been predicted for some EBUE, resulting from the intensification of wind-driven upwelling [*Bakun*, 1990]. The California and Canary Currents have warmed by 0.73 and 0.53°C (*very likely*) (p-value≤0.05, 1950-2009, Table 30-1), respectively, while no significant trend was detected in the sea surface temperatures of the Benguela (p-value = 0.44) and Humboldt Currents (p-value = 0.21) from 1950–2009 (Table 30-1). These trends match shorter-term trends for various EBUE using Pathfinder version 5 data [*Demarcq*, 2009]. These differences are *likely* to be the result of differences in the influence of long-term variability and the specific responses of coastal wind systems to warming, although an analysis of wind data over the same period did not pick up clear trends (*low confidence*, with respect to long-term wind trends) [*Demarcq*, 2009; *Barton et al.*, 2013].

How climate change will influence ocean upwelling is central to resolving ecosystem and fishery responses within each EBUE. There is considerable debate, however, as to whether or not climate change will drive an intensification of upwelling (e.g., [*Bakun et al.*, 2010; *Narayan et al.*, 2010; *Barton et al.*, 2013] in all regions. This debate is outlined in Box CC-UP. EBUE are also areas of naturally low pH and high CO_2 concentrations due to upwelling, and consequently may be vulnerable to ocean acidification and its synergistic impacts [*Barton et al.*, 2012]. A full understanding of the consequences of ocean acidification for marine organisms and ecosystems is discussed elsewhere (Box CC-OA, Box CC-UP, 6.2, 6.3.2, [*Kroeker et al.*, 2013], WGI 6.4).

30.5.5.1.1. Canary Current

Part of the North Atlantic STG, the Canary Current extends from northern Morocco southwestward to the North Atlantic Equatorial Current. It is linked with the Portugal Current (which is sometimes considered part of the Canary Current) upstream and extends downstream to the Atlantic Equatorial Current. The coastal upwelling system, however, is limited to a narrow belt along the Saharan west coast to the coast of Guinea, with the most intense upwelling occurring centrally, along the coasts of Mauritania (15–20º N) and Morocco (21–26° N). Total fish catches, comprising mainly coastal pelagic sardines, sardinellas, anchovies, and mackerel, have fluctuated around 2 million tons yr^{-1} since the 1970s (http://www.seaaroundus.org/lme/27.aspx). Contrasting with the other EBUE, fishing productivity is modest, probably due to the legacy of uncontrolled fishing in the 1960s [*Arístegui et al.*, 2009].

Most observations suggest that the Canary Current has warmed since the early 1980s [*Arístegui et al.*, 2009; *Belkin*, 2009; *Demarcq*, 2009; *Barton et al.*, 2013], with analysis of HadISST1.1 data from 1950–2009 indicating warming of 0.53°C from 1950–2009 (p-value≤0.05, Table 30-1). *Gómez-Gesteira et al.* [2008] suggest a 20% and 45% decrease in the strength of upwelling in winter and summer, respectively, from 1967–2006, consistent with a decrease in wind strength and direction over the past 60 years. More recently, [*Barton et al.*, 2013] show no clear increasing or decreasing trend in wind strength over the past 60 years, and a lack of agreement among wind trends and variability from different wind products, (e.g. PFEL, ICOADS, WASWind). This study presents no evidence for changes in upwelling intensity, with the exception of upwelling off North-west Spain, where winds are becoming slightly less favorable. Alteration of wind direction and strength influences upwelling and hence nutrient concentrations, howevernutrient levels can also change in response to other variables such as the supply of iron-laden dust from the Sahara [*Alonso-Pérez et al.*, 2011]. There is *medium evidence* and *medium agreement* that primary production in the Canary Current has decreased over the past two decades [*Arístegui et al.*, 2009; *Demarcq*, 2009], in contrast to the nearby upwelling region off North-west Spain, where no significant trend was observed

[*Bode et al.*, 2011]. Satellite chlorophyll records (SeaWiFS, MODIS) are relatively short, making it difficult to distinguish the influence of warming oceans from longer-term patterns of variability [*Arístegui et al.*, 2009; *Henson et al.*, 2010]. Changing temperature has resulted in changes to important fisheries species. For example, Mauritanian waters have become more suitable as feeding and spawning areas for some fisheries species (e.g., *Sardinella aurita*) as temperatures increased [*Zeeberg et al.*, 2008]. Clear attribution of these changes depends on the linkage between the Azores High and global temperature, and on longer records for both physical and biological systems as pointed out for data sets in general [*Arístegui et al.*, 2009; *Henson et al.*, 2010].

30.5.5.1.2. Benguela Current

The Benguela Current originates from the eastward-flowing, cold South Atlantic Current, flows northward along the southwest coast of Africa, and is bounded north and south by the warm-water Angola and Agulhas Currents, respectively. Upwelling is strongest and most persistent toward the center of the system in the Lüderitz-Orange River upwelling cell [*Hutchings et al.*, 2009]. Fish catch reached a peak in the late 1970s of 2.8 million tons yr^{-1} (http://www.seaaroundus.org/lme/29/1.aspx), before declines in the northern Benguela, due to overfishing and interdecadal environmental variability, resulted in a reduced catch of around 1 million tons yr^{-1} (present) [*Cury and Shannon*, 2004; *Heymans et al.*, 2004; *Hutchings et al.*, 2009]. Offshore commercial fisheries currently comprise sardine, anchovy, horse mackerel, and hake, while the inshore artisanal and recreational fisheries comprise a variety of fish species mostly caught by hook and line.

Most research on the Benguela Current has focused on fisheries and oceanography, with little emphasis on climate change. As with the other EBUE, strong interannual and interdecadal variability in physical oceanography make the detection and attribution of biophysical trends to climate change difficult. Nevertheless, the physical conditions of the Benguela Current are highly sensitive to climate variability over a range of scales, especially to atmospheric teleconnections that alter local wind stress [*Hutchings et al.*, 2009; *Leduc et al.*, 2010; *Richter et al.*, 2010; *Rouault et al.*, 2010]. Consequently, there is *medium agreement*, despite *limited evidence* [*Demarcq*, 2009], that upwelling intensity and associated variables (e.g., temperature, nutrient, and O_2 concentrations) from the Benguela system will change as a result of climate change (Box CC-UP).

The temperature of the surface waters of the Benguela Current did not increase from 1950 to 2009 (p-value>0.05, Table 30-1), although shorter records show an decrease in the south-central Benguela Current (0.35–0.55 ºC $decade^{-1}$ [*Rouault et al.*, 2010] or an increase for the whole Benguela region (0.24ºC, *Belkin* [2009]). These differences between short versus long records indicate the substantial influence of long-term variability on the Benguela system [*Belkin*, 2009]. Information on other potential consequences of climate-change within the Benguela system is sparse. Sea-level rise is similar to the global mean, although it has not been measured rigorously within the Benguela [*Brundrit*, 1995; *Veitch*, 2007]. Although upwelling water in the northern and southern portions of the Benguela Current exhibits elevated and suppressed pCO_2, respectively [*Santana-Casiano et al.*, 2009]), the consequences of changing upwelling intensity remain poorly explored with respect to ocean acidification. Finally, while periodic hypoxic events in the Benguela system are largely driven by natural advective processes, these may be exacerbated by future climate change [*Monteiro et al.*, 2008; *Bakun et al.*, 2010].

Despite its apparent sensitivity to environmental variability, there is *limited evidence* of ecological changes in the Benguela Current EBUE due to climate change [*Poloczanska et al.*, 2013]. For example, pelagic fish [*Roy et al.*, 2007], benthic crustaceans [*Cockcroft et al.*, 2008], and seabirds [*Crawford et al.*, 2008] have demonstrated general eastward range shifts around the Cape of Good Hope. Although these may be associated with increased upwelling along the South African south coast, specific studies that attribute these changes to anthropogenic climate change are lacking. Trawl surveys of demersal fish and cephalopod species showed consistently predictable 'hotspots' of species richness over a 20–30 year study period (the earliest surveys since 1984 off South Africa) that were associated with greater depths and cooler bottom waters [*Kirkman et al.*, 2013]. However, major changes in the structure and function of the demersal community have been shown in some parts of the Benguela in response to environmental change e.g., due to predominately fishing pressure in the 1960s and environmental forcing in the early 2000s in the southern Benguela [*Howard et al.*, 2007], therefore changes driven by climate change may eventually affect the persistence of these biodiversity hotspots [*Kirkman et al.*, 2013].

30.5.5.1.3. California Current

The California Current spans ~23° of latitude from central Baja California, Mexico, to central British Columbia, Canada, linking the North Pacific Current (Westwind Drift) with the North Equatorial and Kuroshio Currents to form the North Pacific Gyre. High productivity driven by advective transport and upwelling [*Hickey*, 1979; *Chelton et al.*, 1982; *Checkley and Barth,* 2009; *Auad et al.*, 2011] supports well-studied ecosystems and fisheries. Fish catches from the California Current have been approximately 0.6 million tonnes yr^{-1} since 1950 (http://www.seaaroundus.org/lme/3.aspx), which makes it the lowest catch of the four EBUE. The ecosystem supports the foraging and reproductive activities of 2–6 million seabirds from around 100 species [*Tyler et al.*, 1993]. Marine mammals are diverse and relatively abundant, including recovering populations of humpback whales, among others [*Barlow et al.*, 2008].

The average temperature of the California Current warmed by 0.73°C from 1950–2009 (p-value $\leq$0.05, Table 30-1) and by 0.14–0.80°C from 1985–2007 [*Demarcq*, 2009]. Like other EBUE, the California Current is characterized by large-scale interannual and interdecadal climate-ecosystem variability [*McGowan et al.*, 1998; *Hare and Mantua*, 2000; *Chavez et al.*, 2003; *Checkley and Barth*, 2009]. During an El Niño, coastally-trapped Kelvin waves from the tropics deepen the thermocline, thereby severely reducing upwelling and increasing ocean temperatures from California to Washington [*Peterson and Schwing*, 2003; *King et al.*, 2011]. Atmospheric teleconnections to the tropical Pacific alter wind stress and coastal upwelling. Therefore, the ENSO is intimately linked with Bakun's (1990) upwelling intensification hypothesis (Box CC-UP). Interdecadal variability in the California Current stems from variability in the Pacific-North America pattern [*Overland et al.*, 2010], which is influenced by the PDO [*Mantua et al.*, 1997; *Peterson and Schwing*, 2003] and the NPGO [*Di Lorenzo et al.*, 2008]. The major effects of the PDO and NPGO appear north of 39°N [*Di Lorenzo et al.*, 2008; *Menge et al.*, 2009].

There is *robust evidence* and *medium agreement* that the California Current has experienced a decrease in the number of upwelling events (23–40%), but an increase duration of individual events resulting in an increase of the overall magnitude of upwelling events from 1967–2010 (*high confidence*) [*Demarcq*, 2009; *Iles et al.*, 2012]. This is consistent with changes expected under climate change yet remains complicated by the influence of decadal-scale variability (*low confidence*) [*Iles et al.*, 2012]. Oxygen concentrations have also undergone large and consistent decreases from 1984–2006 throughout the California Current, with the largest relative decreases occurring below the thermocline (21% at 300 m). The hypoxic boundary layer (<60 µmol kg^{-1}) has also shoaled by up to 90 m in some regions [*Bograd et al.*, 2008]. These changes are consistent with the increased input of organic carbon into deeper layers from enhanced upwelling and productivity, which stimulates microbial activity and results in the drawdown of O_2 (*likely*), [*Bakun et al.*, 2010] but see also [*McClatchie et al.*, 2010; *Koslow et al.*, 2011]; WGI 3.8.3). These changes are *likely* to have reduced the available habitat for key benthic communities as well as fish and other mobile species [*Stramma et al.*, 2010]. Increasing microbial activity will also increase the partial pressure of CO_2, decreasing pH and the carbonate chemistry of seawater. Together with the shoaling of the saturation horizon, these changes have increased the incidence of low O_2 and low pH water flowing onto the continental shelf (*high confidence*) (40–120 m, [*Feely et al.*, 2008]), causing problems for industries such as the shellfish aquaculture industry [*Barton et al.*, 2012].

30.5.5.1.4. Humboldt Current

The Humboldt Current is the largest of the four EBUE, covering an area larger than the other three combined. It comprises the eastern edge of South Pacific Gyre, linking the northern part of the Antarctic Circumpolar Current with the Pacific South Equatorial Current. Although the primary productivity per unit area is modest compared to that of the other EBUE, the Humboldt Current system has very high levels of fish production. Current catches are in line with a long-term average (since the 1960s) of 8 million tons yr^{-1} (http://www.seaaroundus.org/lme/13/1.aspx), although decadal-scale variations range from 2.5–13 million tons yr^{-1}. While the anchovies currently contribute 80% of the total catch, they alternate with sardines on a multi-decadal scale, with their dynamics mediated by the approach and retreat of sub-tropical waters to and from the coast [*Alheit and Bakun*, 2010]. This variability does not appear to be altering due to anthropogenic climate change. Thus, from the late 1970s to the early 1990s, sardines were more important [*Chavez et al.*, 2003]. The other major commercial fish species are jack mackerel among the pelagic fish, and hake among the demersal fish.

The Humboldt Current EBUE did not show an overall warming trend in SST over the last 60 years (p-value>0.05, Table 30-1), which is consistent with other data sets (1982–2006, HadISST1.1, [*Belkin*, 2009]; 1985-2007, Pathfinder, [*Demarcq*, 2009]). Wind speed has increased in the central portions of the Humboldt Current, although wind has decreased in its southern and northern sections [*Demarcq*, 2009]. The lack of a consistent warming signal may be due to the strong influence of adjacent ENSO activity exerting opposing drivers on upwelling and which, if they intensify, would decrease temperatures (*limited evidence*, *medium agreement*). Similar to the Canary Current EBUE, however, there was a significant increase in the temperatures of the warmest month of the year over the period 1950–2009 ($p\text{-value} \leq 0.05$, Table 30-1).

Primary production is suppressed during warm El Niño events and amplified during cooler La Niña phases, these changes then propagate through to higher trophic levels [*Chavez et al.*, 2003; *Tam et al.*, 2008; *Taylor et al.*, 2008]. However, in addition to trophic changes, there is also a direct thermal impact on organisms, which varies depending on the thermal adaptation window for each species (*high confidence*). A 37-year zooplankton time series for the coast of Peru showed no persistent trend in abundance and diversity [*Ayón et al.*, 2004], although observed shifts coincided with the shifts in the regional SST. As for other EBUE, there is lack of studies that have rigorously attempted to detect and attribute changes to anthropogenic climate change, although at least two studies [*Mendelssohn and Schwing*, 2002; *Gutierrez et al.*, 2011] provide additional evidence that the northern Humboldt Current has cooled (due to upwelling intensification) since the 1950s, a trend matched by increasing primary production. This is not entirely consistent with the lack of significant change over the period 1950–2009 (p-value>0.05, Table 30-1). Nevertheless, these relationships are *likely* to be complex in their origin, especially in their sensitivity to the long-term changes associated with ENSO and PDO, and the fact that areas within the Humboldt Current EBUE may be showing different behaviors.

30.5.5.2. Key Risks and Vulnerabilities

EBUE are vulnerable to changes that influence the intensity of currents, upwelling, and mixing (and hence changes in SST, wind strength and direction), as well as O_2 content, carbonate chemistry, nutrient content, and the supply of organic carbon to deep offshore locations (*robust evidence*, *high agreement*, *high confidence*). The extent to which any particular EBUE is vulnerable to these factors depends on location (Figure 3 from *Gruber* [2011] and other factors such as alternative sources of nutrient input and fishing pressure [*Bakun et al.*, 2010]. This complex interplay between regional and global drivers means that our understanding of how factors such as upwelling within the EBUE will to respond to further climate change is uncertain (Box CC-UP, [*Rykaczewski and Dunne*, 2010]).

In the GCM ensembles examined (Table SM30-3), modest rates of warming (0.22–0.93°C) occur within the four EBUEs in the near-term. Over 2010-2099, however, EBUE SSTs warm by 0.07–1.02ºC under RCP2.6, and 2.52–3.51ºC under RCP8.5 (Table SM30-4). These high temperatures have the potential to increase stratification of the water column and substantially reduce overall mixing in some areas. In contrast, the potential strengthening of coastal wind systems would intensify upwelling and stimulate primary productivity through the increased injection of nutrients into the photic zone of the EBUE (Box CC-UP). *Garreaud and Falvey* [2009] explored how wind stress along the South American coast would change by 2100 under B2 and A2 IPCC scenarios. Using an ensemble of 15 GCMs, southerly wind systems favoring upwelling increased along the sub-tropical coast of South America, extending and strengthening conditions for upwelling.

Changes in the intensity of upwelling within the EBUE will drive fundamental changes to the abundance, distribution, and viability of resident organisms, although an understanding of their nature and direction is limited. In some cases, large-scale decreases in primary productivity and dependent fisheries are projected to occur for EBUE ecosystems [*Blanchard et al.*, 2012], while other projections question the strong connection between primary productivity and fisheries production [*Arístegui et al.*, 2009]. Increased upwelling intensity also has potential disadvantages. Elevated primary productivity may lead to decreasing trophic transfer efficiency, thus increasing the amount of organic carbon exported to the seabed, where it is *virtually certain* to increase microbial respiration and hence increase O_2 stress [*Weeks et al.*, 2002; *Bakun et al.*, 2010]. Increased wind stress may also increase turbulence, breaking up food concentrations (affecting trophic transfer), or causing excessive offshore advection, which could remove plankton from shelf habitats. The central issue for the EBUE is therefore whether or not upwelling will intensify and, if so, whether the negative consequences (e.g., reduced O_2 and elevated CO_2) associated with upwelling intensification will outweigh potential benefits from increased primary production and fisheries catch.

30.5.6. Sub-Tropical Gyres

Sub-Tropical Gyres (STG) dominate the Pacific, Atlantic, and Indian Oceans (Figure 30-1a), and consist of large stable water masses that circulate clockwise (northern hemisphere) and anticlockwise (southern hemisphere) due to the Coriolis Effect. The oligotrophic areas at the core of the STG represent one of the largest habitats on Earth, contributing 21.2% of ocean primary productivity and 8.3% of the global fish catch (Figure 30-1b, Table SM30-1). A number of small island nations are found within this region. While many of the observed changes within these nations have been described in previous chapters (e.g., 5.3-4, 29.3–5), region-wide issues and consequences are discussed here due to the strong linkages between ocean and coastal issues.

30.5.6.1. Observed Changes and Potential Impacts

The central portions of the STG are oligotrophic (Figure SM30-1. Temperatures within the STG of the North Pacific (NPAC), South Pacific (SPAC), Indian Ocean (IOCE), North Atlantic (NATL), and South Atlantic (SATL) have increased at rates of 0.020, 0.024, 0.032, 0.025, and 0.027°C yr^{-1} from 1998–2010, respectively ([*Signorini and McClain*, 2012]. This is consistent with increases observed from 1950–2009 (0.25–0.67ºC, Table 30-1). However differences among studies done over differing time-periods emphasize the importance of long-term patterns of variability. Salinity has decreased across the North and South Pacific STG (Figure 30-6c, WGI 3.3.3.1), consistent with warmer sea temperatures and an intensification of the hydrological cycle [*Boyer*, 2005].

The North and South Pacific STGs have expanded since 1993 (*high confidence*), with these changes *likely* being the consequence of a combination of wind forcing and long-term variability ([*Parrish et al.*, 2000]; (WGI 3.6.3). Chlorophyll levels, as determined by remote-sensing of ocean color (Box CC-UP), have decreased in the NPAC, IOCE, and NATL by 9%, 12%, and 11%, respectively ($p\text{-value}\leq 0.5$; [*Signorini and McClain*, 2012]) over and above the inherent seasonal and interannual variability from 1998–2010 [*Vantrepotte and Mélin*, 2011]. Chlorophyll levels did not change in the remaining two gyres (SPAC and SATL, and confirmed for SPAC by [*Lee and McPhaden*, 2010; *Lee et al.*, 2010]). Furthermore, over the period 1998–2007, median cell diameter of key phytoplankton species exhibited statistically significant linear declines of about 2% in the North and South Pacific, and 4% in the North Atlantic Ocean [*Polovina and Woodworth*, 2012]. Changes in chlorophyll and primary productivity in these sub-regions have been noted before [*McClain et al.*, 2004; *Gregg et al.*, 2005; *Polovina et al.*, 2008] and are influenced by seasonal and longer-term sources of variability (e.g., ENSO, PDO, 6.3.4, Figure 6.9). These changes represent a significant expansion of the world's most unproductive waters, although caution must be exercised given the limitations of satellite detection methods (Box CC-PP) and the shortness of records relative to longer-term patterns of climate variability. There is *high confidence* that changes that reduce the vertical transport of nutrients into the euphotic zone (e.g., decreased wind speed, increasing surface temperatures, and stratification) will reduce the rate of primary productivity and hence fisheries.

30.5.6.1.1. Pacific Ocean STG

Pacific climate is heavily influenced by the position of the Intertropical Convergence Zone (ITCZ) and the South Pacific Convergence Zone (SPCZ), which are part of the ascending branch of the Hadley circulation (WGI 14.3.1). These features are also strongly influenced by interannual to interdecadal climate patterns of variability including ENSO and PDO. The current understanding of how ENSO and PDO will change as average global temperatures increase is not clear (*low confidence*) ([*Collins et al.*, 2010], WGI 12.4.4.2). The position of both the ITCZ and

SPCZ vary seasonally and with ENSO [*Lough et al.*, 2011], with a northward migration during the northern hemisphere summer and a southward migration during the southern hemisphere summer. These changes, along with the West Pacific Monsoon, determine the timing and extent of the wet and dry seasons in SPAC and NPAC sub-regions [*Ganachaud et al.*, 2011]. Tropical cyclones are prominent in the Pacific (particularly the western Pacific), and CBS sub-regions between 10°–30° north and south of the equator, although the associated storm systems may occasionally reach higher latitudes. Spatial patterns of cyclones vary with ENSO, spreading out from the Coral Sea to the Marquesas Islands during El Niño and contracting back to the Coral Sea, New Caledonia, and Vanuatu during La Niña [*Lough et al.*, 2011]. Historically, there have been almost twice as many land-falling tropical cyclones in La Niña as opposed to El Niño years off the east coast of Australia, with a declining trend in the number of severe tropical cyclones from 0.45 per year in the early 1870s to 0.17 per year in recent times [*Callaghan and Power*, 2011].

The Pacific Ocean underwent an abrupt shift to warmer sea temperatures in the mid-1970s as a result of both natural (e.g., Interdecadal Pacific Oscillation (IPO) and climate forcing (*high confidence*)[*Meehl et al.*, 2009]. This change coincided with changes to total rainfall, rain days, and dry spells across the Pacific, with the direction of change depending on the location relative to the SPCZ. Countries such as the Cook Islands, Tonga, Samoa and American Samoa, and Fiji tend to experience drought conditions as the SPCZ (with cooler sea temperatures) moves toward the northeast during El Niño (*high confidence*). The opposite is true during La Niña conditions. The consequences of changing rainfall on the countries of the Pacific STG are discussed in greater detail elsewhere (5.4, 29.3, Table 29.1). While these changes are due to different phases of long-term variability in the Pacific, they illustrate the ramifications and sensitivity of the Pacific to changes in climate change.

Elevated sea temperatures within the Pacific Ocean have increased the frequency of widespread mass coral bleaching and mortality since the early 1980s (*very high confidence*, [*Hoegh-Guldberg and Salvat*, 1995; *Hoegh-Guldberg*, 1999; *Mumby et al.*, 2001; *Baker et al.*, 2008; *Donner et al.*, 2010]. There are few, if any, scientific records of mass coral bleaching and mortality prior to this period (*high confidence* [*Hoegh-Guldberg*, 1999]. Rates of decline in coral cover on coastal coral reef ecosystems range between 0.5–2.0% per year depending on the location within the Indo-Pacific region (*high confidence*, [*Bruno and Selig*, 2007; *Hughes et al.*, 2011; *Sweatman et al.*, 2011; *De'ath et al.*, 2012]. The reasons for this decline are complex and involve non-climate change related factors (e.g., coastal pollution and overfishing) as well as global warming and possibly acidification. A recent comprehensive analysis of the ecological consequences of coral bleaching and mortality concluded that "bleaching episodes have resulted in catastrophic loss of coral reefs in some locations, and have changed coral community structure in many others, with a potentially critical influence on the maintenance of biodiversity in the marine tropics" (*high confidence*, [*Baker et al.*, 2008]. Increasing sea levels have also caused changes in seagrass and mangrove systems. *Gilman et al.* [2007] found a reduction in mangrove area with sea level rise, with the observed mean landward recession of three mangrove areas over four decades being 25, 64, and 72 mm yr^{-1}, 12–37 times faster than the observed rate of sea level rise. Significant interactions exist between climate change and coastal development, where migration shoreward depends on the extent to which coastlines have been modified or barriers to successful migration have been established.

Changes in sea temperature also lead to changes in the distribution of key pelagic fisheries such as skipjack tuna (*Katsuwonus pelamis*), yellowfin tuna (*Thunnus albacares*), big-eye tuna (*T. obesus*) and South Pacific albacore tuna (*T. alalunga*), which make up the majority of key fisheries in the Pacific Ocean. Changes in distribution and recruitment in response to changes in sea temperature as result of ENSO demonstrate the close association of pelagic fish stocks and water temperature. The shift in habitat for top predators in the northeast Pacific was examined by *Hazen et al.* [2012], who used tracking data from 23 marine species and associated environmental variables to predict changes of up to 35% in core habitat for these species within the north Pacific. Potential habitats are predicted to contract for the blue whale, salmon shark, loggerhead turtle, and blue and mako sharks, while potential habitats for the sooty shearwater, black -footed albatross, leatherback turtle, white shark, elephant seal, and albacore, bluefin and yellowfin tuna are predicted to expand [*Hazen et al.*, 2012]. However, expansion of OMZs in the Pacific STG is predicted to compress habitat (depth) for hypoxia-intolerant species such as tuna [*Stramma et al.*, 2010; *Stramma et al.*, 2012].

Reduction of ocean productivity of the STG [*Sarmiento et al.*, 2004; *Signorini and McClain*, 2012] reduces the flow of energy to higher trophic levels such as those of pelagic fish [*Le Borgne et al.*, 2011]. The distribution and abundance of fisheries stocks such as tuna are also sensitive to changes in sea temperature, and hence long-term variability such as ENSO and PDO. The redistribution of tuna in the western central equatorial region has been related to the position of the oceanic convergence zones, where the warm pool meets the cold tongue of the Pacific. These changes have been reliably reproduced by population models that use temperature as a driver of the distribution and abundance of tuna [*Lehodey et al.*, 1997; *Lehodey et al.*, 2006]. Projections of big-eye tuna (*T. obesus*) distributions under SRES A2 show an improvement in spawning and feeding habitats to 2100 in the eastern tropical Pacific and declines in the western tropical Pacific leading to an eastern displacement of tuna stocks [*Lehodey et al.*, 2008; *Lehodey et al.*, 2010b].

30.5.6.1.2. Indian Ocean STG

Like the Pacific Ocean, the Indian Ocean plays a crucial role in global weather patterns, with teleconnections throughout Africa, Australasia, Asia, and the Americas (e.g., [*Clark et al.*, 2000; *Manhique et al.*, 2011; *Meehl and Arblaster*, 2011; *Nakamura et al.*, 2011]. Increasing sea level, temperature, storm distribution and intensity, and changing carbonate chemistry all influence the broad range of physical, chemical, and biological aspects of the Indian Ocean. Coral reef ecosystems in the Indian Ocean gyre system were heavily affected by record positive sea temperature anomalies seen in the southern hemisphere between February–April 1998 (*robust evidence, high agreement, high confidence*) [*Ateweberhan et al.*, 2011]. Coral cover across the Western Indian Ocean declined by an average of 37.7% after the 1998 heat stress event [*Ateweberhan et al.*, 2011]. Responses to the anomalously hot conditions in 1998 varied between sub-regions, with the central Indian Ocean islands (Maldives, Seychelles, Chagos, and Lakshadweep) experiencing major decreases in coral cover directly after the 1998 event (from 40–53% coral cover in 1977–1997 to 7% in 1999–2000) (*high confidence*) [*Ateweberhan et al.*, 2011]. Coral reefs lining the islands of southern India and Sri Lanka experienced similar decreases in coral cover (45%, 1977–1997 to 12%, 1999–2000). Corals in the southwestern Indian Ocean (Comoros, Madagascar, Mauritius, Mayotte, Réunion and Rodrigues) showed less impact (44%, 1977–1997 to 40%, 1999–2000). Recovery from these increases in mortality has been variable, with sites such as those around the central Indian Ocean islands exhibiting fairly slow recovery (13% by 2001–2005) while those around southern India and Sri Lanka are showing much higher rates (achieving a mean coral cover of 37% by 2001–2005, [*Ateweberhan et al.*, 2011]). These changes to the population size of key reef-building species will drive major changes in the abundance and composition of fish populations in coastal areas, and affect other ecosystem services that are important for underpinning tourism and coastal protection (*medium confidence*, Box CC-CR).

Fisheries that exploit tuna and other large pelagic species are very valuable to many small island states within the Indian Ocean). As with Pacific fisheries, the distribution and abundance of large pelagic fish in the Indian Ocean is greatly influenced by sea temperature. The anomalously high sea temperatures of 1997–98 (leading to a deepening of the mixed layer in the west and a shoaling in the east) coincided with anomalously low primary production in the western Indian Ocean and a major shift in tuna stocks (*high confidence*) ([*Menard et al.*, 2007; *Robinson et al.*, 2010]. Fishing grounds in the Western Indian Ocean were deserted and fishing fleets underwent a massive shift toward the eastern basin, which was unprecedented for the tuna fishery (*high confidence*). As a result of these changes, many countries throughout the Indian Ocean lost significant tuna-related revenue [*Robinson et al.*, 2010]. In 2007, tuna fishing revenue was again reduced by strong surface warming and deepening of the mixed layer, and associated with a modest reduction in primary productivity in the west. These trends highlight the overall vulnerability of tuna fishing countries in the Indian Ocean to climate variability, a situation similar to the other major oceans of the world.

30.5.6.1.3. Atlantic Ocean STG

SST has increased within the two STG of the Atlantic Ocean over the last two decades [Belkin, 2009; Signorini and McClain, 2012]. Over longer periods of time (1950–2009), trends in average temperature are not significant for the North Atlantic STG (p-value>0.05) while they remain so for the South Atlantic STG (*very likely*) (0.08°C decade^{-1}, p-value≤0.05, Table 30-1). In both cases, however, temperatures in the coolest and warmest months increased significantly (Table 30-1). The difference between these studies (i.e., over 10–30 years versus 60 years) emphasizes the importance of long-term patterns of variability in the North Atlantic region. Variability in SST at a period of about 60–80 years is associated with the Atlantic Multi-decadal Oscillation (AMO) [*Trenberth and Shea*, 2006]. Sea surface temperatures influence hurricane activity (*very likely*) with recent record SST associated with record hurricane activity in 2005 in the Atlantic [*Trenberth and Shea*, 2006] and mass coral bleaching and mortality in the eastern Caribbean (*high confidence*, [*Eakin et al.*, 2010]. In the former case, analysis concluded that 0.1°C of the SST anomaly was attributable to the state of the AMO while 0.45°C was due to ocean warming as a result of anthropogenic influences [*Trenberth and Shea*, 2006].

These changes have influenced the distribution of key fishery species as well the ecology of coral reefs in Bermuda [*Wilkinson and Hodgson*, 1999; *Baker et al.*, 2008] and in the eastern Caribbean [*Eakin et al.*, 2010]. Small island nations such as Bermuda depend on coral reefs for fisheries and tourism and are vulnerable to further increases in sea temperature that cause mass coral bleaching and mortality (*high confidence*, Box CC-CR, Figure 30-10). As with the other STG, phytoplankton communities and pelagic fish stocks are sensitive to temperature changes that have occurred over the past several decades. Observation of these changes has enabled development of models that have a high degree of accuracy in projecting the distribution and abundance of these elements within the Atlantic region in general [*Cheung et al.*, 2011].

30.5.6.2. Key Risks and Vulnerabilities

Sea surface temperatures of the vast STG of the Atlantic, Pacific, and Indian Oceans are increasing, which is *very likely* to increase stratification of the water column. In turn, this is *likely* to reduce surface concentrations of nutrients and, consequently, primary productivity (*medium confidence*) (Box CC-PP). Warming is projected to continue (Table SM30-4), with substantial increases in the vulnerability and risk associated with systems that have been observed to change so far (*high confidence*) (Figure 30-12). Under RCP2.6, the temperatures of the STG are projected to increase by 0.17–0.56°C in the near-term (over 2010–2039) and between -0.03–0.90°C in the long-term (over 2010-2099) (Table SM30-4). Under RCP8.5, however, surface temperatures of the world's STG are projected to be 0.45–0.91°C warmer in the near-term and 1.90–3.44°C warmer in the long-term (Table SM30-4). These changes in temperature are *very likely* to increase water column stability, reduce the depth of the mixed layer, and influence key parameters such as nutrient availability and O_2 concentrations. It is not clear as to how longer-term sources of variability such as ENSO and PDO will change (WGI 14.4, 14.7.6) and ultimately influence these trends.

The world's most oligotrophic ocean sub-regions are *likely* to continue to expand over coming decades, with consequences for ecosystem services such as gas exchange, fisheries, and carbon sequestration. *Polovina et al.* [2011] explored this question for the North Pacific using a climate model that included a coupled ocean biogeochemical component to investigate potential changes under an SRES A2 scenario (~RCP6.0–8.5; Figure 1.5 [*Rogelj et al.*, 2012]). Model projections indicated the STG expanding by approximately 30% by 2100, driven by the northward drift of the mid-latitude westerlies and enhanced stratification of the water column. The expansion of the STG occurred at the expense of the equatorial upwelling and other regions within the North Pacific. In the North Pacific STG, the total primary production is projected to decrease by 10-20% and large fish catch by 19–29% by 2100 under SRES A2 [*Howell et al.*, 2013; *Woodworth-Jefcoats et al.*, 2013]. However, our understanding of how large-scale eddy systems will change in a warming world is incomplete, as are the implications for primary productivity of these large and important systems (Box CC-PP, Box CC-UP).

Understanding how storm frequency and intensity will change represents a key question for many countries and territories within the various STG. Projections of increasing sea temperature are *likely* to change the behavior of tropical cyclones. At the same time, the maximum wind speed and rainfall associated with cyclones is *likely* to increase, although future trends in cyclones and severe storms are *very likely* to vary from region to region (WGI 14.6). Patterns such as 'temporal clustering' can have a strong influence on the impact of tropical cyclones on ecosystems such as coral reefs [*Mumby et al.*, 2011], although how these patterns will change within all STG is uncertain at this point. However, an intensifying hydrological cycle is expected to increase precipitation in many areas (*high confidence* WGI 2.5, 14.2), although longer droughts are also expected in other STG (*medium* *confidence*). Changes in the hydrological cycle impact on coastal ecosystems, increasing damage through coastal flooding and physical damage from storm waves [*Mumby et al.*, 2011]. Improving our understanding of how weather systems associated with features such as the SPCZ (WGI 14.3.1) will vary is critical to climate change adaptation of a large number of nations associated with the STG. Developing an understanding of how ocean temperature, climate systems such as the SPCZ and ITCZ, and climate change and variability (e.g., ENSO, PDO) interact will be essential in this regard. For example, variability in the latitude of the SPCZ is projected to increase, possibly leading to more extreme events in Pacific island countries [*Cai et al.*, 2012].

The consequences of projected sea temperatures on the frequency of coral bleaching and mortality within key sub-regions of the STG are outlined in Box CC-CR, Figures 30.10 and Figure SM30-3. As with other sub-regions (particularly CBS, STG, and SES) dominated by coral reefs, mass coral bleaching and mortality becomes an annual risk under all scenarios, with mass mortality events beginning to occur every 1–2 years by 2100 (*virtually certain,* Box CC-CR, Figure 30-10, Figure SM30-3). Coral-dominated reef ecosystems (areas with more than 30% coral cover) are *very likely* to disappear under these circumstances by the mid part of this century [*van Hooidonk et al.*, 2013]. The loss of substantial coral communities has implications for the three-dimensional structure of coral reefs (Box CC-CR) and the role of the latter as habitat for organisms such as fish [*Hoegh-Guldberg*, 2011; *Hoegh-Guldberg et al.*, 2011a; *Pratchett et al.*, 2011a; *Bell et al.*, 2013b]. The consequences of increasing sea temperature can be exacerbated by increasing ocean acidification, with potential implications for reef calcification ([*Kleypas et al.*, 1999; *Hoegh-Guldberg et al.*, 2007; *Doney et al.*, 2009], *medium confidence*), reef metabolism and community calcification [*Dove et al.*, 2013], and other key ecological processes ([*Pörtner et al.*, 2001; *Pörtner et al.*, 2007; *Munday et al.*, 2009]. Ocean pH within the STG will continue to decrease as atmospheric CO_2 increases, bringing pH within the STG to 7.9 and 7.7 at atmospheric concentrations of 450 ppm and 800 ppm, respectively (Figure SM30-2a, Box CC-OA). Aragonite saturation states will decrease to around 1.6 (800 ppm) and 3.3 (450 ppm; Figure SM30-2b). Decreasing carbonate ion concentrations and saturation states pose serious risks to other marine calcifiers such as encrusting coralline algae, coccolithophores (phytoplankton), and a range of benthic invertebrates [*Doney et al.*, 2009; *Feely et al.*, 2009]. Increasing sea temperatures and sea level are also *likely* to influence other coastal ecosystems (e.g., mangroves, seagrass meadows) in the Pacific, although significant gaps and uncertainties exist (29.3.4 [*Waycott et al.*, 2007; *Waycott et al.*, 2011]. Many of the negative consequences for coral reefs, mangroves, and seagrass meadows are *likely* to have negative consequences for dependent coastal fisheries (through destruction of habitat) and tourism industries (*medium confidence*) ([*Bell et al.*, 2011b; *Pratchett et al.*, 2011a; *Pratchett et al.*, 2011b; *Bell et al.*, 2013a].

Populations of key large pelagic fish are projected to move many hundreds of kilometers east of where they are today in the Pacific STG (*high confidence*) [*Lehodey et al.*, 2008; *Lehodey et al.*, 2010a; *Lehodey et al.*, 2011; *Lehodey et al.*, 2013], with implications for income, industry, and food security across multiple Pacific Island nations (*high confidence*)[*Cheung et al.*, 2010; *McIlgorm et al.*, 2010; *Bell et al.*, 2011b; *Bell et al.*, 2013a], 7.4.2, Table 29.2-29.3). These predictions of species range displacements, contractions, and expansions in response to anticipated changes in the Ocean (Box CC-MB) present both a challenge and an opportunity for the development of large-scale management strategies to preserve these valuable species. Our understanding of the consequences of reduced O_2 for pelagic fish populations is not clear, although there is *high agreement* on the potential physiological outcomes (6.3.3). Those species that are intolerant to hypoxia, such as skipjack and yellowfin tuna [*Lehodey et al.*, 2011], will have their depth range compressed in the Pacific STG, which will increase their vulnerability to fisheries and reduce overall fisheries habitat and productivity (*medium confidence*) [*Stramma et al.*, 2010; *Stramma et al.*, 2011]. Despite the importance of these potential changes, our understanding of the full range of consequences is *limited* at this point.

30.5.7. Deep Sea (>1000 m)

Assessments of the influence of climate change on the Deep Sea (DS) are challenging due to difficulty of access and scarcity of long-term, comprehensive observations [*Smith et al.*, 2009]. The size of this habitat is also vast, covering well over 54% of the earth's surface and stretching from the top of the mid-oceanic ridges to the bottom of deep ocean trenches [*Smith et al.*, 2009]. The fossil record in marine sediments reveals that the DS has undergone large changes in response to climate change in the past [*Knoll and Fischer*, 2011]. The paleo-skeletal record shows it is the rate, not just the magnitude, of climate change (temperature, O_2, and CO_2) that is critical to marine life in DS. The current rate of change in key parameters *very likely* exceeds that of other major events in Earth history. Two primary time scales are of interest. The first is the slow rate (century-scale) of ocean circulation and mixing, and consequently the slow rate at which DS ecosystems experience physical climate change. The second is the rapid rate at which organic matter enters the deep ocean from primary productivity generated at surface of the Ocean, which represents a critical food supply to DS animals [*Smith and Kaufmann*, 1999; *Smith et al.*, 2009]. It can also represent a potential risk in some circumstances where the flux of organic carbon into the deep ocean, coupled with increased sea temperatures, can lead to anoxic areas (dead zones) as metabolism is increased and O_2 decreased [*Chan et al.*, 2008; *Stramma et al.*, 2010].

30.5.7.1. Observed Changes and Potential Impacts

The greatest rate of change of temperature is occurring in the upper 700 m of the Ocean (WGI 3.2, *very high confidence*), although smaller yet significant changes are occurring at depth. The DS environment is typically cold (~-0.5–3°C; [*Smith et al.*, 2008]), although abyssal temperatures in the SES can be higher (e.g., Mediterranean DS ~12°C, [*Danovaro et al.*, 2010]. In the latter case, DS organisms can thrive in these environments as well, illustrating the variety of temperature conditions that differing species of abyssal life have adapted to. Individual species, however, are typically constrained within a narrow thermal and O_2-demand window of tolerance [*Pörtner*, 2010] and therefore it is *likely* that shifts in the distribution of DS species and regional extinctions will occur. Warming over multiple decades has been observed below 700 m [*Levitus et al.*, 2005; *Levitus et al.*, 2009], with warming being minimal at mid-range depths (2000–3000 m), and increasing towards the sea floor in some sub-regions (e.g., Southern Ocean, WGI Chapter 3). For the deep Atlantic Ocean, the mean age of deep waters (mean time since last exposure to the atmosphere) is ~250 years; the oldest deep waters of the Pacific Ocean are >1000 years old. The patterns of ocean circulation are clearly revealed by the penetration of tracers and the signal of CO_2 released from burning fossil-fuel penetrating into the abyss [*Sabine et al.*, 2004]. It will take many centuries for full equilibration of deep ocean waters and their ecosystems with recent planetary warming and CO_2 levels [*Wunsch and Heimbach*, 2008].

Temperature accounts for ~86% of the variance in the export of organic matter to the DS (*medium confidence*) [*Laws et al.*, 2000]. Consequently, upper ocean warming will reduce the export of organic matter to the DS (*medium confidence*), potentially changing the distribution and abundance of DS organisms and associated food webs, and ecosystem processes [*Smith and Kaufmann*, 1999]. Most organic matter entering the DS is recycled by microbial systems at relatively shallow depths [*Buesseler et al.*, 2007], at rates that are temperature dependent. Upper ocean warming will increase the rate of sub-surface decomposition of organic matter (*high confidence)*, thus intensifying the intermediate depth oxygen minimum zones [*Stramma et al.*, 2008; *Stramma et al.*, 2010] and reducing food supply to the abyssal ocean.

Particulate organic carbon is exported from the surface to deeper layers of the Ocean (>500m) with an efficiency of between 20–50% [*Buesseler et al.*, 2007], much of it being recycled by microbes before it reaches 1000m [*Smith et al.*, 2009]. The export of organic carbon is dependent on surface net primary productivity, which is likely to vary (Box CC-PP), influencing the supply of food to DS [*Laws et al.*, 2000; *Smith et al.*, 2008]. Warming of intermediate waters will also increase respiration at mid-water depths, reducing the flux of organic carbon. Our understanding of other components of DS ecosystems is also relatively poor. For example, there is *limited evidence* and *limited agreement* as to how ocean warming and acidification are *likely* to affect ecosystems such as those associated with hydrothermal vents [*Van Dover*, 2012].

Oxygen concentrations are decreasing in the DS [*Stramma et al.*, 2008; *Helm et al.*, 2011a]. Although, the largest signals occur at intermediate water depths < 1000 m [*Nakanowatari et al.*, 2007; *Whitney et al.*, 2007; *Falkowski et al.*, 2011], some waters >1000 m depth are also experiencing a decline [*Jenkins*, 2008]. The quantity of dissolved O_2 throughout the Ocean will be reduced with warming due to direct effects on solubility (*high confidence*), with these effects being widely distributed [*Shaffer et al.*, 2009]. It is also *virtually certain* that metabolic rates of all animals and microbial respiration rates will increase with temperature [*Brown et al.*, 2004]. Thus, increased microbial activity and reduced O_2 solubility at higher temperatures will have additive consequences for the decline of O_2 (*high* *confidence*) even in the DS. The DS waters are relatively well-oxygenated due to the higher solubility of O_2 in colder waters and the low supply rate of organic matter to great depths. The availability of oxygen to marine animals is governed by a combination of concentration, temperature, pressure, and related properties such as diffusivity. Analysis by [*Hofmann et al.*, 2013] reveals that the supply potential of oxygen to marine animals in cold deep waters is similar to that at much shallower depths *(very high confidence)*.

Anthropogenic CO_2 has penetrated to at least 1000 m in all three ocean basins (particularly the Atlantic; [*Doney et al.*, 2009]. Further declines of calcite and aragonite in already under-saturated DS water will presumably decrease biological carbonate structure formation and increase dissolution, as has happened many times in Earth's past (*high confidence*) [*Zeebe and Ridgwell*, 2011]. Some cold-water corals (reported down to 3500m) already exist in waters under-saturated with respect to aragonite [*Lundsten et al.*, 2009]. While initial investigations suggested that ocean acidification (reduced by 0.15 and 0.30 pH units) would result in a reduction in the calcification rate of deep water corals (30% and 6%, respectively [*Maier et al.*, 2009]), there is accumulating evidence that ocean acidification may have far less impact than previously anticipated on the calcification of some deep water corals (*limited evidence, medium agreement, low confidence*) although it may reduce important habitats given that dead unprotected coral mounds are *likely* to dissolve in under-saturated waters [*Thresher et al.*, 2011; *Form and Riebesell*, 2012; *Maier et al.*, 2013].

30.5.7.2. Key Risks and Vulnerabilities

Rising atmospheric CO_2 poses a risk to DS communities through increasing temperature, and decreasing O_2, carbonate chemistry and pH (*high confidence*) [*Keeling et al.*, 2010]. Risks associated with the DS have implications for the Ocean and planet given the high degree of inherent dependency and connectivity. The resulting changes to the flow of organic carbon to some parts of the DS (e.g., STG) are *very likely* to affect DS ecosystems (*medium confidence*) [*Smith et al.*, 2008]. As with the Ocean generally, there is a need to fill in the substantial gaps that exist in our knowledge and understanding of the world's largest habitat and its responses to rapid anthropogenic climate change.

30.5.8. Detection and Attribution of Climate Change Impacts with Confidence Levels

The analysis in Chapter 30 and elsewhere in AR5 has identified a wide range of physical, chemical, and ecological components that have changed over the last century (Box CC-MB). Figure 30-11 summarizes a number of examples from the Ocean as a region together with the degree of confidence in both the detection and attribution steps. For ocean warming and acidification, confidence is *very high* that changes are being detected and that they are due to changes to the atmospheric greenhouse gas content. There is considerable confidence in both the detection (*very high confidence*) and attribution (*high confidence*) of mass coral bleaching and mortality (Figure 30-11b), given the well-developed understanding of environmental processes and physiological responses driving these events (Box CC-CR, 6.3.1). For other changes, confidence is lower, either because detection of changes has been difficult, or monitoring programs are not long-established (e.g., field evidence of declining calcification) or because detection has been possible but models are in conflict (e.g., wind-driven upwelling). The detection and attribution of recent changes is discussed in further detail in (18.3.3–4).

[INSERT FIGURE 30-11 HERE
Figure 30-11: Expert assessment of degree of confidence in detection and attribution of physical and chemical changes (a) and ecological changes (b) across sub-regions, as designated in Figure 30-1a, and processes in the Ocean (based on evidence explored throughout Chapter 30 and elsewhere in AR5). Further explanation of this figure is given in 18.3.3–4 and 18.6.]

30.6. Sectorial Impacts, Adaptation, and Mitigation Responses

Human welfare is highly dependent on ecosystem services provided by the Ocean. Many of these services are provided by coastal and shelf areas, and are consequently addressed in other chapters (e.g., 5.4.3, 7.3.2.4, 22.3.2.3) Oceans contribute provisioning (e.g., food, raw materials; see 30.6.4.1), regulating (e.g., gas exchange, nutrient recycling, carbon storage, climate regulation, water flux), supporting (e.g., habitat, genetic diversity) and cultural (e.g., recreational, cultural) services [*Millennium-Ecosystem-Assessment*, 2005; *Tallis et al.*, 2013]. The accumulating evidence indicating that fundamental ecosystem services within the Ocean are shifting rapidly should be of major concern, especially with respect to the ability of regulating and supporting ecosystem services to underpin current and future human population demands [*Rockström et al.*, 2009; *Ruckelshaus et al.*, 2013].

Discussion here is restricted to environmental, economic, and social sectors that have direct relevance to the Ocean, namely natural ecosystems, fisheries and aquaculture, tourism, shipping, oil and gas, human health, maritime security, and renewable energy. The influences of climate change on Ocean sectors will be mediated through simultaneous changes in multiple environmental and ecological variables (Figure 30-12), and the extent to which changes can be adapted to and/or risks mitigated (Table 30-3). Both short-term and longer-term adaptation is necessary to address impacts arising from warming, even under the lowest stabilization scenarios assessed.

[INSERT FIGURE 30-12 HERE
Figure 30-12: (a) Examples of projected impacts and vulnerabilities associated with climate change in Ocean sub-regions. (b) Examples of risks to fisheries from observed and projected impacts across Ocean sub-regions. Letters indicate level of confidence: (vL): Very low, (L): Low, (M): Medium, (H): High and (vH): Very high. Details of sub-regions are given in Table 30-1a and 30.1.1.

Sectorial approaches dominate resource management in the Ocean (e.g., shipping tends to be treated in isolation from fishing within an area), yet cumulative and interactive effects of individual stressors are known to be ubiquitous and substantial [*Crain et al.*, 2008]. Climate change consistently emerges as a dominant stressor in regional to global-scale assessments, although land-based pollution, commercial fishing, invasive species, coastal habitat modification, and commercial activities such as shipping all rank high in many places around the world (e.g., 30.5.3, 30.5.4, 5.3.4) [*Halpern et al.*, 2009; *Halpern et al.*, 2010]. Such cumulative effects pose challenges to managing for the full suite of stressors to marine systems, but also present opportunities where mitigating a few key stressors can potentially improve overall ecosystem condition (e.g., [*Halpern et al.*, 2010; *Kelly et al.*, 2011]. The latter has often been seen as a potential strategy for reducing negative consequences of climate impacts on marine ecosystems by boosting ecosystem resilience, thus buying time while the core issue of reducing greenhouse gas emissions is tackled [*West et al.*, 2009].

30.6.1. Natural Ecosystems

Adaptation in natural ecosystems may occur autonomously, such as shifts in species' composition and distributions [*Poloczanska et al.*, 2013] or engineered by human intervention, such as assisted dispersal (4.4, [*Hoegh-Guldberg et al.*, 2008]. Currently, adaptation strategies for marine ecosystems included reducing additional stressors (e.g. maintaining water quality, adapting fisheries management) and maintaining resilience ecosystems (e.g., Marine Protected Areas) and are moving towards whole-of-ecosystem management approaches. Coral reefs, for example, will recover faster from mass coral bleaching and mortality if healthy populations of herbivorous fish are maintained (*medium confidence*, [*Hughes et al.*, 2003], indicating that reducing overfishing will help maintain coral-dominated reef systems while the international community reduces the emissions of greenhouse gases to stabilize global temperature and ocean chemistry.

Approaches such as providing a formal valuation of ecological services from the Ocean have the potential to facilitate adaptation by underpinning more effective governance, regulation, and ocean policy while at the same time potentially improving the management of these often vulnerable services through the development of market mechanisms and incentives [*Beaudoin and Pendleton*, 2012]. Supporting, regulating, and cultural ecosystem services tend to transcend the immediate demands placed on provisioning services and are difficult to value in formal economic terms due to their complexity, problems such as double counting, and the value of non-market goods and services arising from marine ecosystems generally [*Fu et al.*, 2011; *Beaudoin and Pendleton*, 2012].

'Blue Carbon' is defined as the organic carbon sequestered by marine ecosystems such as phytoplankton, mangrove, seagrass, and salt marsh ecosystems [*Laffoley and Grimsditch*, 2009; *Nellemann and Corcoran*, 2009]. In this respect, Blue Carbon will provide opportunities for both adaptation to, and mitigation of, climate change if key uncertainties in inventories, methodologies, and policies for measuring, valuing, and implementing Blue Carbon strategies are resolved [*McLeod et al.*, 2011]. Sediment surface levels in vegetated coastal habitats can rise several meters over thousands of years, building carbon-rich deposits [*Brevik and Homburg*, 2004; *Lo Iacono et al.*, 2008]. The degradation of coastal habitats not only liberates much of the carbon associated with vegetation loss, but can release and oxidize buried organic carbon through erosion of cleared coastlines (*high confidence*) [*Duarte et al.*, 2005]. Combining data on global area, land-use conversion rates, and near-surface carbon stocks for marshes, mangroves, and seagrass meadows, *Pendleton et al.* [2012] revealed that the CO_2 emissions arising from destruction of these three ecosystems was equivalent to 3–19% of the emissions generated by deforestation globally, with economic damages estimated to be US$6–42 billion annually. Similarly, *Luisetti et al.* [2013] estimate the carbon stock of seagrass and salt marshes in Europe, representing <4% of global carbon stocks in coastal vegetation, was valued at US$180 million, at EU Allowance price of €8/tCO_2 in June 2012. A reversal of EU Environmental Protection Directives could result in economic losses of US$1 billion by 2060. Blue Carbon strategies can also be justified in light of the numerous ecosystem services these ecosystems provide, such as protection against coastal erosion and storm damage, and provision of habitats for fisheries species (17.4).

30.6.2. Economic Sectors

30.6.2.1. Fisheries and Aquaculture

The Ocean provided 64% of the production (in tonnes) supplied by world fisheries (capture and aquaculture) in 2010, amounting to 148.5 million tonnes of fish and shellfish [*FAO*, 2012]. This production, valued at US$217.5 billion, and supplied, on average, 18.6 kg of protein-rich food per person to an estimated population of 6.9 billion [*FAO*, 2012]. Marine capture fisheries supplied 77.4 million tonnes with highest production from the northwest Pacific (27%), west-central Pacific (15%), northeast Atlantic (11%) and southeast Pacific (10%)[*FAO*, 2012]. World aquaculture production (59.9 million tonnes in 2010) is dominated by freshwater fishes, nevertheless marine aquaculture supplied 18.1 million tonnes (30%)[*FAO*, 2012].

Marine capture fisheries production increased from 16.8 million tonnes in 1950 to a peak of 86.4 million tonnes in 1996, then declined before stabilising around 80 million tonnes [*FAO*, 2012]. The stagnation of marine capture fisheries production is attributed to full exploitation of around 60% of the world's marine fisheries and overexploitation of 30% (estimates for 2009) [*FAO*, 2012]. Major issues for industrial fisheries include illegal, unreported and unregulated fishing, ineffective implementation of monitoring, control and surveillance, and overcapacity in fishing fleets [*Bank and FAO*, 2008; *FAO*, 2012]. Such problems are being progressively addressed in several developed and developing countries [*Hilborn*, 2007; *Pitcher et al.*, 2009; *Worm et al.*, 2009], where investments have been made in stock assessment, strong management, and application of the FAO Code of Conduct for Responsible Fisheries and the FAO Ecosystem Approach to Fisheries Management.

The significance of marine capture fisheries is illustrated powerfully by the number of people engaged in marine small-scale fisheries (SSF) in developing countries. SSF account for around half of the fish harvested from the Ocean, and provide jobs for more than 47 million people – about 12.5 million fishers and another 34.5 million people engaged in post-harvest activities [*Mills et al.*, 2011]. SSF are often characterized by large numbers of politically-weak fishers operating from decentralized localities, with poor governance, and insufficient data to monitor catches effectively [*Kurien and Willmann*, 2009; *Cochrane et al.*, 2011; *Pomeroy and Andrew*, 2011]. For these SSF, management that aims to avoid further depletion of overfished stocks may be more appropriate in the short-term than management aimed at maximizing sustainable production. These aims are achieved through adaptive management by: (1) introduction of harvest controls (e.g., size limits, closed seasons and areas, gear restrictions, and protection of spawning aggregations) to avoid irreversible damage to stocks in the face of uncertainty [*Cochrane et* *al.*, 2011]; (2) flexible modification of these controls through monitoring [*Plagányi et al.*, 2013]; and (3) investing in the social capital and institutions needed for communities and governments to manage SSF [*Makino et al.*, 2009; *Pomeroy and Andrew*, 2011].

Changes to ocean temperature, chemistry, and other factors are generating new challenges for fisheries resulting in loss of coastal and oceanic habitat [*Hazen et al.*, 2012; *Stramma et al.*, 2012], the movement of species [*Cheung et al.*, 2011], the spread and increase of disease and invading species [*Ling*, 2008; *Raitsos et al.*, 2010; *Chan et al.*, 2011], and changes in primary production[*Chassot et al.*, 2010]. There is *medium evidence* and *medium agreement* that these changes will change both the nature of fisheries and their ability to provide food and protein for hundreds of millions of people (7.2.1.2). The risks to ecosystems and fisheries vary from region to region (7.3.2.4). Dynamic bioclimatic envelope models under SRES A1B project potential increases in fisheries production high latitudes, and potential decreases at lower latitudes by the mid-21st century [*Cheung et al.*, 2010] (6.5). Overall, warming temperatures are projected to shift optimal environments for individual species polewards and redistribute production, however changes will be region specific [*Cheung et al.*, 2010; *Merino et al.*, 2012].

Fisheries, in particular shellfish, are also vulnerable to declining pH and carbonate ion concentrations. As a result, the global production of shellfish fisheries is *likely* to decrease, [*Cooley and Doney*, 2009; *Pickering et al.*, 2011]) with further ocean acidification (*medium confidence*) (6.3.2, 6.3.5, 6.4.1.1, Box CC-OA). Impacts may be first observed in EBUE where upwelled water is already relatively low in O_2 and undersaturated with aragonite (30.5.5). Seasonal upwelling of acidified waters onto the continental shelf in the California Current region, has recently affected oyster hatcheries along the coast of Washington and Oregon (30.5.5.1.1[*Barton et al.*, 2012]). Whether declining pH and aragonite saturation due to climate change played a role is unclear, however future declines will increase the risk of such events occurring.

Most marine aquaculture species are sensitive to changing ocean temperature (6.3.1.4, exposed through pens, cages and racks placed directly in the sea, utilization of seawater in land-based tanks or collection of wild spat) and, for mollusks particularly, changes in carbonate chemistry (6.3.2.4 [*Turley et al.*, 2011; *Barton et al.*, 2012]). Environmental changes can therefore impact farm profitability, depending on target species and farm location. For example, a 1°C rise in SST is projected to shift production of Norwegian salmonids further north but may increase production overall [*Hermansen and Heen*, 2012]. Industries for non-food products, which can be important for regional livelihoods such as Black Pearl in Polynesia, are also affected by rising SST. Higher temperatures are known to affect the quality of pearl nacre, and can increase levels of disease in adult oysters [*Bell et al.*, 2011a; *Pickering et al.*, 2011; *Bell et al.*, 2013b]. Aquaculture production is also vulnerable to extreme events such as storms and floods (e.g., [*Chang et al.*, 2013]). Flooding and inundation by seawater may be a problem to shore facilities on low-lying coasts. For example, shrimp farming operations in the tropics will be challenged by rising sea levels, which will be exacerbated by mangrove encroachment and reduce the ability for thorough-drying of ponds between crops [*Della Patrona et al.*, 2011].

The impacts of climate change on marine fish stocks are expected to affect the economics of fishing and livelihoods in fishing nations through changes in the price and value of catches, fishing costs, income to fishers and fishing companies, national labor markets, and industry re-organization [*Sumaila et al.*, 2011] (6.4.1). A study of the potential vulnerabilities of national economies to the effects of climate change on fisheries, in terms of exposure to warming, relative importance of fisheries to national economies and diets, and limited societal capacity to adapt, concluded that a number countries including Malawi, Guinea, Senegal, Uganda, Sierra Leone, Mozambique, Tanzania, Peru, Columbia, Venezuela, Mauritania, Morocco, Bangladesh, Cambodia, Pakistan, Yemen, and Ukraine are most vulnerable [*Allison et al.*, 2009].

Aquaculture production is expanding rapidly [*Bostock et al.*, 2010] and will play an important role in food production and livelihoods as the human demand for protein grows. This may also add pressure on capture fisheries (7.3.2.6) [*FAO*, 2012; *Merino et al.*, 2012]. Two-thirds of farmed food fish production (marine and freshwater) is achieved with the use of feed derived from wild-harvested, small, pelagic fish and shellfish. Fluctuations in the availability and price of fishmeal and fish oil for feeds, as well as their availability, pose challenges for the growth of sustainable aquaculture production, particularly given uncertainties in changes in EBUE upwelling dynamics to climate change (30.5.5). Technological advances and management change such as increasing feed efficiencies, using alternatives to fishmeal and fish oil, and farming of herbivorous finfish, coupled with economic and regulatory incentives will reduce the vulnerability of aquaculture to the impacts of climate change on small, pelagic fish abundance [*Naylor et al.*, 2009; *Merino et al.*, 2010; *FAO*, 2012].

The challenges of optimizing the economic and social benefits of both industrial fisheries, SSF and aquaculture operations, which often already include strategies to adapt to climatic variability [*Salinger et al*., 2013], are now made more complex by climate change [*Cochrane et al*., 2009; *Brander*, 2010; 2013]. Nevertheless, adaptation options include establishment of early-warning systems to aid decision-making, diversification of enterprises and development of adaptable management systems [*Chang et al.*, 2013]. Vulnerability assessments that link oceanographic, biological, and socio-economic systems can be applied to identify practical adaptations to assist enterprises, communities, and households to reduce the risks from climate change and capitalize on the opportunists [*Pecl et al.*, 2009; *Bell et al.*, 2013b; *Norman-López et al.*, 2013]. The diversity of these adaptation options, and the policies needed to support them, are illustrated by the following examples.

30.6.2.1.1. Tropical fisheries based on large pelagic fish

Fisheries for skipjack, yellowfin, big-eye, and albacore tuna provide substantial economic and social benefits to the people of Small Island Developing States (SIDS). For example, tuna fishing license fees contribute substantially (up to 40%) to the government revenue of several Pacific Island nations [*Gillett*, 2009; *Bell et al.*, 2013b]. Tuna fishing and processing operations also contribute up to 25% of gross domestic product in some of these nations and employ over 12,000 people [*Gillett*, 2009; *Bell et al.*, 2013b]. Considerable economic benefits are also derived from fisheries for top pelagic predators in the Indian and Atlantic Oceans [*FAO*, 2012; *Bell et al.*, 2013a]. Increasing sea temperatures and changing patterns of upwelling are projected to cause shifts in the distribution and abundance of pelagic top predator fish stocks (30.5.2, 30.5.5, 30.5.6), with potential to create ‘winners’ and ‘losers’ among island economies as catches of the trans-boundary tuna stocks change among and within their exclusive economic zones (EEZs;[*Bell et al.*, 2013b; *Bell et al.*, 2013a].

A number of practical adaptation options and supporting policies have been identified to minimize the risks and maximize the opportunities associated with the projected changes in distribution of the abundant skipjack tuna in the tropical Pacific ([*Bell et al.*, 2011; *Bell et al*., 2013a], Table 30-2). These adaptation and policy options include: (1) full implementation of the regional ‘vessel day scheme’, designed to distribute the economic benefits from the resource in the face of climatic variability, and other schemes to control fishing effort in subtropical areas; (2) strategies for diversifying the supply of fish for canneries in the west of the region as tuna move progressively east; (3) continued effective fisheries management of all tuna species; (4) energy efficiency programs to assist domestic fleets to cope with increasing fuel costs and the possible need to fish further from port; and (5) the eventual restructuring of regional fisheries management organizations to help coordinate management measures across the entire tropical Pacific. Provision of operational-level catch and effort data from all industrial fishing operations to improve models for projecting redistribution of tuna stocks and quotas under climate change [*Salinger et al*. 2013][*Nicol et al.*, 2013]. Similar adaptation options and policy responses are expected to be relevant to the challenges faced by tuna fisheries in the tropical and sub-tropical Indian and Atlantic Oceans.

[INSERT TABLE 30-2 HERE
Table 30-2: Examples of priority adaptation options and supporting policies to assist Pacific Island countries and territories to minimize the threats of climate change to the socio-economic benefits derived from pelagic and coastal fisheries and aquaculture, and to maximize the opportunities. These measures are classified as ‘win-win’ (W-W) adaptations, which address other drivers of the sector in the short-term and climate change in the long-term, or ‘lose-win’ (L-W) adaptations, where benefits exceed costs in the short-term but accrue under longer-term climate change (modified from [*Bell et al.*, 2013b]).

30.6.2.1.2. Small-scale fisheries

Small-scale fisheries (SSF) account for 56% of catch and 91% of people working in fisheries in developing countries [*Mills et al.*, 2011]. SSF are fisheries that tend to operate at family or community level, have low levels of capitalization, and make an important contribution to food security and livelihoods. They are often dependent on coastal ecosystems, such as coral reefs, that provide habitats for a wide range of harvested fish and invertebrate species. Despite their importance to many developing countries, such ecosystems are under serious pressure from human activities including deteriorating coastal water quality, sedimentation, ocean warming, overfishing, and acidification (7.2.1.2, 30.3, 30.5, Box CC-CR). These pressures are translating into a steady decline in live coral cover, which is *very likely* to continue over the coming decades, even where integrated coastal zone management is in place (30.5.4, 30.5.6. For example, coral losses around Pacific Islands are projected to be as high as 75% by 2050 [*Hoegh-Guldberg et al.*, 2011a]. Even under the most optimistic projections (a 50% loss of coral by 2050), changes to state of coral reefs (Box CC-CR, Figure 30-10, Figure 30-12) are *very likely* to reduce the availability of associated fish and invertebrates that support many of the SSF in the tropics (*high confidence*). In the Pacific, the productivity of SSF on coral reefs has been projected to decrease by at least 20% by 2050 [*Pratchett et al.*, 2011b], which is also *likely* to occur in other coral reef areas globally given the similar and growing stresses in these other regions (Table SM30-1, 30.5.4).

Adaptation options and policies for building the resilience of coral reef fisheries to climate change suggested for the tropical Pacific include: (1) strengthening the management of catchment vegetation to improve water quality along coastlines; (2) reducing direct damage to coral reefs; (3) maintaining connectivity of coral reefs with mangrove and seagrass habitats; (4) sustaining and diversifying the catch of coral reef fish to maintain their replenishment potential; and (5) transferring fishing effort from coral reefs to skipjack and yellowfin tuna resources by installing anchored fish-aggregating devices (FADs) close to shore [*Bell et al.*, 2011b; *Bell et al.*, 2013b; *Bell et al.*, 2013a], Table 30-2). These adaptation options and policies represent a ‘no regrets’ strategy in that they provide benefits for coral reef fisheries and fishers irrespective of climate change and ocean acidification.

30.6.2.1.3. Northern Hemisphere HLSBS fisheries

The high latitude fisheries in the northern hemisphere span from around 30/35°N to 60°N in the North Pacific and 80°N in the North Atlantic, covering a wide range of thermal habitats supporting subtropical/temperate species to boreal/arctic species. The characteristics of these HLSBS environments, as well as warming trends, are outlined in 30.5.1 and Table 30-1. In part, as a result of 30 years of increase in temperature [*Belkin*, 2009; *Sherman et al.*, 2009], there has been an increase in the size of fish stocks associated with high latitude fisheries in the northern hemisphere. This is particularly the case for the Norwegian spring-spawning herring, which has recovered from near-extinction as a result of overfishing and a cooler climate during the 1960s [*Toresen and Østvedt*, 2000]. The major components of both pelagic and demersal high latitude fish stocks are boreal species located north of 50°N. Climate change is projected to increase high latitude plankton production and displace zooplankton and fish species poleward. As a combined result of these future changes, the abundance of fish (particularly boreal species) may increase in the northernmost part of the high latitude region [*Cheung et al.*, 2011], although increases will only be moderate in some areas.

The changes in distribution and migration of the pelagic fishes shows considerable spatial and temporal variability, which can increase tensions among fishing nations. In this regard, tension over the Atlantic mackerel fisheries has led to what many consider the first climate-change related conflict between fishing nations ([*Cheung et al.*, 2012], 30.6.5), and which has emphasized the importance of developing international collaboration and frameworks for decision making [*Miller et al.*, 2013](30.6.7, 15.4.3.3). The Atlantic mackerel has over the recent decades been a shared stock between the EU and Norway. However, the recent advancement of the Atlantic mackerel into the Icelandic EEZ during summer has resulted in Icelandic fishers operating outside the agreement between the EU and Norway. Earlier records of mackerel from the first half of the 20th and second half of the 19th century show, however, that mackerel was present in Icelandic waters during the earlier warm periods [*Astthorsson et al.*, 2012]. In the Barents Sea, the North-east Arctic cod, *Gadus morhua*, reached record-high abundance during 2012 and also reached its northernmost-recorded distribution (82°N)[*ICES*, 2012]. A further northward migration is impossible since this would be into the Deep Sea Polar Basin, beyond the habitat of shelf species. A further advancement eastwards to the Siberian shelf is, however, possible. The North-east Arctic cod stock is shared exclusively by Norway and Russia, and to date there has been a good agreement between those two nations on the management of the stock. These examples highlight the importance of international agreements and cooperation (Table 30-4).

The HLSBS fisheries constitute a large-scale high-tech industry, with large investments in highly mobile fishing vessels, equipment, and land-based industries with capacity for adapting fisheries management and industries for climate change [*Frontiers-Economics-Ltd*, 2013]. Knowledge of how climate fluctuations and change affect the growth, recruitment, and distribution of fish stocks is presently not incorporated into fisheries management strategies [*Perry et al.*, 2010]. These strategies are vital for fisheries that hope to cope with the challenges of a changing ocean environment, and are centrally important to any attempt to develop ecosystem-based management and sustainable fisheries under climate change. The large pelagic stocks, with their climate-dependent migration pattern, are shared among several nations. Developing equitable sharing of fish quotas through international treaties (Table 30-4) is a necessary adaptation for a sustainable fishery. Factors presently taken into account in determining the shares of quotas are the historical fishery, bilateral exchanges of quotas for various species, and occupation time of the stocks in the various EEZs.

30.6.2.2. Tourism

Tourism recreation represents one of the world's largest industries, accounting for 9% (>US$6 trillion) of global GDP and employing over 255 million people. It is expected to grow by an average of 4% annually and reach 10% of global GDP within the next 10 years [*WTTC*, 2012]. As with all tourism, that which is associated with the Ocean is heavily influenced by climate change, global economic and socio-political conditions, and their interactions ([*Scott et al.*, 2012b]; 10.6.1). Climate change, through impacts on ecosystems (e.g., coral reef bleaching), can reduce the appeal of destinations, increase operating costs, and/or increase uncertainty in a highly sensitive business environment [*Scott et al.*, 2012b].

Several facets of the influence of climate change on the Ocean directly impact tourism (10.6.1, 10.6.2). Tourism is susceptible to extreme events such as violent storms, long periods of drought, and/or extreme precipitation events (5.3.3, 10.6.1, [*IPCC*, 2012]). Sea level rise through its influence on coastal erosion and submergence, salinization of water supplies, and changes to storm surge, increases the vulnerability of coastal tourism infrastructure, tourist safety, and iconic ecosystems (*high confidence*) (5.3.3.2 10.6.1, [*IPCC*, 2012], Table SPM.1). For example, approximately 29% of resorts in the Caribbean are within 1 m of the high tide mark and 60% are at risk of beach erosion from rapid sea level rise [*Scott et al.*, 2012a].

Increasing sea temperatures (30.3.1.1) can change the attractiveness of locations and the opportunities for tourism through their influence on the movement of organisms and the state of ecosystems such as coral reefs (10.6.2, Box CC-CR, [*UNWTO and UNEP*, 2008]). Mass coral bleaching and mortality (triggered by elevated sea temperatures, *high confidence*) can decrease the appeal of destinations for diving-related tourism, although the level of awareness of tourists of impacts (e.g., <50% of tourists were concerned about coral bleaching during 1998) and expected economic impacts have been found to be uncertain [*Scott et al.*, 2012b]. Some studies, however, have noted reduced tourist satisfaction and identified 'dead coral' as one of the reasons for disappointment at the end of the holiday [*Westmacott et al.*, 2001]. Tourists respond to changes in factors such as weather and opportunity by expressing different preferences. For example, preferred conditions and hence tourism are projected to shift towards higher latitudes with climate change, or from summer to cooler seasons [*Amelung et al.*, 2007] (10.6.2).

Options for adaptation by the marine tourism sector include: (1) identifying and responding to inundation risks with current infrastructure, and planning for projected sea level rise when building new tourism infrastructure (5.5, [*Scott et al.*, 2012a]); (2) promoting shoreline stability and natural barriers by preserving ecosystems such as mangroves, salt marshes and coral reefs (5.5, [*Scott et al.*, 2012b]); (3) deploying forecasting and early-warning systems in order to anticipate challenges to tourism and natural ecosystems [*Strong et al.*, 2011; *IPCC*, 2012]; (4) preparation of risk management and disaster preparation plans in order to respond to extreme events; (5) reducing the effect of other stressors on ecosystems and building resilience in iconic tourism features such as coral reefs and mangroves; and (6) educating tourists to improve understanding the negative consequences of climate change over those stemming from local stresses [*Scott et al.*, 2012b; *Scott et al.*, 2012a]. Adaptation plans for tourism industries need to address specific operators and regions. For example, some operators may have costly infrastructure at risk while others may have few assets but are dependent on the integrity of natural environments [*Turton et al.*, 2010].

30.6.2.3. Shipping

International shipping accounts for >80% of world trade by volume [*UNCTAD*, 2009a; b] and ~3% of global CO_2 emissions from fuel combustion although CO_2 emissions are expected to increase 2-3 fold by 2050 [*Heitmann and Khalilian*, 2010], WGIII 8.1, 8.2). Changes in shipping routes [*Borgerson*, 2008], variation in the transport network due to shifts in grain production and global markets, as well as new fuel and weather-monitoring technology, may alter these emission patterns (WGIII 8.3, 8.5). Extreme weather events, intensified by climate change, may interrupt ports and transport routes more frequently, damaging infrastructure and introducing additional dangers to ships, crews, and the environment [*UNCTAD*, 2009a; b; *Pinnegar et al.*, 2012](10.4.4). These issues have been assessed by some countries which have raised concerns over the potential for costly delays and cancellation of services, and the implications for insurance premiums as storminess and other factors change increase risks [*Thornes et al.*, 2012].

Climate change may benefit maritime transport by reducing Arctic sea ice and consequently shorten travel distances between key ports [*Borgerson*, 2008] thus also decreasing total GHG emissions from ships (WGIII 8.5.2). Currently, reliability of this route limits its use [*Schøyen and Bråthen*, 2011], and the potential full operation of the Northwest Passage and Northern Sea Route would require a transit management regime, regulation (e.g., navigation, environmental, safety, and security), and a clear legal framework to address potential territorial claims that may arise, with a number of countries having direct interest in the Arctic. Further discussion of issues around melting Arctic sea ice and the Northern Sea Route are given in Chapter 28 (28.2.5, 28.3.4).

30.6.2.4. Offshore Energy and Mineral Resource Extraction and Supply

The marine oil and gas industry face potential impacts from climate change on its ocean-based activities. Over 100 oil and gas platforms were destroyed in the Gulf of Mexico by the unusually strong hurricanes Katrina and Rita in 2005. Other consequences for oil pipelines and production facilities ultimately reduced US refining capacity by 20% [*IPCC*, 2012]. The increasing demand for oil and gas has pushed operations to waters 2000 m deep or more, far beyond continental shelves. The very large-scale moored developments required are exposed to greater hazards and higher risks, most of which are not well understood by existing climate/weather projections. Although there is a strong trend towards seafloor well completions with a complex of wells, manifolds, and pipes that are not exposed to surface forcing, these systems face different hazards from instability and scouring of the unconsolidated sediments by DS currents [*Randolph et al.*, 2010]. The influence of warming oceans on sea floor stability is widely debated due largely to uncertainties about the effects of methane and methane hydrates [*Sultan et al.*, 2004; *Archer et al.*, 2009; *Geresi et al.*, 2009]. Declining sea ice is also opening up the Arctic to further oil and gas extraction., Discussion of the potential expansion of oil and mineral production in the Arctic is made in Chapter 28 (28.2.5, 28.2.6, 28.3.4).

The principal threat to oil and gas extraction and infrastructure in maritime settings is the impact of extreme weather [*Kessler et al.*, 2011], which is *likely* to increase given that future storm systems are expected to have greater energy [*Emanuel*, 2005; *Trenberth and Shea*, 2006; *Knutson et al.*, 2010]. Events such as Hurricane Katrina have illustrated challenges which will arise for this industry with projected increases in storm intensity [*Cruz and Krausmann*, 2008]. In this regard, early warning systems and integrated planning offer some potential to reduce the effect of extreme events [*IPCC*, 2012].

30.6.3. Human Health

The major threats to public health due to climate change include diminished security of water and food supplies, extreme weather events, and changes in the distribution and severity of diseases, including those due to marine biotoxins ([*Costello et al.*, 2009], 5.4.3.5, 6.4.2.3, 11.2). The predominately negative impacts of disease for human communities are expected to be more serious in low-income areas such as South-east Asia, southern and east Africa, and various sub-regions of South America [*Patz et al.*, 2005], which also have under-resourced health systems [*Costello et al.*, 2009]. Many of the influences are directly or indirectly related to basin-scale changes in the Ocean (e.g., temperature, rainfall, plankton populations, sea level rise, and ocean circulation [*McMichael et al.*, 2006]). Climate change in the Ocean may influence the distribution of diseases like cholera (11.5.2.1), and the distribution and occurrence of harmful algal blooms (HAB). The frequency of cholera outbreaks induced by *Vibrio cholerae* and other enteric pathogens are correlated with sea surface temperatures, multidecadal fluctuations of ENSO, and plankton blooms, which may provide insight into how this disease may change with projected rates of ocean warming [*Colwell*, 1996; *Pascual et al.*, 2000; *Rodó et al.*, 2002; *Patz et al.*, 2005; *Myers and Patz*, 2009; *Baker-Austin et al.*, 2012]. The incidence of diseases such as ciguatera also shows a link to ENSO, with ciguatera becoming more prominent after periods of elevated sea temperature. This indicates that ciguatera may become more frequent in a warmer climate [*Llewellyn*, 2010], particularly given the higher prevalence of ciguatera in areas with degraded coral reefs (*low confidence*) [*Pratchett et al.*, 2011a].

30.6.4. Ocean-based Mitigation

30.6.4.1 Deep Sea Carbon Sequestration

Carbon dioxide capture and storage into the deep sea and geologic structures are also discussed in WGIII Chapter 7 (7.5.5, 7.8.2, 7.10, 7.12) The economic impact of deliberate CO_2 sequestration beneath the sea floor has previously been reviewed [*IPCC*, 2005]. Active CO_2 sequestration from co-produced CO_2 into sub-sea geologic formations is being instigated in the North Sea and in the Santos Basin offshore from Brazil. These activities will increase as offshore oil and gas production increasingly exploits fields with high CO_2 in the source gas and oil. Significant risks from the injection of high levels of CO_2 into deep ocean waters have been identified for DS organisms and ecosystems although chronic effects have not yet been studied. These risks are similar to those discussed previously with respect to ocean acidification and could further exacerbate declining O_2 levels and changing trophic networks in deep water areas [*Seibel and Walsh,* 2001] (6.4.2.2).

There are significant issues within the decision frameworks regulating these activities. Dumping of any waste or other matter in the sea, including the seabed and its subsoil, is strictly prohibited under the 1996 London Protocol (LP) except for those few materials listed in Annex I. Annex 1 was amended in 2006 to permit storage of CO_2 under the seabed. “Specific Guidelines for Assessment of Carbon Dioxide Streams for Disposal into Sub-Seabed Geological Formations” were adopted by the parties to the LP in 2007. The Guidelines take a precautionary approach to the process, requiring Contracting Parties under whose jurisdiction or control such activities are conducted to issue a permit for the disposal subject to stringent conditions being fulfilled [*Rayfuse and Warner*, 2012].

30.6.4.2 Offshore renewable energy

Renewable energy supply from the Ocean includes ocean energy and offshore wind turbines. The global technical potential for ocean and wind energy is not as high as solar energy although considerable potential still remains. Detailed discussion of the potential of renewable energy sources are given in WGIII Chapter 7 (7.4.2, 7.5.3, 7.8.2). There is an increasing trend in the renewable energy sector to offshore wind turbines (10.2.2). At present, there is *high uncertainty* about how changes in wind intensity and patterns, and extreme events, will impact the offshore wind energy sector. Given the design and engineering solutions available to combat climate change impacts (Table 10.1, Table 10.7), it is *unlikely* that this sector will face insurmountable challenges from climate change.

30.6.5. Maritime Security and Related Operations

Climate change and its influence on the Ocean has become an area of increasing concern in terms of the maintenance of national security and the protection of citizens. These concerns have arisen as Nation States increasingly engage in operations ranging from humanitarian assistance in climate-related disasters to territorial issues exacerbated by changing coastlines, human communities, resource access, and new seaways [*Kaye*, 2012; *Rahman*, 2012], 12.6.1). In this regard, increasing sea levels along gently sloping coastlines can have the seemingly perverse outcome that the territorial limits to the maritime jurisdiction of the State might be open to question as the distance from national baselines to the outer limits of the EEZ increases beyond 200 nm over time [*Schofield and Arsana*, 2012].

Changes in coastal resources may also be coupled with decreasing food security to compound coastal poverty and lead, in some cases, to increased criminal activities such as piracy, IUU fishing, and human, arms and drug trafficking [*Kaye*, 2012]. While the linkages have not been clearly defined in all cases, it is possible that changes in the Ocean as result of climate change will increase pressure on resources aimed at maintaining maritime security and countering criminal activity, disaster relief operations, and freedom of navigation (12.6.2). National maritime security capacity and infrastructure may also require rethinking as new challenges present themselves as a result of climate change and ocean acidification (12.6.1-2) [*Allen and Bergin*, 2009; *Rahman*, 2012]. Opportunities may also arise from changes to international geography such as formation of new ice-free seaways through the Arctic, which may benefit some countries in terms of maintaining maritime security and access (28.2.6). Conversely, such new features may also lead to increasing international tensions as States perceive new vulnerabilities from these changes to geography.

Like commercial shipping (30.6.2.3), naval operations in many countries result in significant greenhouse emissions (e.g., the US Navy emits around 2% of the national greenhouse gas emissions, [*Mabus*, 2010]). As a result, there are a number of programs being implemented by navies around the world to try and reduce their carbon footprint and air pollution such as improving engine efficiency, reducing fouling of vessels, increasing the use of biofuels, and using nuclear technology for power generation, amongst other initiatives.

30.7. Synthesis and Conclusions

Evidence that human activities are fundamentally changing the Ocean is *virtually certain*. Sea temperatures have increased rapidly over the past 60 years at the same time as pH has declined, consistent with the expected influence of rising atmospheric concentrations of CO_2 and other greenhouse gases (*very high confidence*). The rapid rate at which these fundamental physical and chemical parameters of the Ocean are changing is unprecedented within the last 65 Ma (*high confidence*) and possibly 300 Ma (*medium confidence*). As the heat content of the Ocean has increased, the Ocean has become more stratified (*very likely*), although there is considerable regional variability. In some cases, changing surface wind has influenced the extent of mixing and upwelling, although our understanding of where and why these differences occur regionally is uncertain. The changing structure and function of the Ocean has led to changes in parameters such as O_2, carbonate ions, and inorganic nutrients concentrations (*high confidence*). Not surprisingly, these fundamental changes have resulted in responses by key marine organisms, ecosystems and ecological processes, with negative implications for hundreds of millions of people that depend on the ecosystem goods and services provided by the Ocean (*very likely*). Marine organisms are migrating at rapid rates towards higher latitudes, fisheries are transforming, and many organisms are shifting their reproductive and migratory activity in concert with the changes in temperature and other parameters. Ecosystems such as coral reefs are declining rapidly (*high confidence*). An extensive discussion of these changes is provided in previous sections and in other chapters of AR5.

[INSERT TABLE 30-3 HERE
Table 30-3 Key risks to ocean and coastal issues from climate change and the potential for risk reduction through mitigation and adaptation. Key risks are identified based on assessment of the literature and expert judgments made by authors of the various WGII AR5 chapters, with supporting evaluation of evidence and agreement in the referenced chapter sections. Each key risk is characterized as very low, low, medium, high, or very high. Risk levels

are presented for the near-term era of committed climate change (here, for 2030–2040), in which projected levels of global mean temperature increase do not diverge substantially across emissions scenarios. Risk levels are also presented for the longer-term era of climate options (here, for 2080–2100), for global mean temperature increases of 2°C and 4°C above pre-industrial levels. For each timeframe, risk levels are estimated for the current state of adaptation and for a hypothetical highly adapted state. As the assessment considers potential impacts on different physical, biological, and human systems, risk levels should not necessarily be used to evaluate relative risk across key risks. Relevant climate variables are indicated by symbols.

30.7.1. Key Risks and Vulnerabilities

The rapid changes in the physical, chemical, and biological state of the Ocean pose a number of key risks and vulnerabilities for ecosystems, communities, and nations worldwide. Table 30-3 and Figure 30-12 summarize risks and vulnerabilities from climate change and ocean acidification, along with adaptation issues and prospects, and a summary of expert opinion on how these risks will change under further changes in environmental conditions.

Rising ocean temperatures are changing the distribution, abundance, and phenology of many marine species and ecosystems, and consequently represent a key risk to food resources, coastal livelihoods, and industries such as tourism and fishing, especially for HLSBS, CBS, STG, and EBUE (Table 30-3, Figure 30-12a-b, 30.5, Box CC-MB, 6.3.1 6.3.4, 7.3.2.4). Key risks involve changes in the distribution and abundance of key fishery species (Figure 30-12a 2, 4; Figure 30-12b *2*; *high confidence*) as well as the spread of disease and invading organisms, each of which has the potential to impact ecosystems as well as aquaculture and fishing (Table 30-3, 6.3.5, 6.4.1.1, 6.5.3, 7.3.2.4, 7.4.2, 29.5.3, 29.5.4). Adaptation to these changes may be possible in the short-term through dynamic fisheries policy and management (i.e., relocation of fishing effort, Table 30-3), as well as monitoring and responding to potential invading species in coastal settings. The increasing frequency of thermal extremes (Box CC-HS) will also increase the risk that the thermal threshold of corals and other organisms is exceeded on a more frequent basis (especially in CBS, STG, SES, HLSBS, and EUS ocean regions; 30.5, Box CC-CR, 6.2). These changes pose a key risk to vulnerable ecosystems such as mangroves and coral reefs, with potential to have a series of serious impacts on fisheries, tourism, and coastal ecosystem services such as coastal protection (Table 30-3, 30.5, Box CC-CR, 5.4.2.4, 6.3.2. 6.3.5, 6.4.1.3, 7.2.1.2, 29.3.1.2). Genetic adaptation of species to increasing levels of stress may not occur fast enough given fairly long generation times of organisms such as reef building corals and many other invertebrates and fish (Table 30-3). In this case, risks may be reduced by addressing non-climate change related stresses (e.g., pollution, overfishing), although this strategy could have minimal impact if further increases in sea temperature occur (*high confidence*). The loss of these important coastal ecosystems is associated with the emerging risks associated with the collapse of some coastal fisheries along with livelihoods, food, and regional security (*medium confidence*). These changes are *likely* to be exacerbated by other key risks such as coastal inundation and habitat loss due to sea level rise, as well is intensified precipitation events (*high confidence*) (5.4, Box CC-CR). Adaptation options in this case include engineered coastal defences, re-establishing coastal vegetation such as mangroves, protecting water supplies from salination, and developing strategies for coastal communities to withdraw to less vulnerable locations over time (5.5).

The recent decline in O_2 concentrations has been ascribed to warming through the effect on ocean mixing and ventilation, as well as the solubility of O_2 and its consumption by marine microbes (30.3.2.3, 30.5.7, 6.1.1.3, 6.3.3). This represents a key risk to ocean ecosystems (Figure 30-12a *6*, Figure 30-12b *3; medium confidence*). These changes increase the vulnerability of marine communities, especially those below the euphotic zone, to hypoxia and ultimately lead to a restriction of suitable habitat (Figure 30-12a *7*, *high confidence*). In the more extreme case, often exacerbated by the contribution of organic carbon from land-based sources, 'dead zones' may form . Decreasing oxygen, consequently, is *very likely* to increase the vulnerability of fisheries and aquaculture (Figure 30-12b *1, 3; medium confidence*), and consequently puts livelihoods at risk, particularly in EBUE (e.g., California and Humboldt Current ecosystems; 30.5.5), SES (e.g., Baltic and Black Seas; 30.5.3) and CBS (e.g., Gulf of Mexico, NE Indian Ocean; 30.5.4, 30.3.2.3). It is *very likely* that the warming of surface waters has also increased the stratification of the upper ocean by about 4% between 0 and 200 m from 1971–2010 in all oceans north of about 40°S. In many cases, there is significant adaptation opportunity to reduce hypoxia locally by reducing the flow of organic carbon and hence microbial activity within these coastal systems (30.5.4). Relocating fishing effort, and modifying procedures associated with industries like aquaculture, may offer some opportunity to adapt to these changes (*likely*). Declining O_2 concentrations is likely to have significant impacts on DS habitats, where organisms are relatively sensitive to environmental changes of this nature due to the very constant conditions under which they have evolved (30.5.7).

Ocean acidification has increased the vulnerability of ocean ecosystems by affecting key aspects of the physiology and ecology of marine organisms (particularly in CBS, STG, and SES regions; Table 30-3; 6.3.2, Box CC-OA). Decreasing pH and carbonate ion concentrations reduce the ability of marine organisms to produce shells and skeletons, and may interfere with a broad range of important processes such as reproduction, navigation, and neural function in a broad range of marine organisms which show minor to major influences of ocean acidification on their biology (30.3.2.2, 6.3.2, Box CC-OA). Natural variability in ocean pH can interact with ocean acidification to create damaging periods of extremes (i.e., high CO_2, low O_2 and pH), which can have a strong effect on coastal activities such as aquaculture (*medium confidence* Figure 30-12b *1*; Box CC-UP, 6.2). There may be opportunity to adapt aquaculture to increasingly acidic conditions by monitoring natural variability and restricting water intake to periods of optimal conditions. Reducing other non-climate change or ocean acidification associated stresses also represents an opportunity to build greater ecological resilience against the impacts of changing ocean carbonate chemistry. Ocean acidification is also an emerging risk for DS habitats as CO_2 continues to penetrate the Ocean, although the impacts and adaptation options are poorly understood and explored. Ocean acidification has heightened importance for some groups of organisms and ecosystems (Box CC-OA). In ecosystems that are heavily dependent on the accumulation of calcium carbonate over time (e.g., coral reefs, *Halimeda* beds), increasing ocean acidification puts at risk ecosystems services which are critical for hundreds of thousands of marine species, plus people and industries, particularly within CBS, STG and SES (*high confidence)*. Further risks may emerge from the non-linear interaction of different factors (e.g., increasing ocean temperature may amplify effects of ocean acidification, and *vice versa*) and via the interaction of local stressors with climate change (e.g., interacting changes may lead to greater ecosystems disturbances than each impact on its own). There is an urgent need to understand these types of interactions and impacts, especially given the long time it will take to return ocean ecosystems to pre-industrial pH and carbonate chemistry (i.e., tens of thousands of years, FAQ 30.1, should CO_2 emissions continue at the current rate).

It is *very likely* that surface warming has increased stratification of the upper ocean is contributing to the decrease in O_2 along with the temperature related decreases in oxygen solubility (WGI 3.8.3). Changes to wind speed, wave height, and storm intensity influence the location and rate of mixing within the upper layers of the Ocean and hence the concentration of inorganic nutrients (e.g., in EBUE, EUS; Figure 30-12a *1, 3*). These changes to ocean structure increase the risks and vulnerability of food webs within the Ocean. However, our understanding of how primary productivity is going to change in a warming and more acidified ocean is limited, as is our understanding of how upwelling will respond to changing surface wind as the world continues to warm (Box CC-PP, Box CC-UP). As already discussed, these types of changes can have implications for the supply of O_2 into the Ocean and the upward transport of inorganic nutrients to the euphotic zone. While our understanding is limited, there is significant potential for regional increases in wind speed to result in greater rates of upwelling and the supply of inorganic nutrients to the photic zone. While this may increase productivity of phytoplankton communities and associated fisheries, greater rates of upwelling can increase the risk of hypoxic conditions developing at depth as excess primary production sinks into the Ocean and stimulates microbial activity at depth (Table 30-3, 30.3.2.3, 30.5.5, 6.1.1.3). Changes in storm intensity can increase the risk of damage to shipping and industrial infrastructure, which increases the risk of accidents and delays to the transport of products between countries, security operations, and the extraction of minerals from coastal and oceanic areas (30.6.2, [*IPCC*, 2012].

The proliferation of key risks and vulnerabilities to the goods and services provided by ocean ecosystems as a result of ocean warming and acidification generate a number of key risks for the citizens of almost every nation. Risks to food security and livelihoods are expected to increase over time, aggravating poverty and inequity (Table 30-3). As these problems increase, regional security is likely to deteriorate as disputes over resources increase, along with increasing insecurity of food and nutrition (Table 30-3, [*IPCC*, 2012], 30.6.5, 12.4-12.6, 29.3).

30.7.2. Global Frameworks for Decision-Making

Global frameworks for decision-making are central to management of vulnerability and risk at the scale and complexity of the world's oceans. General frameworks and conventions for policy development and decision-making within oceanic and coastal regions are important in terms of the management of stressors not directly due to ocean warming or acidification, but which may influence the outcome of these two factors. Table 30-3 and Table 30-4 outlines a further set of challenges arising from multiple interacting stressors, as well as potential risks and vulnerabilities, ramifications, and adaptation options. In the latter case, examples of potential global frameworks and initiatives for initiating and managing these adaptation options are described. These frameworks represent opportunities for global cooperation and the development of international, regional, and national policy responses to the challenges posed by the changing ocean [*Kenchington and Warner*, 2012; *Tsamenyi and Hanich*, 2012; *Warner and Schofield*, 2012].

[INSERT TABLE 30-4 HERE
Table 30-4: Ramifications, adaptation options and frameworks for decision-making for ocean regions. Symbols are as follows: T = sea temperature; UW = upwelling; OA = ocean acidification; NU = nutrient concentration; IC = ice cover; SS = storm strength; SLR = sea level rise (↑ = Increased; ↓ = decreased; italics = uncertain). Acronyms are: CBD (Convention on Biological Diversity); CTI (Coral Triangle Initiative); GEF (Global Environment Facility); IHO (International Hydrographic Organization); ILO (International Labor Organization); IOM (International Organization of Migration); ISPS (International Ship and Port Facility Security); MARPOL (International Convention for the Prevention of Pollution From Ships); PACC (Pacific Adaptation to Climate Change Project); PEMSEA (Partnerships in Environmental Management for the Seas of East Asia); RFMO (Regional Fisheries Management Organizations); SPREP (Secretariat of the Pacific Regional Environment Programme); UNCLOS (United Nations Convention on the Law of the Sea); UNHCR (United Nations High Commissioner for Refugees); UNSFSA (Straddling Fish Stocks Agreement); and WHO (World Health Organization).]

The United Nations Convention on the Law of the Sea (UNCLOS) was a major outcome of the third UN Conference on the Law of the Sea (UNCLOS III). The European Union and 164 countries have joined in the Convention. UNCLOS replaced earlier frameworks that were built around the 'freedom of the seas' concept and which limited territorial rights to 3 nm off a coastline. UNCLOS provides a comprehensive framework for the legitimate use of the Ocean and its resources, including maritime zones, navigational rights, protection and preservation of the marine environment, fishing activities, marine scientific research, and mineral resource extraction from the seabed beyond national jurisdiction. The relationship between climate change and UNCLOS is not clear and depends on interpretation of the key elements within the UNFCCC (United Nations Framework Convention for Climate Change) and Kyoto Protocol [*Boyle*, 2012]. However, UNCLOS provides mechanisms to help structural adaptation in response to challenges posed by climate change. In a similar way, there is a wide range of other policy and legal frameworks that structure and enable responses to the outcomes of rapid anthropogenic climate change in the Ocean.

There are many existing international conventions and agreements that explicitly recognize climate change (Table 30-4). The United Nations Straddling Fish Stocks Agreement (UNSFSA) aims at enhancing international cooperation of fisheries resources, with an explicit understanding under article 6 that management needs to take account "existing and predicted oceanic, environmental and socio-economic conditions" and to undertake "relevant research, including surveys of abundance, biomass surveys, hydro-acoustic surveys, research on environmental factors affecting stock abundance, and oceanographic and ecological studies" (Annex one, article 3). International conventions such as these will become increasingly important as changes to the distribution and abundance of fisheries are modified by climate change and ocean acidification.

Global frameworks for decision-making are increasingly important in the case of the Ocean, most of which falls outside national boundaries [*Elferink*, 2012; *Warner*, 2012]. Approximately 64% of the Ocean (40% of the Earth's surface) is outside EEZs and continental shelves of the world's nations (high seas and seabed beyond national jurisdiction). With rapidly increasing levels of exploitation, there are increasing calls for more effective decision frameworks aimed at regulating fishing and other activities (e.g., bio-prospecting) within these ocean 'commons'. These international frameworks will become increasingly valuable as nations respond to impacts on fisheries resources that stretch across national boundaries. One such example is the multilateral cooperation that was driven by President Yudhoyono of Indonesia in August 2007 and led to the Coral Triangle Initiative on Coral Reefs, Fisheries, and Food Security (CTI), which involves region-wide (involving 6.8 million km^2 including 132,800 km of coastline) cooperation between the governments of Indonesia, the Philippines, Malaysia, Papua New Guinea, the Solomon Islands, and Timor Leste on reversing the decline in coastal ecosystems such as coral reefs [*Clifton*, 2009; *Hoegh-Guldberg et al.*, 2009; *Veron et al.*, 2009]. Partnerships, such as the CTI, have the potential to provide key frameworks to address issues such as interaction between the over-exploitation of coastal fishing resources and the recovery of reefs from mass coral bleaching and mortality, and the implications of the movement of valuable fishery stocks beyond waters under national jurisdiction. An initiative called the Global Partnership for Oceans set out (www.globalpartnershipforoceans.org, March 28, 2012) to establish a global framework with which to share experience, resources and expertise, as well as to engage governments, industry, civil, and public sector interests in both understanding and finding solutions to key issues such as overfishing, pollution, and habitat destruction [*GPO*, 2012]. Similarly, the Areas Beyond National Jurisdiction (ABNJ, Global Environment Facility) Initiative has been established to promote the efficient, collaborative, and sustainable management of fisheries resources and biodiversity conservation across the Ocean.

Global partnerships are also essential for providing support to the many nations that often do not have the scientific or financial resources to solve the challenges that lie ahead [*Busby*, 2009; *Mertz et al.*, 2009]. In this regard, international networks and partnerships are particularly significant in terms of assisting nations in developing local adaptation solutions to their ocean resources. By sharing common experiences and strategies through global networks, nations have the chance to tap into a vast array of options with respect to responding to the negative consequences of climate change and ocean acidification on the world's ocean and coastal resources.

30.7.3. Emerging Issues, Data Gaps, and Research Needs

While there has been an increase in the number of studies being undertaken to understand the physical, chemical, and biological changes within the Ocean in response to climate change and ocean acidification, the number of marine studies still lag significantly behind terrestrial and atmospheric studies [*Hoegh-Guldberg and Bruno*, 2010; *Poloczanska et al.*, 2013]. Rectifying this gap should be a major international objective given the importance of the Ocean in terms of understanding and responding to future changes and consequences from ocean warming and acidification.

30.7.3.1. Changing Variability and Marine Impacts

Understanding the long-term variability of the Ocean is critically important in terms of the detection and attribution of changes to climate change (30.3, 30.5.8), but also in terms of the interaction between variability and anthropogenic climate change. Developing instrument systems that expand the spatial and temporal coverage of the Ocean and key processes will be critical to documenting and understanding its behavior under further increases in average global temperature and changes the atmospheric concentration of CO_2. International collaborations such as the Argo network of oceanographic floats are rapidly improving our understanding of the physical behavior of the Ocean and will provide important insight into its long-term subsurface variability [*Schofield et al.*, 2013].

30.7.3.2. Surface Wind, Storms, and Upwelling

Improving our understanding of the potential behavior of surface wind in a warming world is needed for improving our understanding of how upwelling will change in key regions (e.g., EUS, EBUE; Box CC-UP). Understanding these changes will provide important information for future fisheries management but will also illuminate the potential risks of intensified upwelling leading to hypoxia at depth and the potential expansion of 'dead zones' (30.3.2; 30.5.2-30.5.4). Understanding surface wind in a warming climate will also yield important information on surface mixing as well as how surface wave height might also vary, improving our understanding of potential interactions in coastal areas between wind, waves, and sea level rise (30.3.1). Given the importance of mixing and upwelling to the supply of inorganic nutrients to the surface layers of the ocean, understanding these important phenomena at the ocean-atmosphere interface will provide important insight into how ocean warming and acidification are likely to impact ecosystems, food webs and ultimately central important fisheries such as those found along the west coasts of Africa and the Americas.

30.7.3.3. Declining O_2 Concentrations

The declining level of O_2 in the Ocean is an emerging issue of major importance (30.3.2). Developing a better understanding of the role and temperature sensitivity of microbial systems in determining O_2 concentrations will enable a more coherent understanding of the changes and potential risks to marine ecosystems. Given the importance of microbial systems to the physical, chemical, and biological characteristics of the Ocean, it is extremely important that these systems receive greater focus, especially with regards to their response to ocean warming and acidification. This is particularly important for the DS (>1000 m), which is the most extensive habitat on the planet. In this respect, increasing our understanding of DS habitats and how they may be changing under the influence of climate change and ocean acidification is of great importance. Linkages between changes occurring in the surface layers and those associated with the DS are particularly important in light of our need to understand how rapidly changes are occurring and what the implications are for the metabolic activity and O_2 content of DS habitats.

30.7.3.4. Ocean Acidification

The rapid and largely unprecedented changes to ocean acidification represent an emerging issue given the central importance of pH and the concentration of ions such as carbonate in the biology of marine organisms (Box CC-OA). Despite the relatively short history of research on this issue, there are already a large number of laboratories and field studies that demonstrate a large range of effects across organisms, processes, and ecosystems. Key gaps [*Gattuso et al.*, 2011] remain in our understanding of how ocean acidification will interact with other changes in the Ocean, and whether or not biological responses to ocean acidification are necessarily linear. The vulnerability of fishery species (e.g., mollusks) to ocean acidification represents an emerging issue, with a need for research to understand and develop strategies for industry to minimize the impacts. Understanding of how carbonate structures like coral reefs and *Halimeda* beds, will respond to a rapidly acidifying ocean represents a key gap and research need, especially in understanding the rate at which consolidated carbonate structures and related habitats are likely to erode and dissolve. Interactions between ocean acidification, upwelling, and decreasing O_2 represent additional areas of concern and research. There is also a need to improve our understanding of the socio-economic ramifications of ocean acidification [*Turley et al.*, 2011; *Hilmi et al.*, 2013].

30.7.3.5. Net Primary Productivity

Oceanic phytoplankton are responsible for 50% of global net primary productivity. However, our understanding of how oceanic primary production is likely to change in a warmer and more acidified ocean is uncertain (Box CC-PP; Box CC-UP). Changes in net primary productivity will resonate through food webs and ultimately affect fish production. Given the central role that primary producers and their associated ecological processes play in ocean ecosystem functioning, it is crucial that we improve our understanding of how net primary productivity is likely to vary at global and regional levels (30.5.2, 30.5.5). At the same time, understanding how plankton communities will vary spatially and temporarily will be important in any attempt to understand how fish populations will fare in a warmer and more acidified ocean. The research challenge is to determine when and where net primary production is expected to change, coupled with research on adaptation strategies for changes to the global distribution of seafood procurement, management and food security.

30.7.3.6. Movement of Marine Organisms and Ecosystems

Marine organisms are moving, generally towards higher latitudes or deeper waters, consistent with the expectation of a warming ocean. Our current understanding of which organisms and ecosystems are moving, and the ramifications for reorganisation of ecosystems and communities, and the implications for nations is uncertain at best. Given the implications for fisheries, invasive species, and the spread of disease, it is an imperative that our understanding of the movement of ecosystems is improved. Documentation of species' responses and a deeper understanding of the processes that lead to persistent range shifts, and a focus on the ecosystem, social and economic implications of range shifts is a research need.

30.7.3.7. Understanding Cumulative and Synergistic Impacts

Understanding cumulative and synergistic impacts is poorly developed for ocean systems. Much of our understanding has been built on experimental approaches that are focused on single stressors that respond gradually without interaction or have impacts that accumulate over time (Table 30-3). Multifactorial experiments exploring the impact of combined variables (e.g., elevated temperature and acidification at the same time) will enable more realistic projections of the future to be established. Equally, developing a better understanding of how biological and ecological responses change in relation to key environmental variables should also be a goal of future research. In this regard, assumptions that responses are likely to be gradual and linear over time ultimately have little basis, yet are widespread within the scientific literature.

30.7.3.8. Reorganization of Ecosystems and Food Webs

The pervasive influence of ocean warming and acidification on the distribution, abundance, and function of organisms and processes has and will continue to drive the reorganization of ecosystems and food webs (*virtually certain*) ([*Hoegh-Guldberg and Bruno*, 2010; *Poloczanska et al.*, 2013], Box CC-MB). One of the inevitable outcomes of differing tolerances and responses to climate change and ocean acidification is the development of novel assemblages of organisms in the near future. Such communities are likely to have no past or contemporary counterparts, and will consequently require new strategies for managing coastal areas and fisheries. Changes to a wide array of factors related or not related to climate change have the potential to drive extremely complex changes in community structure and, consequently, food web dynamics. Developing a greater capability for detecting and understanding these changes will be critical for future management of ocean and coastal resources.

30.7.3.9. Socio-ecological Resilience

Many communities depend on marine ecosystems for food and income yet our understanding of the consequences of environmental degradation is poor. For example, while there is *high confidence* that coral reefs will continue to deteriorate at current rates of climate change and ocean acidification [*Gardner et al.*, 2003; *Bruno and Selig*, 2007; *De'ath et al.*, 2012], there is relatively poor understanding of the implications for the hundreds of millions of people who depend on these important coastal ecosystems for food and livelihoods. Improving our understanding of how to reinforce socio-ecological resilience in communities affected by the deterioration of key coastal and oceanic ecosystems is central to developing effective adaptation responses to these growing challenges (30.6 Table 30-3, Table 30-4).

Frequently Asked Questions

FAQ 30.1: Can we reverse the climate change impacts on the ocean? *[to be inserted after Section 30.3.2]*
In less than 150 years, greenhouse gas emissions have resulted in such major physical and chemical changes in our oceans that it will take thousands of years to reverse them. There are a number of reasons for this. Given its large mass and high heat capacity, the ability of the Ocean to absorb heat is 1000 times larger than that of the atmosphere. The Ocean has absorbed at least nine tenths of the Earth's heat gain between 1971 and 2010. To reverse that heating, the warmer upper layers of the Ocean have to mix with the colder deeper layers. That mixing can take up to 1000 years. This means it will take centuries to millennia for deep ocean temperatures to warm in response to today's surface conditions, and at least as long for ocean warming to reverse after atmospheric greenhouse gas

concentrations decrease (*virtually certain*). But climate change-caused alteration of basic conditions in the Ocean is not just about temperature. The Ocean becomes more acidic as more CO_2 enters it and will take tens of thousands of years to reverse these profound changes to the carbonate chemistry of the ocean (*virtually certain*). These enormous physical and chemical changes are producing sweeping and profound changes in marine ecosystems. Large and abrupt changes to these ecosystems are unlikely to be reversible in the short to medium term (*high confidence*).

FAQ30.2: Does slower warming mean less impact on plants and animals? *[to be inserted in Section 30.4]*
The greater thermal inertia of the Ocean means that temperature anomalies and extremes are lower than those seen on land. This does not necessarily mean that impacts of ocean warming are less for the ocean than for land. A large body of evidence reveals that small amounts of warming in the Ocean can have large effects on ocean ecosystems. For example, relatively small increases in sea temperature (as little as 1–2°C) can cause mass coral bleaching and mortality across hundreds of square kilometers of coral reef (*high confidence*). Other analyses have revealed that increased temperatures are spreading rapidly across the world's oceans (measured as the movement of bands of equal water temperature or isotherms). This rate of warming presents challenges to organisms and ecosystems as they try to migrate to cooler regions as the Ocean continues to warm. Rapid environmental change also poses steep challenges to evolutionary processes, especially where long-lived organisms such as corals and fish are concerned (*high confidence*).

FAQ30.3: How will marine primary productivity change? *[to be inserted after Section 30.5.2.2]*
Drifting microscopic plants known as phytoplankton are the dominant marine primary producers, at the base of the marine food chain. Their photosynthetic activity is critically important to life in general. It provides oxygen, supports marine food webs, and influences global biogeochemical cycles. Changes in marine primary productivity in response to climate change remain the single biggest uncertainty in predicting the magnitude and direction of future changes in fisheries and marine ecosystems (*low confidence*). Changes have been reported to a range of different ocean systems (e.g., High Latitude Spring Bloom Systems, Sub-tropical Gyre Systems, Equatorial Upwelling Systems, and Eastern Boundary Upwelling Ecosystems), some of which are consistent with changes in ocean temperature, mixing, and circulation. However, direct attribution of these changes to climate change is made difficult by long-term patterns of variability that influence productivity of different parts of the Ocean (e.g., Pacific Decadal Oscillation). Given the importance of this question for ocean ecosystems and fisheries, longer time series studies to understand how these systems are changing as a result of climate change are a priority (*high agreement*).

FAQ30.4: Will climate change cause 'dead zones' in the oceans? *[to be inserted after Section 30.5.5.2]*
Dissolved oxygen is a major determinant of the distribution and abundance of marine organisms. Dead zones are persistent hypoxic conditions where the water doesn't have enough dissolved oxygen to support oxygen-dependent marine species. These areas exist all over the world and are expanding, with impacts on coastal ecosystems and fisheries (*high confidence*). Dead zones are caused by several factors, particularly eutrophication where too many nutrients run off coastal cities and agricultural areas into rivers that carry these materials out to sea. This stimulates primary production leading to a greater supply of organic carbon, which can sink into the deeper layers of the ocean. As microbial activity is stimulated, there is a sharp reduction in dissolved oxygen levels and an increased risk of dead zones (*high confidence*). Climate change can influence the distribution of dead zones by increasing water temperature and hence microbial activity, as well as reducing mixing of the ocean (i.e., increasing layering or stratification) of the Ocean – which have different temperatures, densities, salinities – and reducing mixing of oxygen-rich surface layers into the deeper parts of the Ocean. In other areas, increased upwelling can lead to stimulated productivity, which can also lead to more organic carbon entering the deep ocean, where it is consumed, decreasing oxygen levels (*medium confidence*). Managing local factors such as the input of nutrients into coastal regions can play an important role in reducing the rate at which dead zones are spreading across the world's oceans (*high agreement).*

FAQ30.5: How can we use non-climate factors to manage climate change impacts on the oceans?
[to be inserted after Section 30.7.1]
Like most natural system, the Ocean is exposed to a range of stresses that may or may not be related to climate change. Human activities can result in pollution, eutrophication (too many nutrients), habitat destruction, invasive species, destructive fishing, and over-exploitation of marine resources. Sometimes, these activities can increase the impacts of climate change, although they can, in a few circumstances, dampen the effects as well. Understanding

how these factors interact with climate change and ocean acidification is important in its own right. However, reducing the impact of these non-climate factors may reduce the overall rate of change within ocean ecosystems. Building ecological resilience through ecosystem-based approaches to the management of the marine environment, for example, may pay dividends in terms of reducing and delaying the effects of climate change (*high confidence*).

Cross-Chapter Boxes

Box CC-CR. Coral Reefs

[Jean-Pierre Gattuso (France), Ove Hoegh-Guldberg (Australia), Hans-Otto Pörtner (Germany)]

Coral reefs are shallow-water ecosystems that consist of reefs made of calcium carbonate which is mostly secreted by reef-building corals and encrusting macroalgae. They occupy less than 0.1% of the ocean floor yet play multiple important roles throughout the tropics, housing high levels of biological diversity as well as providing key ecosystem goods and services such as habitat for fisheries, coastal protection and appealing environments for tourism (Wild *et al*., 2011). About 275 million people live within 30 km of a coral reef (Burke *et al*., 2011) and derive some benefits from the ecosystem services that coral reefs provide (Hoegh-Guldberg, 2011) including provisioning (food, livelihoods, construction material, medicine), regulating (shoreline protection, water quality), supporting (primary production, nutrient cycling) and cultural (religion, tourism) services. This is especially true for the many coastal and small island nations in the world's tropical regions (29.3.3.1).

Coral reefs are one of the most vulnerable marine ecosystems (*high confidence*; 5.4.2.4, 6.3.1, 6.3.2, 6.3.5, 25.6.2, and 30.5) and more than half of the world's reefs are under medium or high risk of degradation (Burke *et al*., 2011). Most human-induced disturbances to coral reefs were local until the early 1980s (e.g., unsustainable coastal development, pollution, nutrient enrichment and overfishing) when disturbances from ocean warming (principally mass coral bleaching and mortality) began to become widespread (Glynn, 1984). Concern about the impact of ocean acidification on coral reefs developed over the same period, primarily over the implications of ocean acidification for the building and maintenance of the calcium carbonate reef framework (Box CC-OA).

[INSERT FIGURE CR-1 HERE
Figure CR-1: A and B: the same coral community before and after a bleaching event in February 2002 at 5 m depth, Halfway Island, Great Barrier Reef. Coral cover at the time of bleaching was 95% bleached almost all of it severely bleached, resulting in mortality of 20.9% (Elvidge *et al*., 2004). Mortality was comparatively low due in part because these coral communities were able to shuffle their symbiont to more thermo-tolerant types (Berkelmans and van Oppen, 2006; Jones *et al*., 2008). C and D: three CO_2 seeps in Milne Bay Province, Papua New Guinea show that prolonged exposure to high CO_2 is related to fundamental changes in the ecology of coral reefs (Fabricius *et al*., 2011), including reduced coral diversity (-39%), severely reduced structural complexity (-67%), lower density of young corals (-66%) and fewer crustose coralline algae (-85%). At high CO_2 sites (panel D; median pH_T ~7.8), reefs are dominated by massive corals while corals with high morphological complexity are underrepresented compared with control sites (D; median pH ~8.0). Reef development ceases at pH_T values below 7.7. pH_T: pH on the total scale. E: temporal trend in coral cover for the whole Great Barrier Reef over the period 1985–2012 (N, number of reefs, mean ± 2 standard errors; De'ath et al., 2012). F: composite bars indicate the estimated mean coral mortality for each year, and the sub-bars indicate the relative mortality due to crown-of-thorns starfish, cyclones, and bleaching for the whole Great Barrier Reef (De'ath et al., 2012). Photo credit: R. Berkelmans (A and B) and K. Fabricius (C and D).]

A wide range of climatic and non-climatic drivers affect corals and coral reefs and negative impacts have already been observed (5.4.2.4, 6.3.1, 6.3.2, 25.6.2.1, 30.5.3, 30.5.6). Bleaching involves the breakdown and loss of endosymbiotic algae, which live in the coral tissues and play a key role in supplying the coral host with energy (see 6.3.1. for physiological details and 30.5 for a regional analysis). Mass coral bleaching and mortality, triggered by positive temperature anomalies (*high confidence*), is the most widespread and conspicuous impact of climate change (Figure CR-1A and B, Figure 5-3; 5.4.2.4, 6.3.1, 6.3.5, 25.6.2.1, 30.5 and 30.8.2). For example, the level of thermal stress at most of the 47 reef sites where bleaching occurred during 1997-98 was unmatched in the period 1903 to 1999 (Lough, 2000). Ocean acidification reduces biodiversity (Figure CR-1C and D) and the calcification rate of corals (*high confidence*; 5.4.2.4, 6.3.2, 6.3.5) while at the same time increasing the rate of dissolution of the reef framework (*medium confidence*; 5.2.2.4) through stimulation of biological erosion and chemical dissolution. Taken together, these changes will tip the calcium carbonate balance of coral reefs towards net dissolution (*medium confidence*; 5.4.2.4). Ocean warming and acidification have synergistic effects in several reef-builders (5.2.4.2, 6.3.5). Taken together, these changes will erode habitats for reef-based fisheries, increase the exposure of coastlines to waves and storms, as well as degrading environmental features important to industries such as tourism (*high confidence*; 6.4.1.3, 25.6.2, 30.5).

A growing number of studies have reported regional scale changes in coral calcification and mortality that are consistent with the scale and impact of ocean warming and acidification when compared to local factors such as declining water quality and overfishing (Hoegh-Guldberg *et al*., 2007). The abundance of reef building corals is in rapid decline in many Pacific and SE Asian regions (*very high confidence*, 1-2% per year for 1968-2004; Bruno and Selig, 2007). Similarly, the abundance of reef-building corals has decreased by over 80% on many Caribbean reefs (1977 to 2001; Gardner *et al*., 2003), with a dramatic phase shift from corals to seaweeds occurring on Jamaican reefs (Hughes, 1994). Tropical cyclones, coral predators and thermal stress-related coral bleaching and mortality have led to a decline in coral cover on the Great Barrier Reef by about 51% between 1985 and 2012 (Figure CR-1E and F). Although less well documented, benthic invertebrates other than corals are also at risk (Przeslawski *et al*., 2008). Fish biodiversity is threatened by the permanent degradation of coral reefs, including in a marine reserve (Jones *et al*., 2004).

Future impacts of climate-related drivers (ocean warming, acidification, sea level rise as well as more intense tropical cyclones and rainfall events) will exacerbate the impacts of non-climate related drivers (*high confidence*). Even under optimistic assumptions regarding corals being able to rapidly adapt to thermal stress, one-third (9 to 60%, 68% uncertainty range) of the world's coral reefs are projected to be subject to long-term degradation (next few decades) under the RCP3-PD scenario (Frieler *et al*., 2013). Under the RCP4.5 scenario, this fraction increases to two-thirds (30 to 88%, 68% uncertainty range). If present day corals have residual capacity to acclimate and/or adapt, half of the coral reefs may avoid high frequency bleaching through 2100 (*limited evidence, limited agreement*; Logan *et al*., 2013). Evidence of corals adapting rapidly, however, to climate change is missing or equivocal (Hoegh-Guldberg, 2012).

Damage to coral reefs has implications for several key regional services:

- *Resources*: Coral reefs account for 10 to 12% of the fish caught in tropical countries, and 20 to 25% of the fish caught by developing nations (Garcia and Moreno, 2003). Over half (55%) of the 49 island countries considered by Newton *et al*. (2007) are already exploiting their coral reef fisheries in an unsustainable way and the production of coral reef fish in the Pacific is projected to decrease 20% by 2050 under the SRES A2 emissions scenario (Bell *et al*., 2013).
- *Coastal* protection: Coral reefs contribute to protecting the shoreline from the destructive action of storm surges and cyclones (Sheppard *et al*., 2005), sheltering the only habitable land for several island nations, habitats suitable for the establishment and maintenance of mangroves and wetlands, as well as areas for recreational activities. This role is threatened by future sea level rise, the decrease in coral cover, reduced rates of calcification and higher rates of dissolution and bioerosion due to ocean warming and acidification (5.4.2.4, 6.4.1, 30.5).
- *Tourism*: More than 100 countries benefit from the recreational value provided by their coral reefs (Burke *et al*., 2011). For example, the Great Barrier Reef Marine Park attracts about 1.9 million visits each year and generates A$ 5.4 billion to the Australian economy and 54,000 jobs (90% in the tourism sector; Biggs, 2011).

Coral reefs make a modest contribution to the Global Domestic Product but their economic importance can be high at the country and regional scales (Pratchett *et al*., 2008). For example, tourism and fisheries represent 5% of the GDP of South Pacific islands (average for 2001-2011; Laurans *et al*., 2013). At the local scale, these two services provided in 2009-2011 at least 25% of the annual income of villages in Vanuatu and Fiji (Pascal, 2011; Laurans *et al*., 2013).

Isolated reefs can recover from major disturbance, and the benefits of their isolation from chronic anthropogenic pressures can outweigh the costs of limited connectivity (Gilmour *et al*., 2013). Marine protected areas (MPAs) and fisheries management have the potential to increase ecosystem resilience and increase the recovery of coral reefs after climate change impacts such as mass coral bleaching (McLeod *et al*., 2009). Although they are key conservation and management tools, they are unable to protect corals directly from thermal stress (Selig *et al*., 2012) suggesting that they need to be complemented with additional and alternative strategies (Rau *et al*., 2012; Billé *et al*., 2013). While MPA networks are a critical management tool, they should be established considering other forms of resource management (e.g., fishery catch limits and gear restrictions) and integrated ocean and coastal management to control land-based threats such as pollution and sedimentation. There is *medium confidence* that networks of highly protected areas nested within a broader management framework can contribute to preserving coral reefs under increasing human pressure at local and global scales (Salm *et al*. 2006). Locally, controlling the input of nutrients and sediment from land is an important complementary management strategy (Mcleod *et al*., 2009) because nutrient enrichment can increase the susceptibility of corals to bleaching (Wiedenmann *et al*., 2012) and coastal pollutants enriched with fertilizers can increase acidification (Kelly *et al.*, 2011). In the long term, limiting the amount of ocean warming and acidification is central to ensuring the viability of coral reefs and dependent communities (*high confidence*; 5.2.4.4, 30.5).

Box CC-HS. Heat Stress and Heat Waves

[Lennart Olsson (Sweden), Dave Chadee (Trinidad and Tobago), Ove Hoegh-Guldberg (Australia), John Porter (Denmark), Hans-O. Pörtner (Germany), Kirk Smith (USA), Maria Isabel Travasso (Argentina), Petra Tschakert (USA)]

Heat waves are periods of abnormally and uncomfortably hot weather during which the risk of heat stress on people and ecosystems is high. The number and intensity of hot days have increased markedly in the last three decades (Coumou et al., 2013) (*high confidence*). According to WG I, it is *likely* that the occurrence of heat waves has more than doubled in some locations due to human influence and it is *virtually certain* that there will be more frequent hot extremes over most land areas in the latter half of the 21st century. Coumou et al. (2013) predicted that, under a medium warming scenario, the number of monthly heat records will be over 12 times more common by the 2040s compared to a non-warming world. In a longer time perspective, if the global mean temperature increases to +10C or more, the habitability of large parts of the tropics and mid-latitudes will be at risk (Sherwood and Huber, 2010). Heat waves affect natural and human systems directly, often with severe losses of lives and assets as a result, and they may act as triggers for tipping points (Hughes et al., 2013). Consequently, heat waves play an important role in several key risks noted in Chapter 19 and CC-KR.

Economy and Society [Ch 10, 11, 12, 13]

Environmental heat stress has already reduced the global labor capacity to 90% in peak months with a further predicted reduction to 80% in peak months by 2050. Under a high warming scenario (RCP8.5), labor capacity is expected to be less than 40% of present day conditions in peak months by 2200 (Dunne et al., 2013). Adaptation costs for securing cooling capacities and emergency shelters during heat waves will be substantial.

Heat waves are associated with social predicaments such as increasing violence (Anderson, 2012) as well as overall health and psychological distress and low life satisfaction (Tawatsupa et al., 2012). Impacts are highly differential with disproportional burdens on poor people, elderly people, and those who are marginalized (Wilhelmi et al., 2012). Urban areas are expected to suffer more due to the combined effect of climate and the urban heat island effect (Fischer et al., 2012). In LICs and MICs, adaptation to heat stress is severely restricted for most people in poverty and particularly those who are dependent on working outdoors in agriculture, fisheries, and construction. In small-scale agriculture, women and children are particularly at risk due to the gendered division of labor (Croppenstedt et al., 2013). The expected increase in wildfires as a result of heat waves (Pechony and Shindell, 2010) is a concern for human security, health, and ecosystems. Air pollution from wildfires already causes an estimated 339,000 premature deaths per year worldwide (Johnston et al., 2012).

Human Health [Ch 11]

Morbidity and mortality due to heat stress is now common all over the world (Barriopedro *et al.*, 2011; Rahmstorf and Coumou, 2011; Nitschke et al., 2011; Diboulo et al., 2012; Hansen et al., 2012). People in physical work are at particular risk as such work produces substantial heat within the body, which cannot be released if the outside temperature and humidity is above certain limits (Kjellstrom et al., 2009). The risk of non-melanoma skin cancer from exposure to UV radiation during summer months increases with temperature (van der Leun, Jan C et al., 2008). Increase in ozone concentrations due to high temperatures affects health (Smith et al., 2010), leading to premature mortality, e.g. cardiopulmonary mortality (Smith et al., 2010). High temperatures are also associated with an increase in air-borne allergens acting as a trigger for respiratory illnesses such as asthma, allergic rhinitis, conjunctivitis, and dermatitis (Beggs, 2010).

Ecosystems [Ch 4, 5, 6, 30]

Tree mortality is increasing globally (Williams et al., 2012) and can be linked to climate impacts, especially heat and drought (Reichstein et al., 2013), even though attribution to climate change is difficult due to lack of time series and confounding factors. In the Mediterranean region, higher fire risk, longer fire season, and more frequent large, severe fires are expected as a result of increasing heat waves in combination with drought (Duguy et al., 2013), Box 4.2.

Marine ecosystem shifts attributed to climate change are often caused by temperature extremes rather than changes in the average (Pörtner and Knust, 2007). During heat exposure near biogeographical limits, even small (<0.5°C) shifts in temperature extremes can have large effects, often exacerbated by concomitant exposures to hypoxia and/or elevated CO_2 levels and associated acidification (Hoegh-Guldberg et al., 2007), Figure 6-5, (*medium confidence*) [Ch 6.3.1, 6.3.5; 30.4; 30.5; CC-MB]

Most coral reefs have experienced heat stress sufficient to cause frequent mass coral bleaching events in the last 30 years, sometimes followed by mass mortality (Baker et al., 2008). The interaction of acidification and warming exacerbates coral bleaching and mortality (*very high confidence*).Temperate seagrass and kelp ecosystems will decline with the increased frequency of heat waves and through the impact of invasive subtropical species (*high confidence*). [Ch 5, 6, 30.4-30.5, CC-CR, CC-MB]

Agriculture [Ch 7]

Excessive heat interacts with key physiological processes in crops. Negative yield impacts for all crops past +3C of local warming without adaptation, even with benefits of higher CO_2 and rainfall, are expected even in cool environments (Teixeira et al., 2011). For tropical systems where moisture availability or extreme heat limits the length of the growing season, there is a high potential for a decline in the length of the growing season and

suitability for crops (*medium evidence, medium agreement*) (Jones and Thornton, 2009). For example, half of the wheat-growing area of the Indo-Gangetic Plains could become significantly heat-stressed by the 2050s.

There is *high confidence* that high temperatures reduce animal feeding and growth rates (Thornton et al., 2009). Heat stress reduces reproductive rates of livestock (Hansen, 2009), weakens their overall performance (Henry et al., 2012), and may cause mass mortality of animals in feedlots during heat waves (Polley et al., 2013). In the U.S., current economic losses due to heat stress of livestock are estimated at several billion USD annually (St-Pierre et al., 2003).

Box CC-MB. Observed Global Responses of Marine Biogeography, Abundance, and Phenology to Climate Change

[Elvira Poloczanska (Australia), Ove Hoegh-Guldberg (Australia), William Cheung (Canada), Hans O. Pörtner (Germany), Michael Burrows (UK)]

WGII AR4 presented detection and attribution of a global climate change fingerprint on natural systems (AR4, Ch 1, SPM Figure 1), but studies from marine systems were mostly absent. Since AR4, there has been a rapid increase in studies that focus on climate change impacts on marine species, which represents an opportunity to move from more anecdotal evidence to examining and potentially attributing detected changes within the Ocean to climate change (6.3, Figure MB-1). Recent changes in populations of marine species and the associated shifts in diversity patterns are resulting, at least partly, from climate change-mediated biological responses across ocean regions (6.2, Table 6.7, 30.5) (*robust evidence, high agreement, high confidence*).

Poloczanska *et al*. (2013) assess a potential pattern in responses of ocean life to recent climate change using a global database of 208 peer-reviewed papers. Observed responses (n=1735) were recorded from 857 species or assemblages across regions and taxonomic groups, from phytoplankton to marine reptiles and mammals (Figure MB-1). Observations were defined as those where the authors of a particular paper assessed the occurrence change in a biological parameter (including distribution, phenology, abundance, demography or community composition) and, if change occurs, the consistency of the change with that expected under climate change. Studies from the peer-reviewed literature were selected using three criteria: (1) authors inferred or directly tested for trends in biological and climatic variables; (2) included data after 1990; and (3) observations spanned at least 19 years, to reduce bias resulting from biological responses to short-term-climate variability.

[INSERT FIGURE MB-1 HERE
Figure MB-1: 1735 observed responses to climate change from 208 single- and multi-species studies. Changes attributed to climate change (blue), inconsistent with climate change (red) and are equivocal (yellow). Each circle

represents the centre of a study area. Where points fall on land, it is because they are centroids of distribution that surround an island or peninsula. Pie charts show the proportions within regions bounded by red squares and in the Mediterranean; numbers indicate the total (consistent, opposite or equivocal) observations within each region. Note: 57% of the studies included were published since AR4 (from Poloczanska *et al.*, 2013).]

The results of this meta-analysis show that climate change has already had widespread impacts on species' distribution, abundance, phenology, and subsequently, species richness and community composition across a broad range of taxonomic groups (plankton to top predators). Of the observations that showed a response in either direction, changes in phenology, distribution and abundance were overwhelmingly (81%) in a direction that was consistent with theoretical responses to climate change (6.2). Knowledge gaps exist, especially in equatorial sub-regions and the Southern Hemisphere (Figure MB-1).

The timing of many biological events (phenology) had an earlier onset. For example, over the last 50 years, spring events shifted earlier for many species with an average advancement of 4.4 ± 0.7 days decade^{-1} (mean ± SE) and summer events by 4.4 ± 1.1 days decade^{-1} (*robust evidence, high agreement, high confidence*) (Figure MB-2). Phenological observations included in the study, range from shifts in peak abundance of phytoplankton and zooplankton, to reproduction and migration of invertebrates, fishes and seabirds (6.3.2, 30.5).

The distributions of benthic, pelagic and demersal species and communities have shifted by 10s to 1000s of km, although the range shifts have not been uniform across taxonomic groups or ocean regions (6.3.2, 30.5) (*robust evidence, high agreement, high confidence*). Overall, leading range edges expanded in a poleward direction at 72.0 ± 13.5 km decade^{-1} and trailing edges contracted in a poleward direction at 15.8 ± 8.7 km decade^{-1} (Figure MB-2) revealing much higher current rates of migration than the potential maximum rates reported for terrestrial species (Figure 4.6) despite slower warming of the Ocean than land surface (WG1 3.2).

[INSERT FIGURE MB-2 HERE
Figure MB-2. Rates of change in distribution (km decade^{-1}) for marine taxonomic groups, measured at the leading edges (red) and trailing edges (brown). Average distribution shifts calculated using all data, regardless of range location, are in black. Distribution rates have been square-root transformed; standard errors may be asymmetric as a result. Positive distribution changes are consistent with warming (into previously cooler waters, generally poleward). Means ± standard error are shown, along with number of observations (from Poloczanska et al., 2013).]

Poleward distribution shifts have resulted in increased species richness in mid to high latitude regions (Hiddink and ter Hofstede, 2008) and changing community structure (Simpson *et al.,* 2011) (28.2.2). Increases in warm-water components of communities concurrent with regional warming have been observed in mid to high latitude ocean regions including the Bering Sea, Barents Sea, Nordic Sea, North Sea, and Tasman Sea (Box 6.1, 30.5). Observed changes in species composition of catches from 1970–2006 that is partly attributed to long-term ocean warming suggest increasing dominance of warmer water species in sub-tropical and higher latitude regions, and reduction in abundance of sub-tropical species in equatorial waters (Cheung *et al*., 2013), with implications for fisheries (6.5, 7.4.2, 30.6.2.1)

The magnitude and direction of distribution shifts can be related to temperature velocities (i.e., the speed and direction at which isotherms propagate across the Ocean's surface (30.3.1.1, Burrows *et al.* 2011). Pinsky *et al.* (2013) showed that shifts in both latitude and depth of benthic fish and crustaceans could be explained by climate velocity with remarkable accuracy, using a database of 128 million individuals across 360 marine taxa from surveys of North American coastal waters conducted over 1968 to 2011. Poloczanska *et al.* (2013) found that faster distribution shifts generally occur in regions of highest surface temperature velocity, such as the North Sea and sub-Arctic Pacific Ocean. Observed marine species shifts, since approximately 1950s, have generally been able to track observed velocities (Fig MB-3), with phyto- and zooplankton distribution shifts vastly exceeding climate velocities, but with considerable variability within and among taxonomic groups (Poloczanska *et al.* 2013).

Biogeographic shifts are also be influenced by other factors such as nutrient and stratification changes, species' interactions, habitat availability and fishing (6.3). Rate and pattern of biogeographic shifts in sedentary organisms and benthic macroalgae are complicated by the influence of local dynamics and topographic features (islands, channels, coastal lagoons, e.g., of the Mediterranean (Bianchi, 2007), coastal upwelling e.g., Lima *et al.* (2007)). Geographical barriers constrain range shifts and may cause a loss of endemic species (Ben Rais Lasram *et al.*, 2010), with associated niches filled by alien species, either naturally migrating or artificially introduced (Philippart *et al.*, 2011).

Whether marine species can continue to keep pace as warming rates, hence climate velocities, increase (Fig MB-3b) is a key uncertainty. Climate velocities on land are expected to outpace the ability of many terrestrial species to track climate velocities this century (4.3.2.5, Figure 4.6) For marine species, the observed rates of shift are generally much faster than those land for land species, particularly for primary producers and lower trophic levels (Poloczanska *et al. 2013*). Phyto- and zooplankton communities (excluding larval fish) have extended distributions at remarkable rates (Figure MB-3b), such as in the North-east Atlantic (30.5.1) with implications for marine food webs.

Geographical range shifts and depth distribution vary between coexisting marine species (Genner *et al*., 2004; Perry *et al*., 2005; Simpson *et al*., 2011) as a consequence of species-specific thermal window widths and associated vulnerabilities (Figure 6.5). Warming therefore causes differential changes in growth, reproductive success, larval output, early juvenile survival, and recruitment, implying shifts in the relative performance of animal species and, thus, their competitiveness (Pörtner and Farrell, 2008; Figure 6.7A). Such effects may underlie abundance losses or local extinctions, “regime shifts” between coexisting species, or critical mismatches between predator and prey organisms. Changes in local and regional species richness, abundance, community composition, productivity, energy flows and invasion resistance result. Even among Antarctic stenotherms such differences related to mode of life, phylogeny and associated metabolic capacities exist (6.3.1.4). As a consequence, marine ecosystem functions may be substantially reorganized at the regional scale, potentially triggering a range of cascading effects (Hoegh-Guldberg and Bruno, 2010). A focus on understanding the mechanisms underpinning the nature and magnitude of responses of marine organisms to climate change can help forecast impacts and the associated costs to society and facilitate adaptive management strategies effective in mitigating these impacts (6.3, 6.4).

[INSERT FIGURE MB-3 HERE
Figure MB-3. A. Rate of climate change for the Ocean (sea surface temperature (SST) °C); B. corresponding climate velocities for the Ocean and median velocity from land (adapted from Burrows et al., 2011); and C. observed rates of displacement of marine taxonomic groups over several decades until 2010. The thin dotted red arrows give an example of interpretation. Rates of climate change of 0.008 °C yr^{-1} correspond to ca. 2.4 km yr^{-1}median climate velocity in the Ocean. When compared to observed rates of displacement, many marine taxonomic groups have been able to track these velocities, except phyto- and zooplankton where rates of displacement greatly exceed climate velocity. All values are calculated for ocean surface with the exclusion of polar seas (Figure 30-1a). (A) Observed rates of climate change for Ocean SST (Black dotted line) are derived from HadISST1.1 data set, all other rates are calculated based on the average of the CMIP5 climate model ensembles (Table S30-3) for the historical period and for the future based on the four RCP emissions scenarios. Data were smoothed using a 20-year sliding window. (B) Median climate velocity calculated from HadISST1.1 dataset over 1960–2010 using the methods of Burrows et al., 2011. The three axes represent estimated median climate velocities are representative of areas of slow velocities such as Pacific subtropical gyre (STG) system (Purple line), the global Ocean surface (excluding polar seas, Blue line), and areas of high velocities such as the Coral Triangle and North Sea (Orange line). Figure 30-3 shows climate velocities over the ocean surface calculated over 1960–2010. The Red line corresponds to the median rate over global land surface calculated using historical surface temperatures from the CMIP5 model ensemble (Table S30-3). (C) Rates of displacement for marine taxonomic groups estimated by Poloczanska et al. 2013 using published studies (Figure MB-2 Black data set). Note the displacement rates for phytoplankton exceed the axis, so values are given.]

Box CC-OA. Ocean Acidification

[Jean-Pierre Gattuso (France), Peter Brewer (USA), Ove Hoegh-Guldberg (Australia), Joan A. Kleypas (USA), Hans-Otto Pörtner (Germany), Daniela Schmidt (UK)]

Anthropogenic ocean acidification and global warming share the same primary cause, which is the increase of atmospheric CO_2 (Figure OA-1A; WGI, 2.2.1). Eutrophication, loss of sea ice, upwelling and deposition of atmospheric nitrogen and sulphur all exacerbate ocean acidification locally (5.3.3.6, 6.1.1, 30.3.2.2).

[INSERT FIGURE OA-1 HERE
Figure OA-1: A: Overview of the chemical, biological, socio-economic impacts of ocean acidification and of policy options (adapted from Turley and Gattuso, 2012). B: Multi-model simulated time series of global mean ocean surface pH (on the total scale) from CMIP5 climate model simulations from 1850 to 2100. Projections are shown for emission scenarios RCP2.6 (blue) and RCP8.5 (red) for the multi-model mean (solid lines) and range across the distribution of individual model simulations (shading). Black (grey shading) is the modelled historical evolution using historical reconstructed forcings. The models that are included are those from CMIP5 that simulate the global carbon cycle while being driven by prescribed atmospheric CO_2 concentrations. The number of CMIP5 models to calculate the multi-model mean is indicated for each time period/scenario (WGI AR5 Figure 6.28). C: Effect of near future acidification (seawater pH reduction of 0.5 unit or less) on major response variables estimated using weighted random effects meta-analyses, with the exception of survival which is not weighted (Kroeker et al., 2013). The log-transformed response ratio (LnRR) is the ratio of the mean effect in the acidification treatment to the mean effect in a control group. It indicates which process is most uniformly affected by ocean acidification but large variability exists between species. Significance is determined when the 95% bootstrapped confidence interval does not cross zero. The number of experiments used in the analyses is shown in parentheses. * denotes a statistically significant effect.]

Chemistry and Projections

The fundamental chemistry of ocean acidification is well understood (*robust evidence, high agreement*). Increasing atmospheric concentrations of CO_2 result in an increased flux of CO_2 into a mildly alkaline ocean, resulting in a reduction in pH, carbonate ion concentration, and the capacity of seawater to buffer changes in its chemistry (*very high confidence*). The changing chemistry of the surface layers of the open ocean can be projected at the global scale with high accuracy using projections of atmospheric CO_2 levels (Fig. CC-OA-1B). Observations of changing upper ocean CO_2 chemistry over time support this linkage (WGI Table 3.2 and Figure 3.18; Figures 30.8, 30.9). Projected changes in open ocean, surface water chemistry for year 2100 based on representative concentration pathways (WGI, Figure 6.28) compared to preindustrial values range from a pH change of -0.14 unit with RCP 2.6 (421 ppm CO_2, +1 ºC, 22% reduction of carbonate ion concentration) to a pH change of -0.43 unit with RCP 8.5 (936 ppm CO_2, +3.7 ºC, 56% reduction of carbonate ion concentration). Projections of regional changes, especially in the highly complex coastal systems (5.3.3.6, 30.3.2.2), in polar regions (WGI 6.4.4), and at depth are more difficult but generally follow similar trends.

Biological, Ecological, and Biogeochemical Impacts

Investigations of the effect of ocean acidification on marine organisms and ecosystems have a relatively short history, recently analyzed in several metaanalyses (6.3.2.1, 6.3.5.1). A wide range of sensitivities to projected rates of ocean acidification exists within and across diverse groups of organisms, with a trend for greater sensitivity in early life stages (*high confidence*; 5.4.2.2, 5.4.2.4, 6.3.2). A pattern of positive and negative impacts emerges (*high confidence*; Fig. OA-1C) but key uncertainties remain in our understanding of the impacts on organisms, life histories and ecosystems. Responses can be influenced, often exacerbated by other drivers, such as warming, hypoxia, nutrient concentration, and light availability (*high confidence*; 5.4.2.4, 6.3.5).

Growth and primary production are stimulated in seagrass and some phytoplankton (*high confidence*; 5.4.2.3, 6.3.2.2-3, 30.5.6). Harmful algal blooms could become more frequent (*limited evidence, medium agreement*). Ocean acidification may stimulate nitrogen fixation (*limited evidence, low agreement*; 6.3.2.2). It decreases the rate of calcification of most, but not all, sea-floor calcifiers (*medium agreement*, *robust evidence*) such as reef-building corals (Box CC-CR), coralline algae, bivalves and gastropods reducing the competitiveness with non-calcifiers (5.4.2.2, 5.4.2.4, 6.3.2.5). Ocean warming and acidification promote higher rates of calcium carbonate dissolution resulting in the net dissolution of carbonate sediments and frameworks and loss of associated habitat (*medium confidence*; 5.4.2.4, 6.3.2.5, 6.3.5.4-5). Some corals and temperate fishes experience disturbances to behavior, navigation and their ability to tell conspecifics from predators (6.3.2.4). However, there is no evidence for these effects to persist on evolutionary timescales in the few groups analyzed (6.3.2).

Some phytoplankton and mollusks displayed adaptation to ocean acidification in long-term experiments (*limited evidence, medium agreement*; 6.3.2.1), indicating that the long-term responses could be less than responses obtained in short-term experiments. However, mass extinctions in Earth history occurred during much slower rates of ocean acidification, combined with other drivers changing, suggesting that evolutionary rates are not fast enough for sensitive animals and plants to adapt to the projected rate of future change (*medium confidence*; 6.1.2).

Projections of ocean acidification effects at ecosystem level are made difficult by the diversity of species-level responses. Differential sensitivities and associated shifts in performance and distribution will change predator-prey relationships and competitive interactions (6.3.2.5, 6.3.5-6), which could impact food webs and higher trophic levels (*limited evidence, high agreement*). Natural analogues at CO_2 vents indicate decreased species diversity, biomass and trophic complexity of communities (Box CC-CR; 5.4.2.3, 6.3.2.5, 30.3.2.2, 30.5). Shifts in community structure have also been documented in regions with rapidly declining pH (5.4.2.2).

Due to an incomplete understanding of species-specific responses and trophic interactions the effect of ocean acidification on global biogeochemical cycles is not well understood (*limited evidence, low agreement*) and represents an important knowledge gap. The additive, synergistic or antagonistic interactions of factors such as temperature, concentrations of oxygen and nutrients, and light are not sufficiently investigated yet.

Risks, Socioeconomic Impacts and Costs

The risks of ocean acidification to marine organisms, ecosystems, and ultimately to human societies, include both the probability that ocean acidification will affect fundamental physiological and ecological processes of organisms (6.3.2.1), and the magnitude of the resulting impacts on ecosystems and the ecosystem services they provide to society (Box 19-2). For example, ocean acidification under RCP4.5 to RCP8.5 will impact formation and maintenance of coral reefs (*high confidence*; Box CC-CR, 5.4.2.4) and the goods and services that they provide such as fisheries, tourism and coastal protection (*limited evidence, high agreement*; Box CC-CR, 6.4.1.1,19.5.2, 27.3.3, 30.5, 30.6). Ocean acidification poses many other potential risks, but these cannot yet be quantitatively assessed due to the small number of studies available, particularly on the magnitude of the ecological and socioeconomic impacts (19.5.2).

Global estimates of observed or projected economic costs of ocean acidification do not exist. The largest uncertainty is how the impacts on lower trophic levels will propagate through the food webs and to top predators. However, there are a number of instructive examples that illustrate the magnitude of potential impacts of ocean acidification. A decrease of the production of commercially-exploited shelled mollusks (6.4.1.1) would result in a reduction of US production of 3 to 13% according to the SRES A1FI emission scenario (*low confidence*). The global cost of production loss of mollusks could be over 100 billion USD by 2100 (*limited evidence, medium agreement*). Models suggest that ocean acidification will generally reduce fish biomass and catch (*low confidence*) and that complex additive, antagonistic and/or synergistic interactions will occur with other environmental (warming) and human (fisheries management) factors (6.4.1.1). The annual economic damage of ocean-acidification-induced coral reef loss by 2100 has been estimated, in 2009, to be 870 and 528 billion USD, respectively for the A1 and B2 SRES emission scenarios (*low confidence*; 6.4.1). Although this number is small compared to global GDP, it can represent a very large GDP loss for the economies of many coastal regions or small islands that rely on the ecological goods and services of coral reefs (25.7.5, 29.3.1.2).

Mitigation and Adaptation

Successful management of the impacts of ocean acidification includes two approaches: mitigation of the source of the problem (i.e. reduce anthropogenic emissions of CO_2), and/or adaptation by reducing the consequences of past and future ocean acidification (6.4.2.1). Mitigation of ocean acidification through reduction of atmospheric CO_2 is the most effective and the least risky method to limit ocean acidification and its impacts (6.4.2.1). Climate geoengineering techniques based on solar radiation management will not abate ocean acidification and could increase it under some circumstances (6.4.2.2). Geoengineering techniques to remove carbon dioxide from the atmosphere could directly address the problem but are very costly and may be limited by the lack of CO_2 storage capacity (6.4.2.2). Additionally, some ocean-based approaches, such as iron fertilization, would only re-locate ocean acidification from the upper ocean to the ocean interior, with potential ramifications on deep-water oxygen levels (6.4.2.2; 30.3.2.3 and 30.5.7). A low-regret approach, with relatively limited effectiveness, is to limit the number and the magnitude of drivers other than CO_2, such as nutrient pollution (6.4.2.1). Mitigation of ocean acidification at the local level could involve the reduction of anthropogenic inputs of nutrients and organic matter in the coastal ocean (5.3.4.2). Some adaptation strategies include drawing water for aquaculture from local watersheds only when pH is in the right range, selecting for less sensitive species or strains, or relocating industries elsewhere (6.4.2.1).

Box CC-PP. Net Primary Production in the Ocean

[Philip W. Boyd (New Zealand), Svein Sundby (Norway), Hans-Otto Pörtner (Germany)]

Net Primary Production (NPP) is the rate of photosynthetic carbon fixation minus the fraction of fixed carbon used for cellular respiration and maintenance by autotrophic planktonic microbes and benthic plants (6.2.1, 6.3.1). Environmental drivers of NPP include light, nutrients, micronutrients, carbon dioxide, and temperature (Panel A). These drivers in turn, are influenced by oceanic and atmospheric processes, including cloud cover, sea-ice extent, mixing by winds, waves and currents, convection, density stratification, and various forms of upwelling induced by eddies, frontal activity and boundary currents. Temperature has multiple roles as it influences rates of phytoplankton physiology and heterotrophic bacterial recycling of nutrients, in addition to stratification of the water column and sea-ice extent (Panel A). Climate change is projected to strongly impact NPP through a multitude of ways that depend on the regional and local physical settings (WGI, Ch. 3), and on ecosystem structure and functioning (*medium confidence*, 6.3.4, 6.5.1). The influence of environmental drivers on NPP causes as much as a 10-fold variation in regional productivity: from <50 g C m^{-2} $year^{-1}$ in nutrient-poor subtropical waters and light-limited Arctic waters to >> 300 g C m^{-2} $year^{-1}$ in productive upwelling regions and highly eutrophic coastal regions (Panel B).

The oceans currently provide ~50 x 10^{15} g C $year^{-1}$, or about half of global NPP (Field *et al*. 1998). Global estimates of NPP are mainly obtained from satellite remote-sensing (6.1.2), which provides unprecedented spatial and temporal coverage, and may be validated regionally against oceanic measurements. Observations reveal significant changes in rates of NPP when environmental controls are altered by episodic natural perturbations, such as volcanic eruptions enhancing iron supply, as observed in high-nitrate low-chlorophyll waters of the NE Pacific (Hamme *et al*., 2010). Climate variability can drive pronounced changes in NPP (Chavez *et al*., 2011), such as during El Niño to La Niña transitions in Equatorial Pacific, when vertical nutrient and trace element supply are enhanced (Chavez *et al*., 1999).

Multi-year time-series records of NPP have been used to assess spatial trends in NPP in recent decades. Behrenfeld *et al*. (2006) using satellite data, reported a prolonged and sustained global NPP decrease of 190 x 10^{12} g C $year^{-1}$, for the period 1999 to 2005 - an annual reduction of ~0.4 % of global NPP. In contrast, a time-series of directly measured NPP between 1988 to 2007 by Saba *et al*. (2010) (i.e. *in situ* incubations using the radiotracer ^{14}C-bicarbonate) revealed an increase (2 % $year^{-1}$) in NPP for two low latitude open ocean sites. This discrepancy between *in situ* and remotely-sensed NPP trends points to uncertainties in either the methodology used and/or the extent to which discrete sites are representative of oceanic provinces (Saba *et al*., 2010, 2011). Modeling studies have subsequently revealed that the <15 year archive of satellite-derived NPP is insufficient to distinguish climate-change mediated shifts in NPP from those driven by natural climate variability (Henson *et al*., 2010; Beaulieu *et al*., 2013). Although multidecadal, the available time-series of oceanic NPP measurements are also not of sufficient duration relative to the timescales of climate variability modes (up to 60-70 years for AMO, for example, Figure 6-1). Recent attempts to synthesize longer (i.e. centennial) records of chlorophyll as a proxy for phytoplankton stocks (e.g., Boyce *et al*., 2010) have been criticized for relying on questionable linkages between different proxies for chlorophyll over a century of records (e.g., Rykaczewski and Dunne, 2011).

Models in which projected climate-change alters the environmental drivers of NPP provide estimates of spatial changes and of the rate of change of NPP. For example, four global coupled climate-ocean biogeochemical Earth System Models (WGI Ch. 6) projected an increase in NPP at high latitudes as a result of alleviation of light and temperature limitation of NPP particularly in Northern and Southern Hemisphere 'subpolar gyre' biomes (Steinacher *et al*., 2010). However, this regional increase in NPP was more than offset by decreases in NPP at lower latitudes and at mid-latitudes due to the reduced input of macro-nutrients into the photic zone. The reduced mixed-layer depth and reduced rate of circulation may cause a decrease in the flux of macronutrients to the photic zone (Figure 6-2). These changes to oceanic conditions result in a reduction in global mean NPP by 2 to 13% by 2100 relative to 1860 under a high emission scenario (Polovina *et al*., 2011; SRES A2, between RCP6.0 and RCP8.5). This is consistent with a more recent analysis based on 10 Earth System Models (Bopp *et al*., 2013), which project decreases in global NPP by 8.6 (±7.9), 3.9 (±5.7), 3.6 (±5.7), 2.0 (±4.1) % in the 2090s relative to the 1990s, under the scenarios RCP8.5, RCP6.0, RCP4.5 and RCP2.6, respectively. However, the magnitude of projected changes varies widely between models (e.g. from 0 to 20% decrease in NPP globally under RCP 8.5). The various models show very large differences in NPP at regional (i.e. provinces, see panel B) scales.

Earlier model projections had predicted changes in global NPP from a decrease of > 10% (Field *et al*., 1998; Boyd and Doney, 2002) to an increase of up to 8.1% under an intermediate scenario (SRES A1B, similar to RCP6.0) (Sarmiento *et al*., 2004; Schmittner *et al*., 2008). These projections did not consider the potential contribution of primary production derived from atmospheric nitrogen fixation in tropical and subtropical regions, favoured by increasing stratification and reduced nutrient inputs from mixing. This mechanism is potentially important, although such episodic increases in nitrogen fixation are not sustainable without the presence of excess phosphate (e.g. Moore *et al*., 2009; Boyd *et al*., 2010). This may lead to an underestimation of NPP (Mohr *et al*., 2010; Mulholland *et al*., 2012; Wilson *et al*., 2012), however, the extent of such underestimation is unknown (Luo *et al*., 2012).

Care must be taken when comparing global, provincial (e.g. low latitude waters, for example Behrenfeld *et al*., 2006) and regional trends in NPP derived from observations, as some regions have additional local environmental influences such as enhanced density stratification of the upper ocean from melting sea ice. For example, a longer phytoplankton growing season, due to more sea-ice free days, may have increased NPP (based on a regionally validated time-series of satellite NPP) in Arctic waters (Arrigo and van Dijken, 2011) by an average of 8.1 Tg C year^{-1} between 1998 and 2009. Other regional trends in NPP are reported in 30.5.1-6. In addition, although future model projections of global NPP from different models (Steinacher *et al*., 2010; Bopp *et al*., 2013) are comparable, regional projections from each of the models differ substantially. This raises concerns as to which aspect(s) of the different model NPP parameterizations are responsible for driving regional differences in NPP, and moreover, how accurate model projections are of global NPP.

From a global perspective, open ocean NPP will decrease moderately by 2100 under both low (SRES B1 or RCP4.5) and high emission scenarios (A2 or RCP6.0 - 8.5, 6.3.4, 6.5.1, *medium confidence*), paralleled by an increase in NPP at high latitudes and a decrease in the tropics (*medium confidence*). However, there is *limited evidence* and *low agreement* on the direction, magnitude and differences of a change of NPP in various ocean regions and coastal waters projected by 2100 (*low confidence*).

[INSERT FIGURE PP-1 HERE
Figure PP-1: A) Environmental factors controlling Net Primary Production (NPP). NPP is mainly controlled by three basic processes: 1) Light conditions in the surface ocean, i.e. the photic zone where photosynthesis occurs, 2) upward flux of nutrients and micronutrients from underlying waters into the photic zone, 3) Regeneration of nutrients and micronutrients via the breakdown and recycling of organic material before it sinks out of the photic zone. All three processes are influenced by physical, chemical and biological processes and vary across regional ecosystems. In addition, water temperature strongly influences the upper rate of photosynthesis for cells that are resource-replete. Predictions of alteration of primary productivity under climate change depend on correct parameterizations and simulations of each of these variables and processes for each region. B) Annual composite map of global areal NPP rates (derived from MODIS Aqua satellite climatology from 2003-2012; NPP was calculated with the Carbon-based Production Model (CbPM, Westberry *et al*., 2008)). Overlaid is a grid of (thin black lines) that represent 51 distinct global ocean biogeographical provinces (after Longhurst, 1998 and based on Boyd and Doney, 2002). The characteristics and boundaries of each province are primarily set by the underlying regional ocean physics and chemistry. Box CC-UP. Uncertain Trends in Major Upwelling Ecosystems

[Salvador E. Lluch-Cota (Mexico), Ove Hoegh-Guldberg (Australia), David Karl (USA), Hans O. Pörtner (Germany), Svein Sundby (Norway), Jean-Pierre Gatusso (France)]

Upwelling is the vertical transport of cold, dense, nutrient-rich, relatively low-pH and often oxygen-poor waters to the euphotic zone where light is abundant. These waters trigger high levels of primary production and a high biomass of benthic and pelagic organisms. The driving forces of upwelling include wind stress and the interaction of ocean currents with bottom topography. Upwelling intensity also depends on water column stratification. The major upwelling systems of the Planet, the Equatorial Upwelling System (EUS, 30.5.2, Figure 30.1A) and the Eastern Boundary Upwelling Ecosystems (EBUE, 30.5.5, Figure 30.1A), represent only 10% of the ocean surface but contribute nearly 25 % to global fish production (Figure 30.1B, Table S30.1).

Marine ecosystems associated with upwelling systems can be influenced by a range of 'bottom-up' trophic mechanisms, with upwelling, transport, and chlorophyll concentrations showing strong seasonal and interannual couplings and variability. These, in turn, influence trophic transfer up the food chain, affecting zooplankton, foraging fish, seabirds and marine mammals.

There is considerable speculation as to how upwelling systems might change in a warming and acidifying ocean. Globally, the heat gain of the surface ocean has increased stratification by 4% (WGI 3.2, 3.4.4, 3.8), which means that more wind energy is needed to bring deep waters to the surface. It is as yet unclear to what extent wind stress can offset the increased stratification, due to the uncertainty in wind speed trends (WGI, 3.4.4). In the tropics, observations of reductions in trade winds over several decades contrast more recent evidence indicating their strengthening since the early 1990s (WGI, 9.4.1.3.4). Observations and modelling efforts in fact show diverging trends in coastal upwelling at the eastern boundaries of the Pacific and the Atlantic. Bakun (1990) proposed that the the difference in heat gaining rates between land and ocean causes an increase in the pressure gradient, which results in increased alongshore winds and leads to intensified offshore transport of surface water through Ekman pumping, and the upwelling of nutrient rich, cold waters (Figure CC-UP). Some regional records support this hypothesis, others do not. There is considerable variability in warming and cooling trends over the past decades both within and among systems making it difficult to predict changes in the intensity of all Eastern Boundary Upwelling Ecosystems (30.5.5).

Understanding whether upwelling and climate change will impact resident biota in an additive, synergistic or antagonistic manner is important for projections of how ecological goods and services provided for human society will change. Even though upwellings may prove more resilient to climate change than other ocean ecosystems because of their ability to function under extremely variable conditions (Capone and Hutchins, 2013), consequences of their shifts are highly relevant since these are the most biologically active systems in the ocean. Increased upwelling would enhance fisheries yields. However, the export of organic material from surface to deeper layers of the ocean may increase and stimulate its decomposition by microbial activity, thereby enhancing oxygen depletion and CO_2 enrichment in deeper water layers. Once this water returns to the surface through upwelling benthic and pelagic coastal communities will be exposed to acidified and deoxygenated water which may combine with anthropogenic impact to negatively affect marine biota and ecosystem structure of the upper ocean (high confidence, 6.3.2, 6.3.3; 30.3.2.2, 30.3.2.3). Extreme hypoxia may result in abnormal mortalities of fishes and invertebrates (Keller *et al.*, 2010), reduce the fisheries catch potential and impact aquaculture in coastal areas (5.4.3.3, 6.3.7, 30.5.1.1.2, 30.5.5.1.3, Barton *et al.*, 2012). Shifts in upwelling also coincide with an apparent increase in the frequency of submarine eruptions of methane and hydrogen sulphide gas, caused by enhanced formation and sinking of phytoplankton biomass to the hypoxic or anoxic sea floor . This combination of factors has been implicated in the extensive mortality of coastal fishes and invertebrates (Bakun and Weeks, 2004), resulting in significant reductions in fishing productivity, such as Cape hake (*Merluccius capensis*), Namibia's most valuable fishery (Hamukuaya *et al*., 1998).

Reduced upwelling would also reduce the productivity of important pelagic fisheries, such as for sardines, anchovies and mackerel, with major consequences for the economies of several countries (6.4.1, Chp 7, Figure 30.1A, B, Table S30.1). However, under projected scenarios of reduced upward supply of nutrients due to stratification of the open ocean , upwelling of both nutrients and trace elements may become increasingly important to maintaining upper ocean nutrient and trace metal inventories. It has been suggested that upwelling areas may also increase nutrient content and productivity under enhanced stratification, and that upwelled and partially denitrified waters containing excess phosphate may select for N_2-fixing microorganisms (Deutsch *et al*., 2007; Deutsch and Weber, 2012), but field observations of N2 fixation in these regions have not supported these predictions (Fernandez *et al*., 2011; Franz *et al*., 2012). The role of this process in global primary production thus needs to be validated (*low confidence*).

The central question therefore is whether or not upwelling will intensify, and if so, whether the effects of intensified upwelling on O_2 and CO_2 inventories will outweigh its benefits for primary production and associated fisheries and aquaculture (*low confidence*). In any case increasing atmospheric CO_2 concentrations will equilibrate with upwelling waters that may cause them to become more corrosive, depending upon pCO_2 of the upwelled water, and potentially increasingly impact the biota of Eastern Boundary Upwelling Ecosystems.

[INSERT FIGURE UP-1 HERE
Figure UP-1: Upper panel: Schematic hypothetic mechanism of increasing coastal wind-driven upwelling at eastern boundary systems, where differential warming rates between land and ocean results in increased land-ocean pressure gradients (1) that produce stronger alongshore winds (2) and offshore movement of surface water through Ekman transport (3), and increased upwelling of deep cold nutrient rich waters to replace it (4). Lower panel: potential consequences of climate change in upwelling systems. Increasing stratification and uncertainty in wind stress trends result in uncertain trends in upwelling. Increasing upwelling may result in higher input of nutrients to the euphotic zone, and increased primary production, which in turn may enhance pelagic fisheries, but also decreased coastal fisheries due to an augmented exposure of coastal fauna to hypoxic, low pH waters. Decreased upwelling may result in lower primary production in these systems with direct impacts on pelagic fisheries productivity.]

Table 30-1: Regional changes in sea surface temperature (SST) over the period 1950–2009 using the Ocean regionalization specified in Figure 30-1a (for further detail of regions defined for analysis, see Figure SM30-1 and Table 30-2, column 1). A linear regression was fitted to the average of all 1×1 degree monthly SST data extracted from the HadISST1.1 data set [*Rayner et al.*, 2003] for each sub-region over the period 1950–2009. All SST values less than -1.8ºC, together with all SST pixels that were flagged as being sea ice, were reset to the freezing point of seawater (-1.8ºC) to reflect the sea temperature under the ice. Separate analyses were also done to explore trends in the temperatures extracted from the coldest-ranked and the warmest-ranked month of each year (Table SM30-2). The table includes the slope of the regression (°C $decade^{-1}$), the p-value for the slope being different from zero and the total change over 60 years (i.e., the slope of linear regression multiplied by 6 decades) for each category. The p-values that exceed 0.05 plus the associated slope and change values have a gray background, denoting the lower statistical confidence in the slope being different from zero (no slope). Note, changes with higher p-values may still describe informative trends although the level of confidence is lower that the slope is different from zero.

	Regression slope			**Total change over 60 years**			**p value, slope different from zero**		
Sub-region	**°C/Decade Coolest Month**	**°C/Decade All months**	**°C/Decade Warmest Month**	**Change over 60 years (coolest month)**	**Change over 60 years (all months)**	**Change over 60 years (warmest month)**	**°C/Decade Coolest Month**	**°C/Decade All months**	**°C/Decade Warmest Month**

Table 30-2: Examples of priority adaptation options and supporting policies to assist Pacific Island countries and territories to minimize the threats of climate change to the socio-economic benefits derived from pelagic and coastal fisheries and aquaculture, and to maximize the opportunities. These measures are classified as 'win-win' (W-W) adaptations, which address other drivers of the sector in the short-term and climate change in the long-term, or 'lose-win' (L-W) adaptations, where benefits exceed costs in the short-term but accrue under longer-term climate change (modified from [*Bell et al.*, 2013b]).

Adaptation options	Supporting policies
Economic development	
• Full implementation of the vessel day scheme (VDS) to control fishing effort by the Parties to the Nauru Agreements (W-W). • Diversify sources of fish for canneries in the region and maintain trade agreements, e.g., an Economic Partnership Agreement with the European Union (W-W). • Continued conservation and management measures for all species of tuna to maintain stocks at healthy levels and make these valuable species more resilient to climate change (W-W). • Energy efficiency programmes to assist fleets to cope with oil price rises and minimise CO_2 emissions, and reduce costs of fishing further afield as tuna distributionsshift east (W-W). • Pan-Pacific tuna management through merger of the Western and Central Pacific Fisheries Commission (WCPFC) and Inter-American Tropical Tuna Commission to coordinate management measures across the tropical Pacific (L-W).	• Strengthen national capacity to administer the VDS. • Adjust national tuna management plans and marketing strategies to provide flexible arrangements to buy and sell tuna. • Include implications of climate change in management objectives of the WCPFC. • Apply national management measures to address climate change effects for subregional concentrations of tuna in archipelagic waters beyond the mandate of WCPFC. • Require all industrial tuna vessels to provide operational-level catch and effort data to improve the models for redistribution of tuna stocks during climate change.
Food security	
• Manage catchment vegetation to reduce transfer of sediments and nutrients to coasts to reduce damage to adjacent coastal coral reefs, mangroves and seagrasses that support coastal fisheries (W-W). • Foster the care of coral reefs, mangroves and seagrasses by preventing pollution, managing waste and eliminating direct damage to these coastal fish habitats (W-W). • Provide for migration of fish habitats by prohibiting construction adjacent to mangroves and seagrasses and installing culverts beneath roads to help the plants colonise landward areas as sea level rises; (L-W). • Sustain and diversify catches of demersal coastal fish to maintain the replenishment potential of all stocks (L-W). • Increase access to tuna caught by industrial fleets through storing and selling tuna and by-catch landed at major ports to provide inexpensive fish for rapidly growing urban populations (W-W). • Install fish aggregating devices (FADs) close to the coast to improve access to fish for rural communities	• Strengthen governance for sustainable use of coastal fish habitats by: (1) building national capacity to understand the threats of climate change; (2) empowering communities to manage fish habitats; and (3) changing agriculture, forestry and mining practices to prevent sedimentation and pollution. • Minimise barriers to landward migration of coastal habitats during development of strategies to assist other sectors to respond to climate change. • Apply 'primary fisheries management' to stocks of coastal fish and shellfish to maintain their potential for replenishment. • Allocate the necessary quantities of tuna from total national catches to food security to increase access to fish for both urban and coastal populations. • Dedicate a proportion of the revenue from fishing licences to improve access to tuna for food security. • Include anchored inshore FADs as part of national infrastructure for food security.

as human populations increase and demersal fish decline (W-W). • Develop coastal fisheries for small pelagic fish species, e.g. mackerel, anchovies, pilchards, sardines and scads (W-W?). • Promote simple post-harvest methods, such as traditional smoking, salting and drying, to extend the shelf life of fish when abundant catches are landed (W-W).	
Livelihoods	
• Relocate pearl farming operations to deeper water and to sites closer to coral reefs and seagrass/algal areas where water temperatures and aragonite saturation levels are likely to be more suitable for good growth and survival of pearl oysters, and formation of high-quality pearls (L-W). • Raise the walls and floor of shrimp ponds so that they drain adequately as sea level rises (L-W). • Identify which shrimp ponds may need to be rededicated to producing other commodities (L-W).	• Provide incentives for aquaculture enterprises to assess risks to infrastructure so that farming operations and facilities can be ‘climate-proofed’ and relocated if necessary. • Strengthen environmental impact assessments for coastal aquaculture activities to include the additional risks posed by climate change. • Develop partnerships with regional technical agencies to provide support for development of sustainable aquaculture.

a = The Parties to the Nauru Agreement (PNA) are Palau, Federated States of Micronesia, Papua New Guinea, Solomon Islands, Marshall Islands, Nauru, Kiribati, and Tuvalu.

Table 30-3: Key risks to ocean and coastal issues from climate change and the potential for risk reduction through mitigation and adaptation. Key risks are identified based on assessment of the literature and expert judgments made by authors of the various WGII AR5 chapters, with supporting evaluation of evidence and agreement in the referenced chapter sections. Each key risk is characterized as very low, low, medium, high, or very high. Risk levels are presented for the near-term era of committed climate change (here, for 2030–2040), in which projected levels of global mean temperature increase do not diverge substantially across emissions scenarios. Risk levels are also presented for the longer-term era of climate options (here, for 2080–2100), for global mean temperature increases of 2°C and 4°C above pre-industrial levels. For each timeframe, risk levels are estimated for the current state of adaptation and for a hypothetical highly adapted state. As the assessment considers potential impacts on different physical, biological, and human systems, risk levels should not necessarily be used to evaluate relative risk across key risks. Relevant climate variables are indicated by symbols.

Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
Risks to ecosystems and adaptation options					
Changes in ecosystem productivity associated with the redistribution and loss of net primary productivity in open oceans, with regional differences in gains and losses (*medium confidence*)	To maintain existing levels of seafood production, adaptation options are limited to the relocation of industrial fishing activities due to regional decreases (low latitude) versus increases (high latitude) in productivity, and/or to the expansion of aquaculture.		6.1.1, 6.3.4, 6.5.1, 30.5.1-2, Table 30-4 Box CC-PP	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Very low – Medium – Very high
Distributional shift in fish and invertebrate species, fall in fishery catch potential at low latitudes, e.g., in EUS, CBS and STG regions (*high confidence*)	Evolutionary adaptation potential of fish and invertebrate species to warming is limited. Human adaptation options involve adjusting fishing gears and fishing grounds, and the large scale relocation of industrial fishing activities following the regional decreases (low latitude) versus (possibly transient) increases (high latitude) in catch potential, as well deploying flexible management that can react to variability and change. Further options include building resilience by reducing other stressors like pollution and eutrophication, diversification of fish catches, or the expansion of aquaculture.		6.1.1, 6.3.1, 6.5.2-3 30.5.1-4, 30.5.6, 30.6.2, Box CC-MB	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Very low – Medium – Very high
High mortalities and loss of habitat to larger fauna including commercial species due to hypoxia expansion and effects, particularly in EBUE, some SES and CBS regions (*high confidence*)	Human adaptation options involve the large scale relocation of fishing activities as a consequence of the hypoxia induced decreases in biodiversity and fisheries catch of pelagic fish and squid. Specific fisheries may benefit (Humboldt squid). Reducing the amount of organic carbon running of coastlines by controlling nutrients and pollution running off agricultural areas can reduce microbial activity and consequently limit the extent of the oxygen drawdown and the formation of coastal dead zones.		6.1.1, 6.3.3, 30.5.3-5	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Very low – Medium – Very high
Ocean acidification: Reduced growth and survival of commercially valuable shellfish and other calcifiers, e.g., reef building corals, calcareous red algae (*high confidence*)	Evidence for differential resistance and evolutionary adaptation of some species exists but is likely to be limited at higher CO2 concentrations and temperatures reached; adaptation options include the shift to exploiting more resilient species or the protection of habitats with low natural CO2 levels, as well as the reduction of other stresses, mainly pollution and limiting pressures from tourism and fishing.		5.3.3.5, 6.1.1, 6.3.2, 6.4.1.1, 30.3.2.2, Box CC-OA	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Very low – Medium – Very high
Reduced biodiversity, fisheries abundance and coastal protection by coral reefs due to heat induced mass coral bleaching and mortality increases, e.g., in CBS, SES, and STG regions (*high confidence*)	Evidence of rapid evolution by corals is limited or non-existent. Some corals may migrate to higher latitudes. However, the movement of entire reef systems is unlikely. Human adaptation options are limited to reducing other stresses, mainly enhancing water quality and limiting pressures from tourism and fishing. This option will delay the impacts of climate change by a few decades but is likely to disappear as thermal stress increases.		5.4.2.4, 6.3.1-2, 6.4.2, 30.5.4-6 Box CC-CR	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Very low – Medium – Very high
Coastal inundation and habitat loss due to sea level rise and intensified precipitation and flood events, e.g., in CBS and STG subregions (*medium to high confidence*)	Options to maintain ecosystem integrity are limited to the reduction of other stresses, mainly pollution and limiting pressures from tourism, fishing and aquaculture. Loss of ecosystems such as sea grass, mangroves and coral reefs can be reduced by reducing deforestation and increasing reforestation of river catchments and coastal areas to retain sediments and nutrients. Application of "Blue Carbon' strategies to avoid degradation of coastal vegetated habitats and loss of carbon sinks, and enhance carbon sequestration.		5.4.2.3-7, 30.6.1, 30.6.2.2 Box CC-CR	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Very low – Medium – Very high
Marine biodiversity loss with high rate of climate change (*medium confidence*)	Adaptation options are limited to the reduction of other stresses, mainly to reducing pollution and to limiting pressures from coastal human activities such as tourism and fishing.		6.3.1-3, 6.4.1.2-3 Table 30.4 Box CC-MB	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Very low – Medium – Very high

Climatic drivers of impacts: Warming trend; Extreme temperature; Precipitation; Extreme precipitation; Damaging cyclone; Sea level; Hypoxia; Ocean acidification

Risk & potential for adaptation: Potential for adaptation to reduce risk; Risk level with **high** adaptation; Risk level with **current** adaptation

Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
Risks to fisheries					
Decreased production of global shellfish fisheries, especially in HLSBS, EBUE and CBS (*high confidence*)	Help facilitate shift to alternative livelihoods by vulnerable people, changes in food consumption patterns and adjustment of (global) markets.		6.3.2, 6.3.5, 6.4.1.1, 30.5.5, 30.6.2, Box CC-OA	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high
Global redistribution and decrease of low latitude fisheries yields are paralleled by a global trend to catches having smaller fishes, particularly in STG and CBS (*medium confidence*)	Reduced food security and the increasing coastal poverty at low latitudes as fisheries becomes smaller - partially compensated by the expansion of aquaculture and marine spatial planning, to protect and enhance fisheries production as well as enhanced industrialized fishing efforts.		6.3.1, 6.4.1, 6.5.3, 30.5.4, 30.5.6, 30.6.2, Table 30-3	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high
Redistribution of catch potential of large pelagic-highly migratory fish resources, such as tropical Pacific and Indian Ocean tuna fisheries (*high confidence*)	International fisheries agreements and instruments, such as cooperative agreements over tuna, may have limited success in establishing sustainable fisheries yields.		6.3.1, 6.4.3, Table 30-2, Table 30-4	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high
Variability of small pelagic fishes in EBUE and EUS is becoming more extreme at interannual to multidecadal scales, making industry and management decisions more uncertain (*medium confidence*)	Development of new and specific management tools and models may have limited success to sustain yields. Reduction in fishing intensity has potential to increase resilience of the fisheries. Reduction of aquaculture dependance on fishmeal and fishoil from small pelagic fish.		6.3.2-3, 30.5.2, 30.5.5, 30.6.2 Table 30.4 Box CC-UP	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high
Decrease in catch and species diversity of fisheries in tropical coral reefs, exacerbated by interactions with other human drivers such as eutrophication and habitat destruction (*high confidence*)	Restoration of overexploited fisheries and reduction of other stressors on coral reefs delay ecosystem changes. Human adaptation includes the usage of alternative livelihoods and food sources (e.g., coastal aquaculture).		6.4.1, 30.5.3-4, 30.5.6, Table 30-3, Table 30-4 Box CC-CR	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high
Current spatial management units, especially the MPAs may fail in the future due to shifts in species distribution and community structure (*high confidence*) MPA: Marine Protected Area	Continuous revision and shifts of MPA borders, and of MPA goals and performance.		6.3.1, 6.4.2.1, 30.5.1, Box CC-MB	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high
Risks to humans and infrastructure					
Coastal socio-economic security from changing habitat and ecosystem structure, as well as sea level rise (*high confidence*)	Human adaptation options involve (1) Protection using coastal defences (e.g. seawalls) and soft measures (e.g. mangrove replanting and enhancing coral growth), (2) Accommodation to allow continued occupation of coastal areas by making changes to human activities and infrastructure, and (3) Managed retreat may represent only option in some areas. Vary from large-scale engineering works to smaller scale community projects. Options are available under the more traditional CZM (coastal zone management) framework but increasingly under DRR (disaster risk reduction) and CCA (climate change adaptation) frameworks.		5.5.2, 5.5.4, 30.6.5, 30.7.1, Table 30-3, Table 30-4	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high *
Reduced livelihoods and increased poverty (*medium confidence*)	Human adaptation options involve the large scale relocation of industrial fishing activities following the regional decreases (low latitude) versus increases (high latitude) in catch potential and shifts in biodiversity. Artisanal local fisheries are extremely limited in their adaptation options by available financial resources and technical capacities, except for their potential shift to other target species.		6.4.1-2, 30.6.2, 30.6.5, Table 30-3	Present; Near-term (2030-2040); Long-term (2080-2100) 2°C, 4°C	Very low – Medium – Very high

*high confidence in existence of adaptation measures, low confidence in magnitude of risk reduction

Climatic drivers of impacts: Warming trend; Extreme temperature; Precipitation; Extreme precipitation; Damaging cyclone; Sea level; Hypoxia; Ocean acidification

Risk & potential for adaptation: Potential for adaptation to reduce risk; Risk level with **high** adaptation; Risk level with **current** adaptation

Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
Risks to humans and infrastructure (continued)					
Impacts due to increased frequency of harmful algal blooms (*medium confidence*)	Adaptation options include improved monitoring and early warning system, reduction of stresses favouring harmful algal blooms, mainly pollution and eutrophication, as well as the avoidance of contaminated areas and fisheries products.		6.4.2.3, 30.6.3, Table 30-4	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Impacts on marine resources threatening regional security as territorial disputes and food security challenges increase (*limited evidence, medium agreement*)	Decrease in marine resources, movements of fish stocks and opening of new seaways , and impacts of extreme events coupled with increasing populations will increase the potential for conflict in some regions, drive potential migration of people and increase humanitarian crises.		AR5 SREX, 30.6.5, 30.7.2 12.4-12.6, 29.3	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Impacts on shipping and infrastructure for energy and mineral extraction increases as storm intensity and wave height increase in some regions (e.g., high latitudes) (*high confidence*)	Adaptation options are to limit activities to particular times of the year and/or develop strategies to decrease the vulnerability of structures and operations.		AR5 SREX, 30.6.2.3-4, Table 30-4	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	

Table 30-4: Ramifications, adaptation options and frameworks for decision-making for ocean regions. Symbols are as follows: T = sea temperature; UW = upwelling; OA = ocean acidification; NU = nutrient concentration; IC = ice cover; SS = storm strength; SLR = sea level rise (↑ = Increased; ↓ = decreased; italics = uncertain). Acronyms are: CBD (Convention on Biological Diversity); CTI (Coral Triangle Initiative); GEF (Global Environment Facility); IHO (International Hydrographic Organization); ILO (International Labor Organization); IOM (International Organization of Migration); ISPS (International Ship and Port Facility Security); MARPOL (International Convention for the Prevention of Pollution From Ships); PACC (Pacific Adaptation to Climate Change Project); PEMSEA (Partnerships in Environmental Management for the Seas of East Asia); RFMO (Regional Fisheries Management Organizations); SPREP (Secretariat of the Pacific Regional Environment Programme); UNCLOS (United Nations Convention on the Law of the Sea); UNHCR (United Nations High Commissioner for Refugees); UNSFSA (Straddling Fish Stocks Agreement); and WHO (World Health Organization).

Primary driver(s)	**Biophysical change projected**	**Key risks and vulnerabilities**	**Ramifications**	**Adaptation options**	**Policy frameworks and initiatives (examples)**	**Key References and Chapter sections**
↑**T**, ↑*OA*	Spatial and temporal variation in primary productivity (*medium confidence* at global scales, Box CC-PP)	Reduced fisheries production impacts important sources of income to some countries while others may see increase productivity (e.g., as tuna stocks shift eastwards in the Pacific)(*medium confidence*).	Reduced national income, increased unemployment, plus increase in poverty. Potential increase in disputes over national ownership of key fishery resources (*likely*)	Increased international cooperation over key fisheries. Improved understanding of linkages between ocean productivity, recruitment and fisheries stock levels. Implementation of the regional 'vessel day scheme', provide social and economic incentives to fisheries and fishersfor adaptation,.	LOSC, PEMSEA, CTI, RFMO agreements, UNSFSA,	[*Tsamenyi and Hanich*, 2012] [*Bell et al.*, 2011; *Bell et al.*, 2013a] 6.4.1, 6.5.3, 30.6.2.1, 30.7.2, Box CC-PP,
↑**T**, ↑*OA*	Ecosystem regime shifts (e.g., coral to algal reefs; structural shifts in phytoplankton communities, *medium confidence*)	Reduced fisheries production as coastal habitats and ecosystems such as coral reefs (*medium confidence*).	Decreased food and employment security and human migration away from coastal zone (*likely*)	Strengthen coastal zone management to reduce contributing stressors (e.g., coastal pollution, over-harvesting and physical damage to coastal resources). Promote Blue Carbon* initiatives.	PEMSEA, CTI, PACC, MARPOL, UNHCR, CBD, IOM, GEF, ILO	[*Bell et al.*, 2013a]; 5.4.3, 6.3.1-2, 12.4, 30.5.2-4, 29.3.1, 29.3.3, 30.5.6, 30.6.1, 30.6.2.1, Box CC-CR
		Tourist appeal of coastal assets decreases as ecosystems change to less 'desirable' state reducing income to some countries (*low confidence*).	Increased levels of coastal poverty in some countries as tourist income decreases (*likely*).	As above, strengthen coastal zone management and reduce additional stressors on tourist sites; implement education programs and awareness among visitors. Diversify tourism activities.	CBD, PEMSEA, CTI, PACC, UNHCR, MARPOL	[*Kenchington and Warner*, 2012], 5.5.4.1, 6.4.1–2, 10.6, 30.6.2.2,

Primary driver(s)	Biophysical change projected	Key risks and vulnerabilities	Ramifications	Adaptation options	Policy frameworks and initiatives (examples)	Key References and Chapter sections
		Increased risk of some diseases (e.g., ciguatera, harmful algal blooms) as temperatures increase shift and ecosystems shift away from coral dominance (*low confidence*)	Increased disease and mortality; decreases in coastal food resources and fisheries income (*likely*).	Increased monitoring and education surrounding key risks (e.g., ciguatera); develop alternate fisheries and income for periods when disease incidence increases, develop or update health response plans.	National policy strategies as well as and regional cooperation needed	[*Llewellyn*, 2010] 6.4.2.3, 10.6, 29.3.3.2, 29.5.3, 30.6.3,
		Increased poverty and dislocation of coastal people (particularly in the tropics) as coastal resources such as fisheries degrade (*medium confidence*).	Increased population pressure on migration destinations (e.g. large regional cities), and reduced freedom to navigate in some areas (as criminal activity increases; *likely*).	Develop alternative industries and income for affected coastal people. Strengthen coastal security both nationally and across regions. Increase cooperation over criminal activities.	UNCLOS, PEMSEA, CTI, ISPS, IMO, Bali Process on Transnational Crime ASEAN Mutual legal Assistance treaty and bilateral extradition and MLA agreements	[*Kaye*, 2012; *Rahman*, 2012] 12.4-6,29.3.3, 29.6.2, 30.6.5
↑T	Migration of organisms and ecosystems to higher latitudes (*high confidence*).	Reorganization of commercial fish stocks and ecological regime shifts (medium to high confidence).	Social and economic disruption (*very likely*)	Increased international cooperation and improve understanding of regime changes; early-detection monitoring of physical and biological variables and regional seasonal forecasting; include related uncertainties into fisheries management; social and economic incentives for industry.	UNCLOS, CBD, RFMO agreements, UNSFSA	7.4.2, 6.5, 30.5, 30.6.2.1, Box CC-MB,
		Increased in abundance, growing season and distributional extent ofpests and fouling species (*medium confidence*).	Increased disease risk to aquaculture and fisheries. Income loss and increased operating and maintenance costs (*very likely*)	Increase environmental monitoring; ; technological advances to deal with pest and fouling organisms; increase vigilance and control related to biosecurity.	IMO, BWM, Anti Fouling Convention	6.4.1.5, 7.3.2.4, 29.5.3-4, 30.6.2.1, Box CC-MB
		Threats to human health increase due to expansion of pathogens distribution to higher latitudes (*low confidence*).	Increased disease and mortality in some coastal communities (*likely*)	Reduce exposure through increased monitoring and education, adoption or update of health response plans to outbreaks	UNICEF, WHO, IHOs, and national governments.	[*Myers and Patz*, 2009]; 6.4.3, 10.8.2, 11.7, 29.3.3, 30.6.3, Box CC-MB

Primary driver(s)	**Biophysical change projected**	**Key risks and vulnerabilities**	**Ramifications**	**Adaptation options**	**Policy frameworks and initiatives (examples)**	**Key References and Chapter sections**
↑T, ↑NU, ↑*OA*	Increased incidence of harmful algal blooms (HABs, *low confidence*).	Increased threats to ecosystems, fisheries and human health (*medium confidence*).	Reduced supply of marine fish and shellfish and greater incidence of disease among some coastal communities (*likely*).	Provide early-detection monitoring and improve predictive models, provide education and adoption or update of health response plans.	CTI, PEMSEA, WHO, MARPOL	[*Llewellyn*, 2010], 30.6.3, 11.7, 6.4.2.3
↑T	Increased precipitation as a result of intensified hydrological cycle in some coastal areas (*medium confidence*)	Increased freshwater, sediment and nutrients flow into coastal areas, increase in number and severity of flood events(*medium to high confidence*).	Increasing damage to coastal reef systems with ecological regime shifts in many cases (*very likely*).	Improve management of catchment and coastal processes; expand riparian vegetation along creeks and rivers; improve agricultural retention of soils and nutrients.	CTI, PEMSEA, SPREP	3.4, 29.3.1, 30.5.4, 30.6.1
↑T	Changing weather patterns,, storm frequency , *medium confidence*)	Increased risk of damage to infrastructure such as that involved in shipping, and oil and gas exploration and extraction (*medium to low confidence*).	Increased damage and associated costs (*likely*)	Adjust infrastructure specifications, Developearly-warning systems and update emergency response plans to extreme events.	IMO	[*IPCC*, 2012], 10.4.4, 29.3, 30.6.2.3-4
↑SLR, **↑*SS***	Increased wave exposure of coastal areas and increased sea level (*high confidence*)	Exposure of coastal infrastructure and communities to damage and inundation, increase coastal erosion (*high confidence*)	Increased costs to human towns and settlements, numbers of displaced people and human migration (*very likely*).	Develop integrated coastal management that consider SLR in planning and decision-making; increase understanding of the issues through education.	UNICEF, IHOs, and national governments.	[*Warner*, 2012] 5.5, 12.4.1, 29.5.1, 30.3.1.2, 30.6.5
		Inundation of coastal aquifers reduces water supplies and decreased coastal agricultural productivity (*high confidence*).	Reduced food and water security leads to increased coastal poverty, reduced food security, and migration (*very likely*).	Assist communities to find alternatives for food and water, or assist in relocation of populations and agriculture from vulnerable areas.	UNICEF, IHOs, and national governments.	[*Warner*, 2012], 5.4.3, 12.4.1, 29.3.2, 30.3.1.2

Primary driver(s)	Biophysical change projected	Key risks and vulnerabilities	Ramifications	Adaptation options	Policy frameworks and initiatives (examples)	Key References and Chapter sections
↑SLR	Risk of inundation and coastal erosion, especially in low-lying countries (*high confidence*).	UNCLOS defined limits of maritime jurisdiction will contract as national baselines shift inland. Potential uncertainty increases in some areas with respect to the international boundaries to maritime jurisdiction (*high confidence*).	Lack of clarity increases as do disputes over maritime limits and maritime jurisdiction. Some nations at risk of major losses to their territorial waters (*very likely*).	Seek resolution of 'shifting national baselines' issue (retreat and redefinition, stabilization, or fixation of EEZ and other currently defined maritime jurisdiction limits.	UNCLOS	[*IPCC*, 2012; *Schofield and Arsana*, 2012; *Warner and Schofield*, 2012] 5.5, 30.6.5
↑T, ↓IC	Loss of summer sea ice (*high confidence*)	Access to northern coasts of Canada, USA and Russia increases security concerns (*high confidence*).	Potential for increased tension on different interpretations of access rights and boundaries (*likely to very likely*).	Seek early resolution of areas in dispute currently and in the future.	UNCLOS	Chapter 28
		New resources become available as ice retreats, increasing vulnerability of international borders in some cases (*medium confidence*).	Tensions over maritime claims and ownership of resources (*likely*).	International agreements need to be sorted.	UNCLOS	Chapter 28

*Blue Carbon initiatives include conservation and restoration of mangroves, saltmarsh and seagrass beds as carbon sinks (30.6.1).

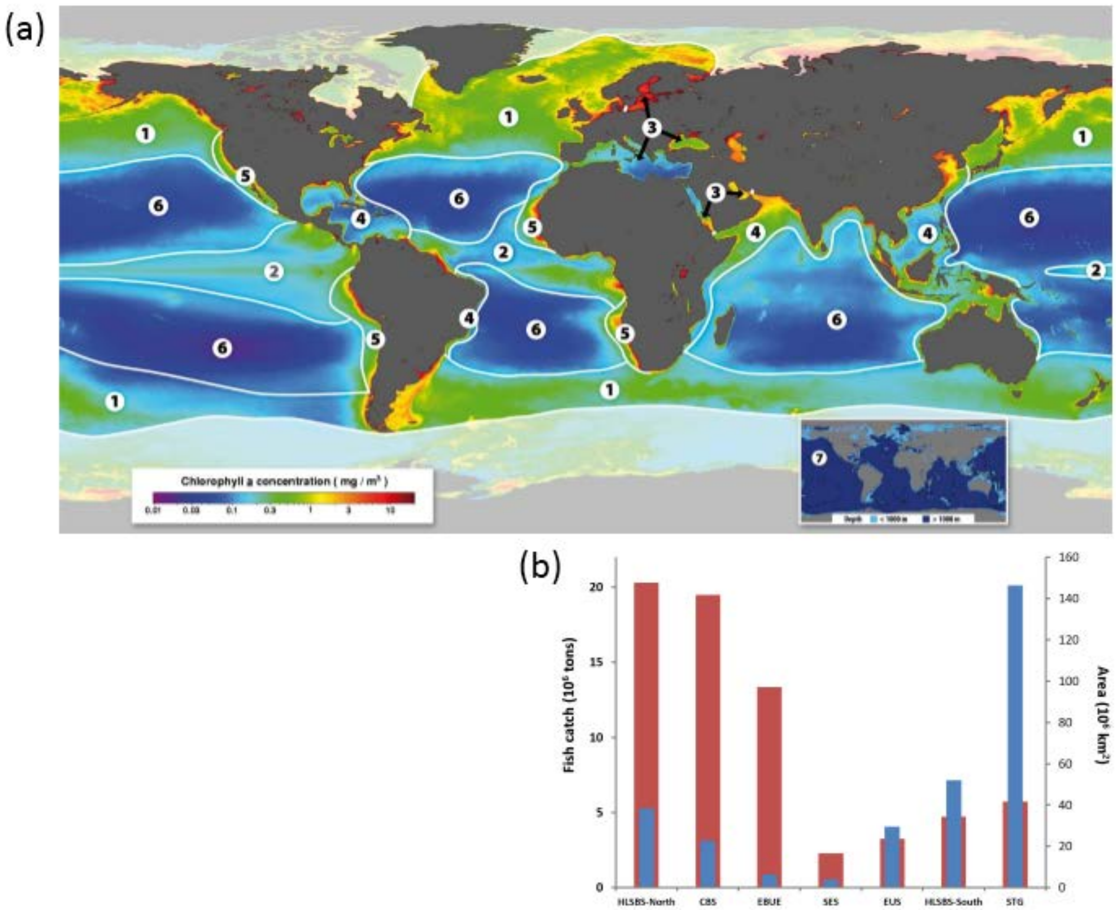

Figure 30-1: (a) Separation of the world's non-polar oceans into seven major sub-regions (excluding the polar oceans, which are considered in Chapter 28). The chlorophyll-*a* signal measured by SeaWiFS and averaged over the period from Sep 4, 1997 to 30 Nov 2010 (NASA) is provides a proxy for differences in marine productivity (with the caveats provided in Box CC-PP). Ecosystem structure and functioning, as well as key oceanographic features provided the basis for separating the Ocean into the sub-regions shown. The map insert shows the distribution of Deep Sea (DS) habitat (>1000 m; Bathypelagic and Abyssopelagic habitats combined). Numbers refer to: 1 = High Latitude Spring Bloom Systems (HLSBS); 2 = Equatorial Upwelling Systems (EUS); 3 = Semi-Enclosed Seas (SES); 4 = Coastal Boundary Systems (CBS); 5 = Eastern Boundary Upwelling Ecosystems (EBUE); 6 = Sub-Tropical Gyres (STG); and 7 = DS (>1000 m). (b) Relationship between fish catch and area for each ocean sub-region is shown in (a). Red columns: average fish catch (as millions tons yr^{-1}) for the period 1970–2006. Blue columns: area (millions km^2). The four left-hand columns (sub-regions HLSBS-North, CBS, EBUE, and SES) cover 20 % of the world oceans' area and deliver 80% of the world's fish catches. The values for the percent area of the Ocean, primary productivity, and fishery catch for the major sub-regions are listed in Table SM30-1.
[Illustration to be redrawn to conform to IPCC publication specifications.]

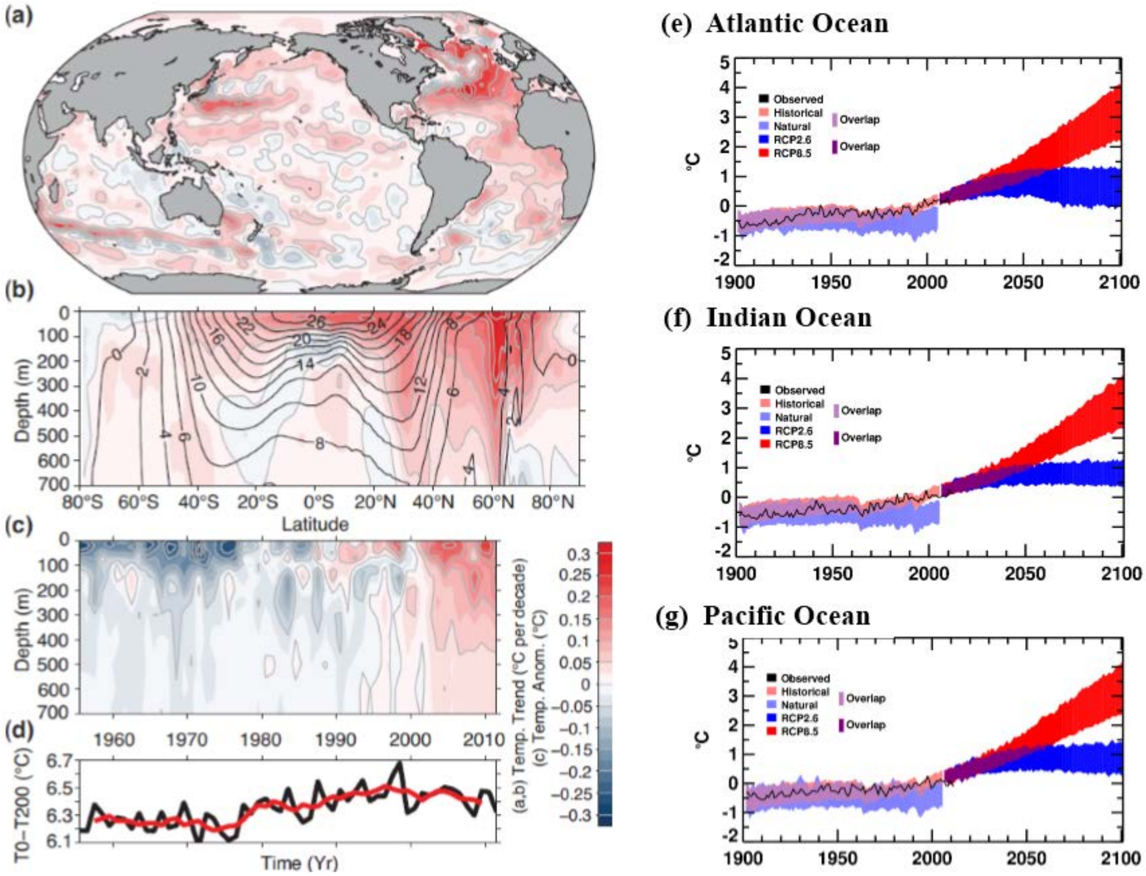

Figure 30-2: (a) Depth-averaged 0–700 m temperature trend for 1971–2010 (longitudinal versus latitude, colors and gray contours in °C per decade). (b) Zonally averaged temperature trends (latitude versus depth, colors and gray contours in °C per decade) for 1971–2010, with zonally averaged mean temperature over plotted (black contours in °C). (c) Globally-averaged temperature anomaly (Time versus depth, colors and grey contours in °C) relative to the 1971–2010 mean. (d) Globally-averaged temperature difference between the Ocean surface and 200 m depth (Black: annual values; red: five year running mean). Panels (a)–(d) from WGI Figure 3.1. (e)–(g) Observed and simulated variations in past and projected future annual average SST over three ocean basins (excluding regions within 300 km of the coast). The black line shows estimates from HadISST1.1 observational measurements. Shading denotes the 5–95 percentile range of climate model simulations driven with 'historical' changes in anthropogenic and natural drivers (62 simulations), historical changes in 'natural' drivers only (25), and the Representative Concentration Pathways: Dark Blue: RCP2.6; Light Blue: RCP4.5; Green: RCP6.0, and Red: RCP8.5). Data are anomalies from the 1986–2006 average of the HadISST1.1 data (for the HadISST1.1 time series) or of the corresponding historical all-forcing simulations. Further details are given in Box 21-2.
[Illustration to be redrawn to conform to IPCC publication specifications.]

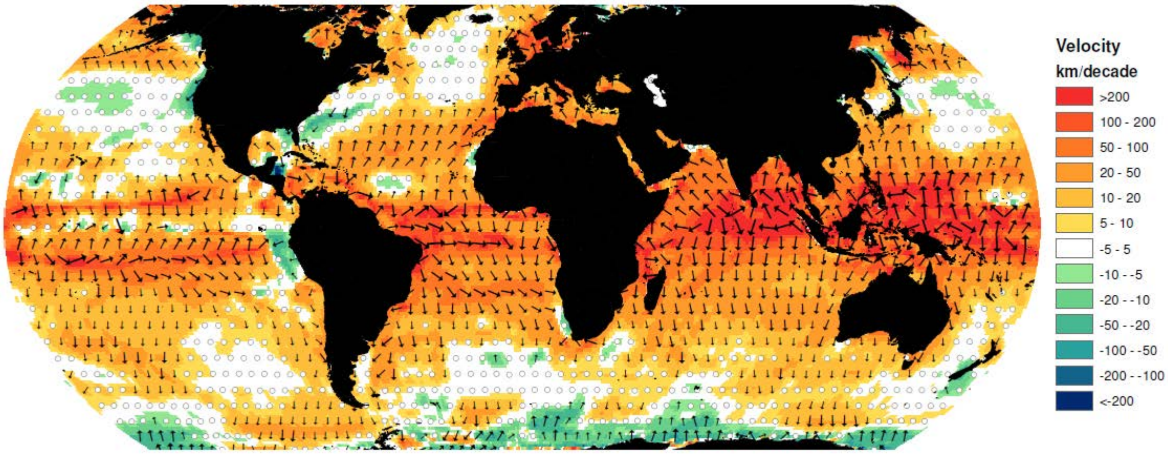

Figure 30-3: Velocity at which sea surface temperature (SST) isotherms shifted (km decade^{-1}) over the period 1960–2009 calculated using HaDISST1.1, with arrows indicating the direction and magnitude of shifts. Velocity of climate change is obtained by dividing the temperature trend in °C decade^{-1} by the local spatial gradient °C km^{-1}. The direction of movement of SST is denoted by the direction of the spatial gradient and the sign of the temperature trend: towards locally cooler areas with a local warming trend or towards locally warmer areas where temperatures are cooling. Adapted from [*Burrows et al.*, 2011].

[Illustration to be redrawn to conform to IPCC publication specifications.]

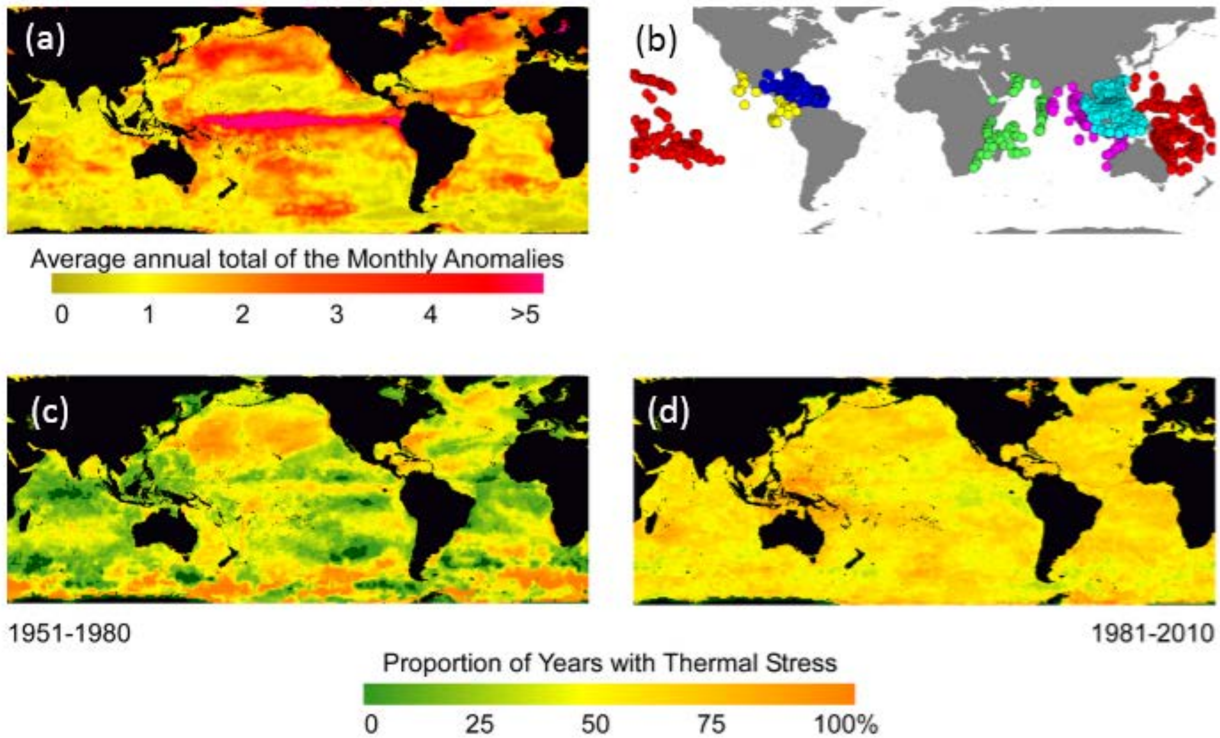

Figure 30-4: Recent changes in thermal stress calculated using HadISST1.1 data. A monthly climatology was created by averaging the HadISST monthly SST values over the period 1985–2000 to create twelve averages, one for each month of the year. The Maximum Monthly Mean (MMM) climatology was created by selecting the hottest month for each pixel. Anomalies were then created by subtracting this value from each SST value, but only allowing values to be recorded if they were greater than zero [*Donner et al.*, 2007]. Two measures of the change in thermal stress were calculated as a result: (a) The total thermal stress for the period 1981–2010, calculated by summing all monthly thermal anomalies for each grid cell. (b) The location of coral reef grid cells used in Table 30-1 and for comparison to regional heat stress here. Each dot is positioned over a 1×1 degree grid cell within which lies at least one carbonate coral reef. The latitude and longitude of each reef is derived from data provided by the World Resources Institute's *Reefs at Risk* report (http://www.wri.org). The six regions are as follows: Red – Western Pacific Ocean; Yellow – Eastern Pacific Ocean; Dark Blue – Caribbean & Gulf of Mexico; Green – Western Indian Ocean; Pink – Eastern Indian Ocean; and Light Blue – Coral Triangle & SE Asia. (c) Proportion of years with thermal stress, which is defined as any year that has a thermal anomaly, for the periods 1951–1980 and (d) 1981–2010. **[Illustration to be redrawn to conform to IPCC publication specifications.]**

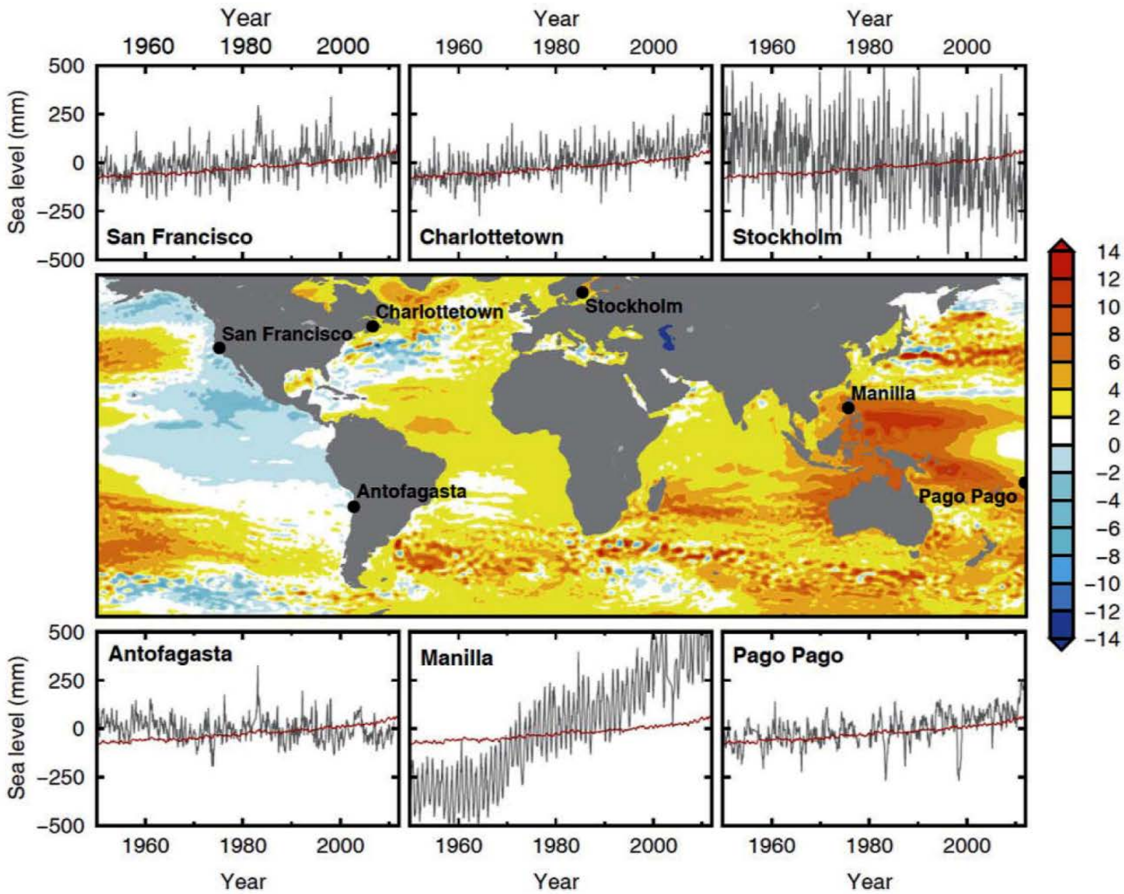

Figure 30-5. Map of the rate of change in sea surface height (geocentric sea level) for the period 1993–2012 derived from satellite altimetry. Also shown are relative sea level changes (gray lines) from selected tide gauge stations for the period 1950–2012. For comparison, an estimate of global mean sea level change is shown (red lines) with each tide gauge time series. The relatively large short-term oscillations in local sea level (gray lines) are due to the natural climate variability and ocean circulation. For example, the large regular deviations at Pago Pago are associated with the El Niño-Southern Oscillation. Figure originally presented in WGI FAQ 13.1, Figure 1).
[Illustration to be redrawn to conform to IPCC publication specifications.]

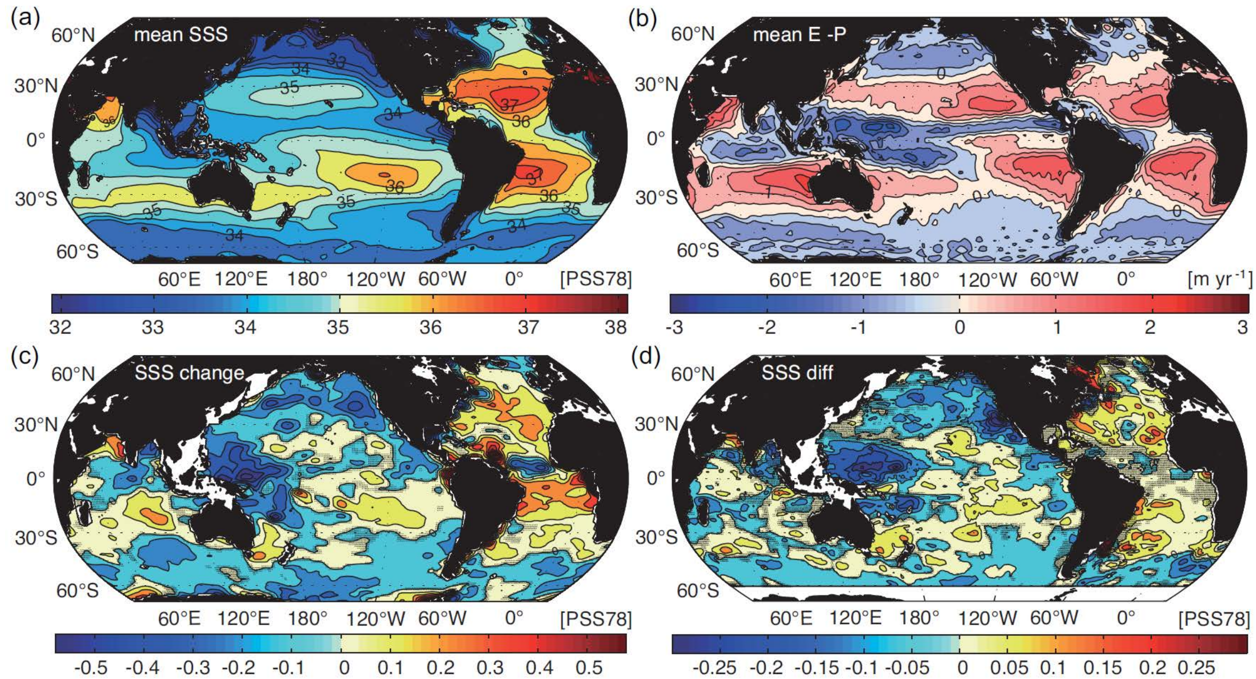

Figure 30-6: (a) The 1955–2005 climatological-mean sea surface salinity [*Antonov et al.*, 2010] color contoured at 0.5 PSS78 intervals (black lines). (b) Annual mean evaporation-precipitation averaged over the period 1950–2000 (NCEP) color contoured at 0.5 m yr–1 intervals (black lines). (c) The 58-year (2008 minus 1950) sea surface salinity change derived from the linear trend (PSS78), with seasonal and ENSO signals removed [*Durack and Wijffels,* 2010] color contoured at 0.116 PSS78 intervals (black lines). (d) The 30-year (2003–2007 average centered at 2005, minus the 1960–1989 average centered at 1975) sea surface salinity difference (PSS78) color contoured at 0.06 PSS78 intervals (black lines). Contour intervals in (c) and (d) are chosen so that the trends can be easily compared, given the different time intervals in the two analyzes. White areas in (c) and (d) are marginal seas where the calculations are not carried out. Regions where the change is not significant at the 99% confidence level are stippled in gray. Figure originally presented as WGI Figure 3.4 in WGI.
[Illustration to be redrawn to conform to IPCC publication specifications.]

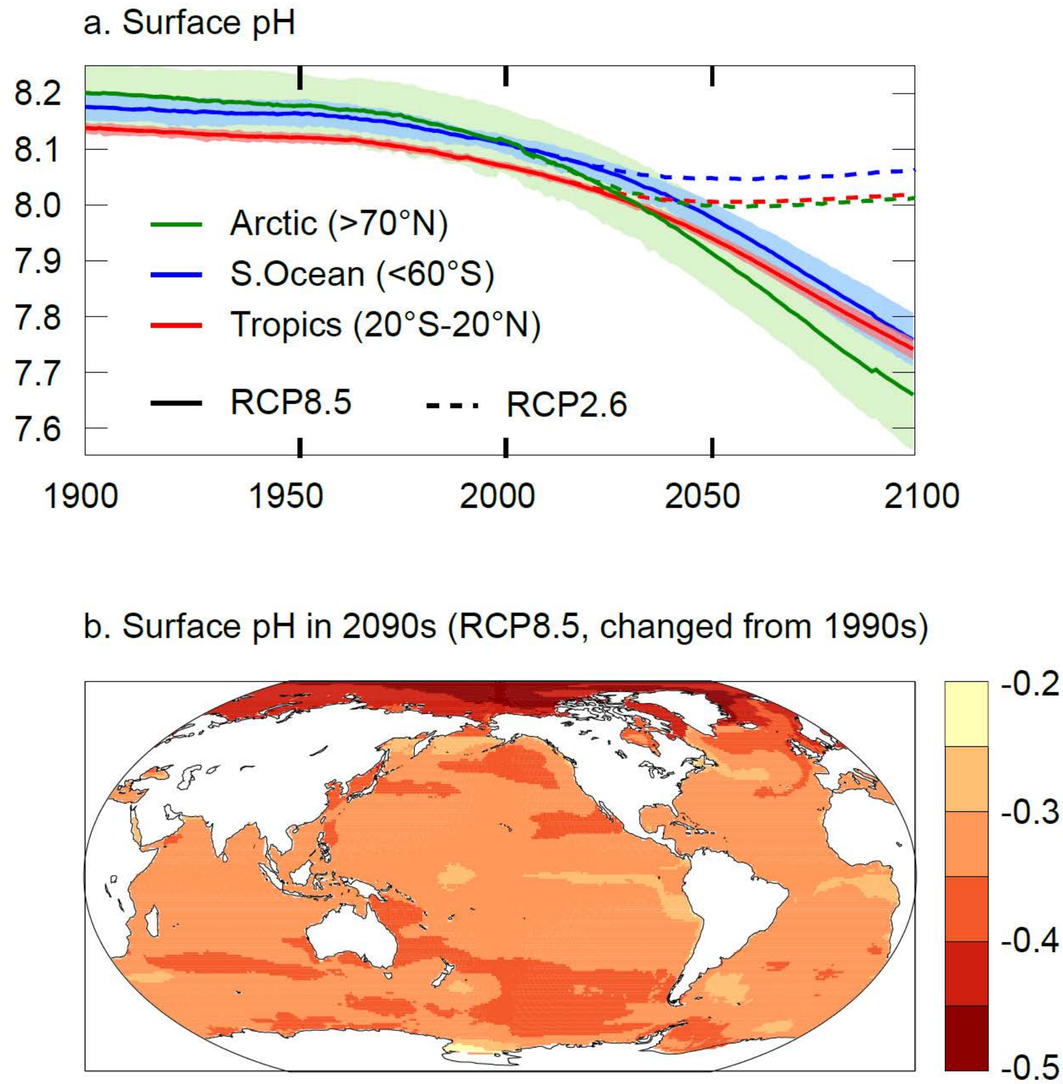

Figure 30-7: Projected ocean acidification from 11 CMIP5 Earth System models under RCP8.5 (other RCP scenarios have also been run with the CMIP5 models): (a) Time series of surface pH shown as the mean (solid line) and range of models (filled), given as area-weighted averages over the Arctic Ocean (green), the tropical oceans (red) and the Southern Ocean (blue). (b) Maps of the median model's change in surface pH from 1850–2100. Panel (a) also includes mean model results from RCP2.6 (dashed lines). Over most of the Ocean, gridded data products of carbonate system variables are used to correct each model for its present-day bias by subtracting the model-data difference at each grid cell following [*Orr et al.*, 2005]. Where gridded data products are unavailable (Arctic Ocean, all marginal seas and the Ocean near Indonesia), the results are shown without bias correction. The bias correction reduces the range of model projections by up to a factor of 4, e.g., in panel (a) compare the large range of model projections for the Arctic (without bias correction) to the smaller range in the Southern Ocean (with bias correction). Figure originally presented in WGI Figure 6.28 in WGI.
[Illustration to be redrawn to conform to IPCC publication specifications.]

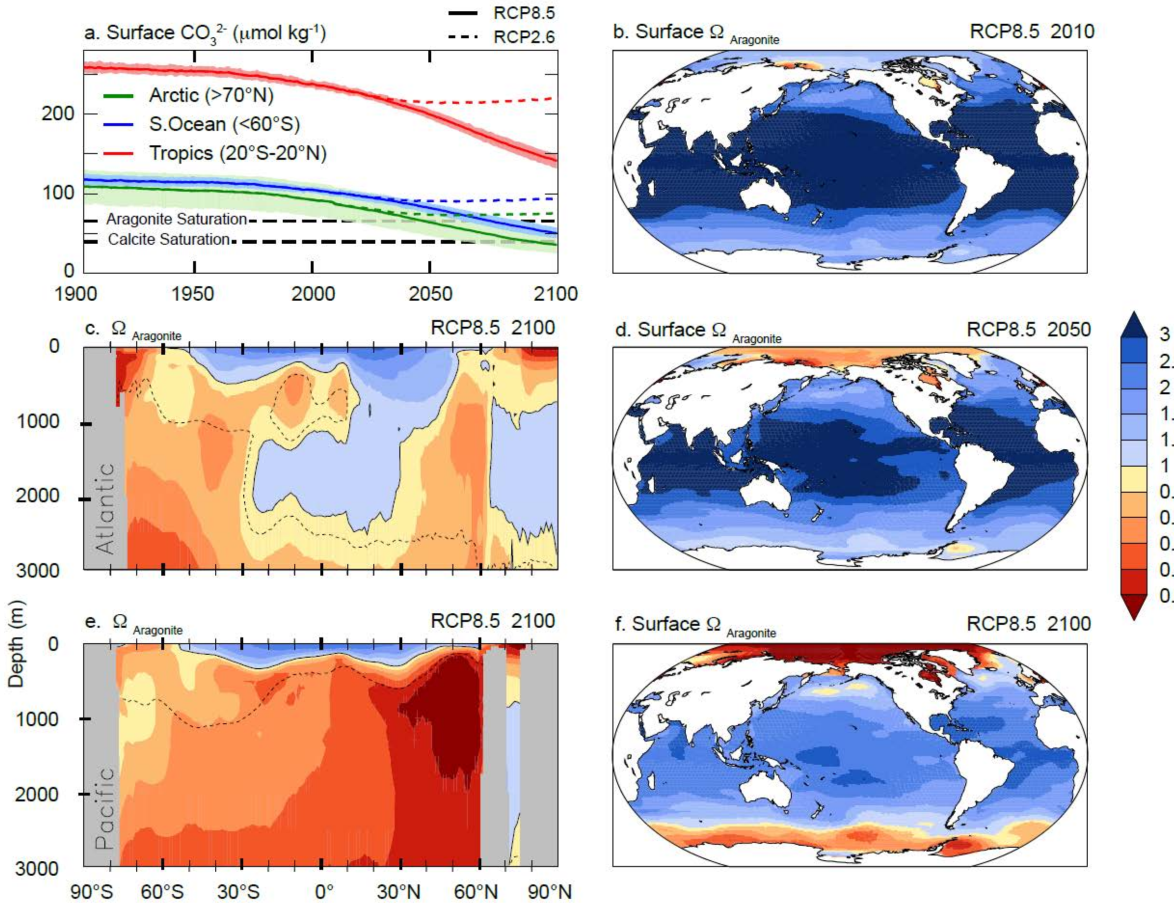

Figure 30-8: Projected aragonite saturation state from 11 CMIP5 Earth System models under RCP8.5 scenario: (a) time series of surface carbonate ion concentration shown as the mean (solid line) and range of models (filled), given as area weighted averages over the Arctic Ocean (green), the tropical oceans (red), and the Southern Ocean (blue); maps of the median model's surface ΩA in (b) 2010, (d) 2050, and (f) 2100; and zonal mean sections (latitude versus depth) of ΩA in 2100 over (c) the Atlantic Ocean and (e) the Pacific Ocean, while the ASH (Aragonite Saturation Horizon) is shown for 2010 (dotted line) and 2100 (solid line). Panel (a) also includes mean model results from RCP2.6 (dashed lines). As for Figure 30-7, gridded data products of carbonate system variables [*Key et al.*, 2004] are used to correct each model for its present-day bias by subtracting the model-data difference at each grid cell following [*Orr et al.*, 2005]. Where gridded data products are unavailable (Arctic Ocean, all marginal seas and the Ocean near Indonesia), results are shown without bias correction. Reprinted from Figure 6.29 in WGI.
[Illustration to be redrawn to conform to IPCC publication specifications.]

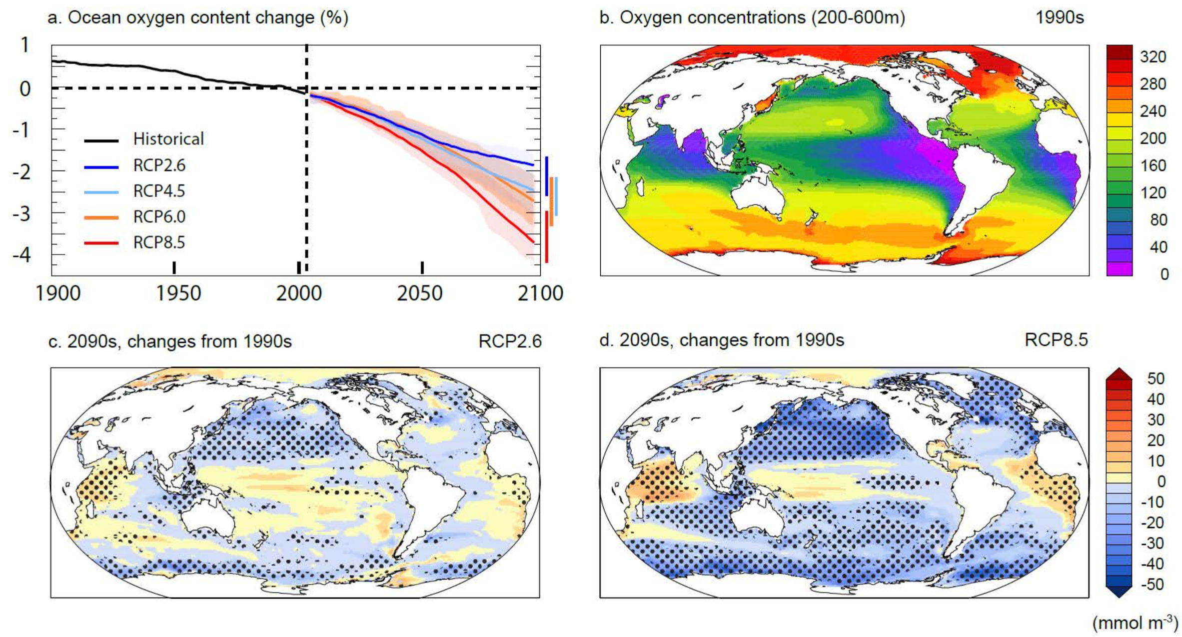

Figure 30-9: (a) Simulated changes in dissolved O_2 (mean and model range as shading) relative to 1990s for RCP2.6, RCP4.5, RCP6.0, and RCP8.5. (b) Multi-model mean dissolved O_2 (μmol m^{-3}) in the main thermocline (200–600 m depth average) for the 1990s, and changes in the 2090s relative to 1990s for RCP2.6 (c) and RCP8.5 (d). To indicate consistency in the sign of change, regions are stippled when at least 80% of models agree on the sign of the mean change. These diagnostics are detailed in [*Cocco et al.*, 2013] in a previous model inter-comparison using the SRES-A2 scenario and have been applied to CMIP5 models here. Models used: CESM1-BGC, GFDL-ESM2G, GFDL-ESM2M, HadGEM2-ES, IPSL-CM5A-LR, IPSL-CM5A-MR, MPI-ESM-LR, MPI-ESM-MR, NorESM1. Figure originally presented in WGI Figure 6.30 in WGI.

Figure 30-10: Annual maximum proportions of reef pixels with Degree Heating Months [*Donner et al.*, 2007]; DHM)≥1 (used for projecting coral bleaching; [*Strong et al.*, 1997; *Strong et al.*, 2011]) and DHM≥5 (associated with bleaching across 100% of affected areas with significant mortality, [*Eakin et al.*, 2010] for the period 1870–2009 for each of the six coral regions (Figure 30-4d) using the HadISST1.1 data set. The black line on each graph is the maximum annual area value for each decade over the period 1870–2009. This value is continued through 2010–2099 using CMIP5 data and splits into the four Representative Concentration Pathways (RCP2.6, 4.5, 6.0, and 8.5). DHM were produced for each of the four RCPs using the ensembles of CMIP models. From these global maps of DHM, the annual percentage of grid cells with DHM≥1 and DHM≥5 were calculated for each coral region. These data were then grouped into decades from which the maximum annual proportions were derived. The plotted lines for 2010–2099 are the average of these maximum proportion values for each RCP. Monthly SST anomalies were derived using a 1985–2000 maximum monthly mean (MMM) climatology derived in the calculations for Figure 30-4. This was done separately for HadISST1.1, the CMIP5 models, and each of the four RCPs, at each grid cell for every region. DHMs were then derived by adding up the monthly anomalies using a 4-month rolling sum. Figure SM30-3 presents past and future sea temperatures for the six major coral reef provinces under historic, un-forced, RCP4.5 and RCP8.5 scenarios.]

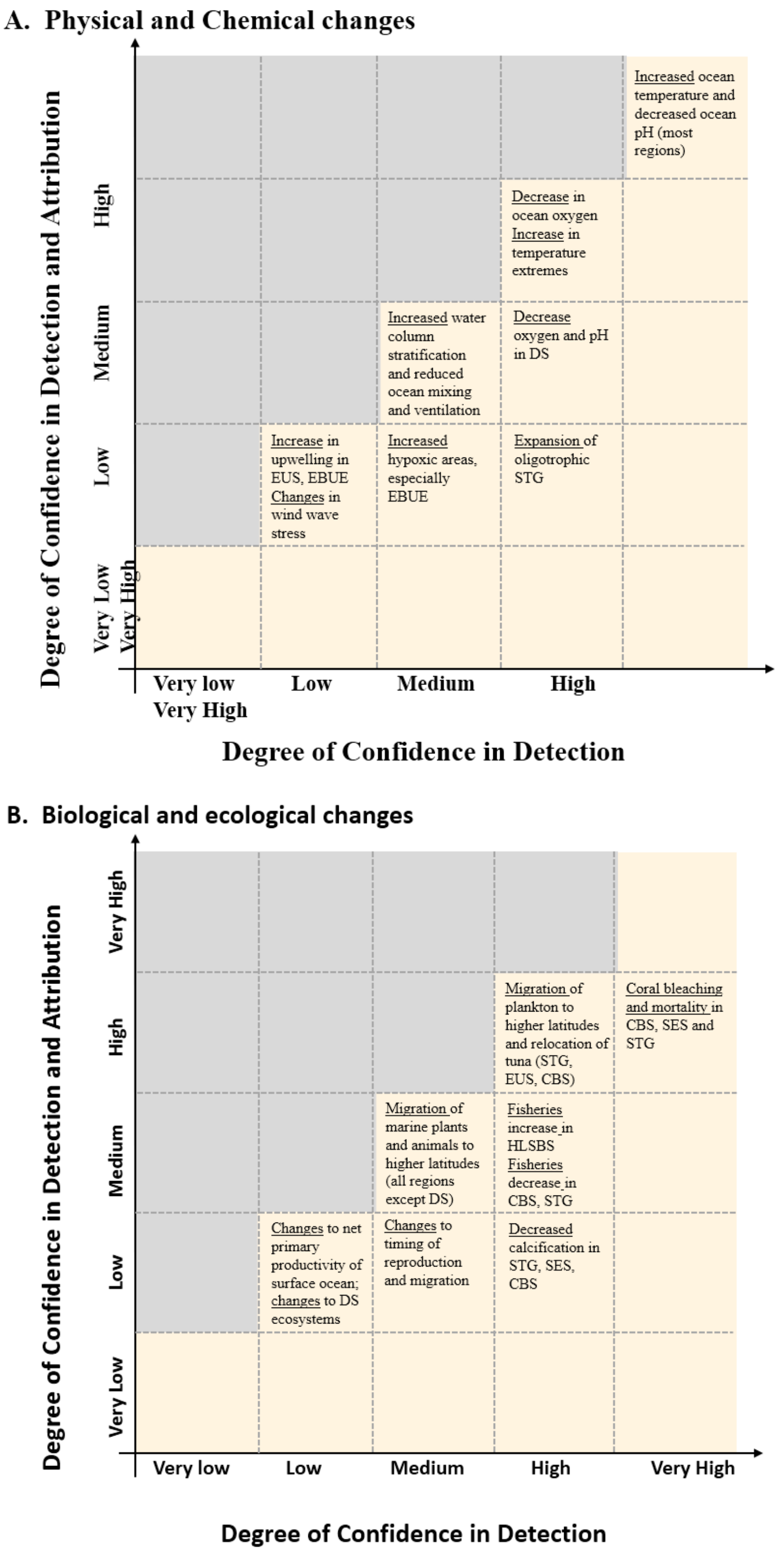

Figure 30-11: Expert assessment of degree of confidence in detection and attribution of physical and chemical changes (a) and ecological changes (b) across sub-regions, as designated in Figure 30-1a, and processes in the Ocean (based on evidence explored throughout Chapter 30 and elsewhere in AR5). Further explanation of this figure is given in 18.3.3–4 and 18.6. **[Illustration to be redrawn to conform to IPCC publication specifications.]**

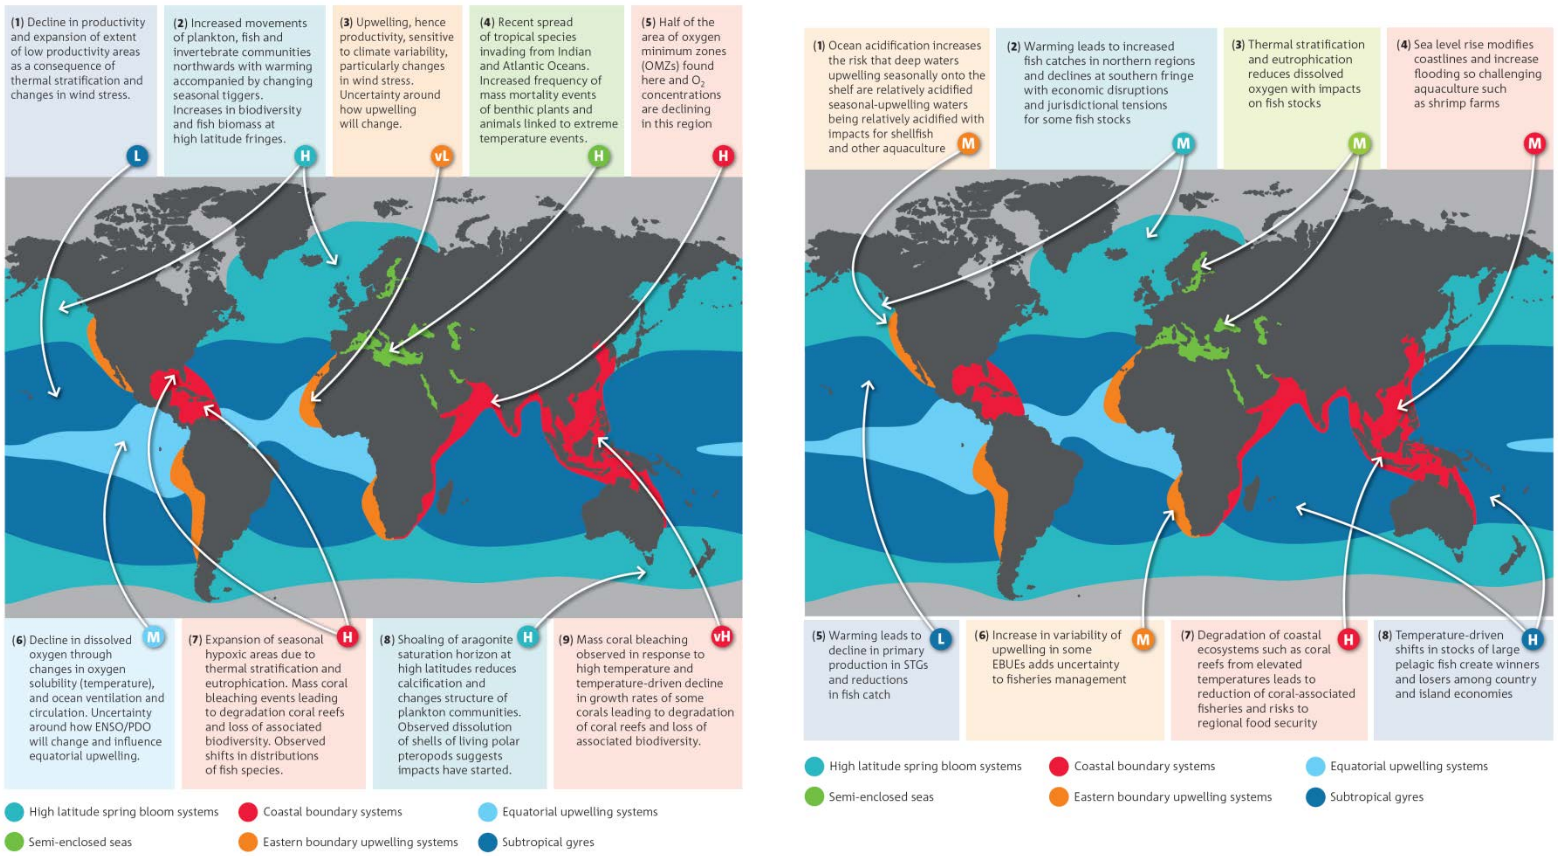

Figure 30-12: (a) Examples of projected impacts and vulnerabilities associated with climate change in Ocean sub-regions. (b) Examples of risks to fisheries from observed and projected impacts across Ocean sub-regions. Letters indicate level of confidence: (vL): Very low, (L): Low, (M): Medium, (H): High and (vH): Very high. Details of sub-regions are given in Table 30-1a and 30.1.1. **[Illustration to be redrawn to conform to IPCC publication specifications.]**

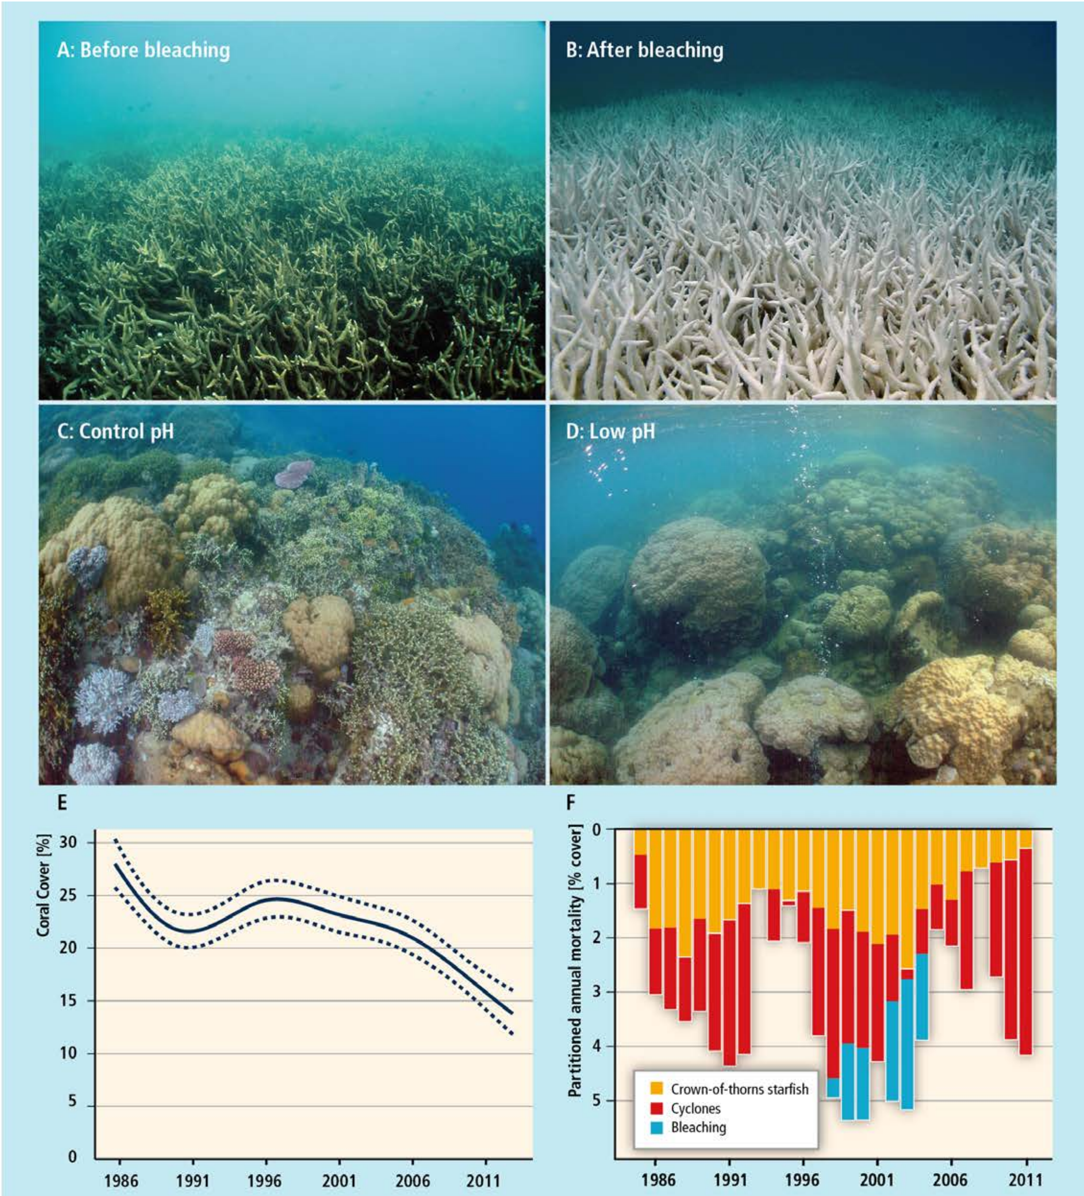

Figure CR-1: A and B: the same coral community before and after a bleaching event in February 2002 at 5 m depth, Halfway Island, Great Barrier Reef. Coral cover at the time of bleaching was 95% bleached almost all of it severely bleached, resulting in mortality of 20.9% (Elvidge *et al*., 2004). Mortality was comparatively low due in part because these coral communities were able to shuffle their symbiont to more thermo-tolerant types (Berkelmans and van Oppen, 2006; Jones *et al*., 2008). C and D: three CO_2 seeps in Milne Bay Province, Papua New Guinea show that prolonged exposure to high CO_2 is related to fundamental changes in the ecology of coral reefs (Fabricius *et al*., 2011), including reduced coral diversity (-39%), severely reduced structural complexity (-67%), lower density of young corals (-66%) and fewer crustose coralline algae (-85%). At high CO_2 sites (panel D; median pH_T ~7.8), reefs are dominated by massive corals while corals with high morphological complexity are underrepresented compared with control sites (D; median pH ~8.0). Reef development ceases at pH_T values below 7.7. pH_T: pH on the total scale. E: temporal trend in coral cover for the whole Great Barrier Reef over the period 1985–2012 (N, number of reefs, mean ± 2 standard errors; De'ath et al., 2012). F: composite bars indicate the estimated mean coral mortality for each year, and the sub-bars indicate the relative mortality due to crown-of-thorns starfish, cyclones, and bleaching for the whole Great Barrier Reef (De'ath et al., 2012). Photo credit: R. Berkelmans (A and B) and K. Fabricius (C and D).

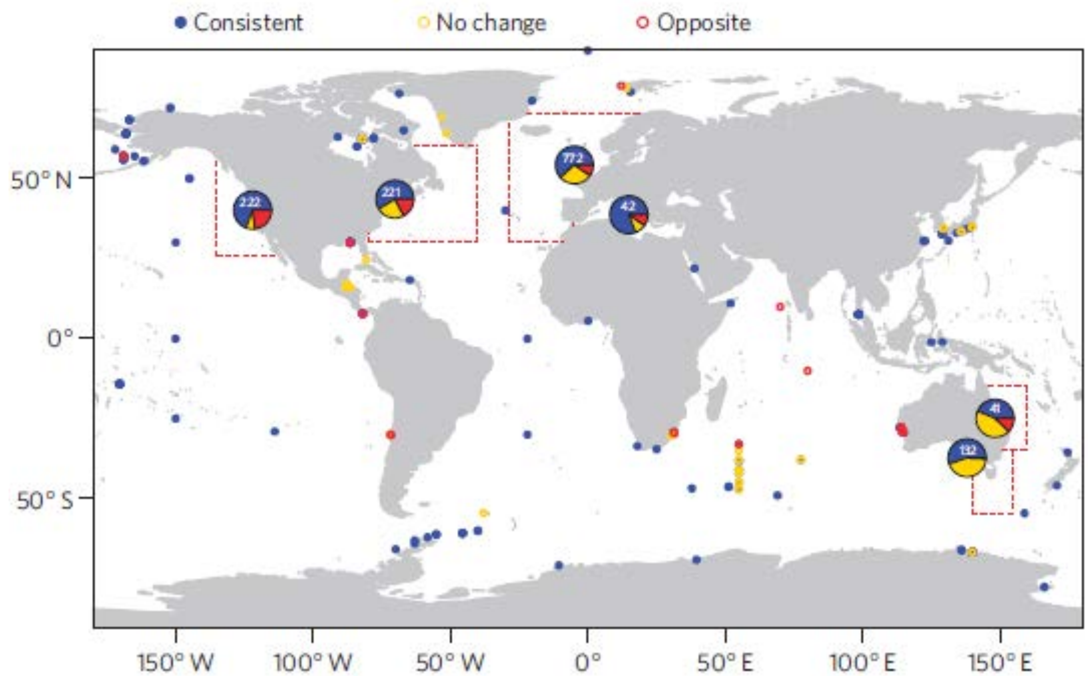

Figure MB-1: 1735 observed responses to climate change from 208 single- and multi-species studies. Changes attributed to climate change (blue), inconsistent with climate change (red) and are equivocal (yellow). Each circle represents the centre of a study area. Where points fall on land, it is because they are centroids of distribution that surround an island or peninsula. Pie charts show the proportions within regions bounded by red squares and in the Mediterranean; numbers indicate the total (consistent, opposite or equivocal) observations within each region. Note: 57% of the studies included were published since AR4 (from Poloczanska *et al.*, 2013).
[Illustration to be redrawn to conform to IPCC publication specifications.]

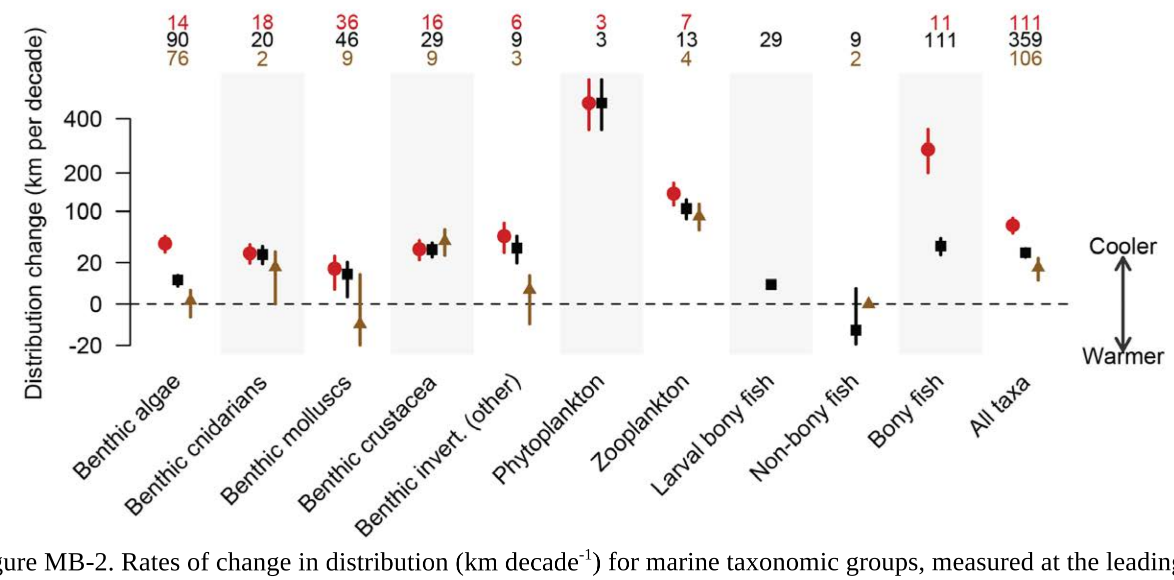

Figure MB-2. Rates of change in distribution (km decade^{-1}) for marine taxonomic groups, measured at the leading edges (red) and trailing edges (brown). Average distribution shifts calculated using all data, regardless of range location, are in black. Distribution rates have been square-root transformed; standard errors may be asymmetric as a result. Positive distribution changes are consistent with warming (into previously cooler waters, generally poleward). Means ± standard error are shown, along with number of observations (from Poloczanska et al., 2013).
[Illustration to be redrawn to conform to IPCC publication specifications.]

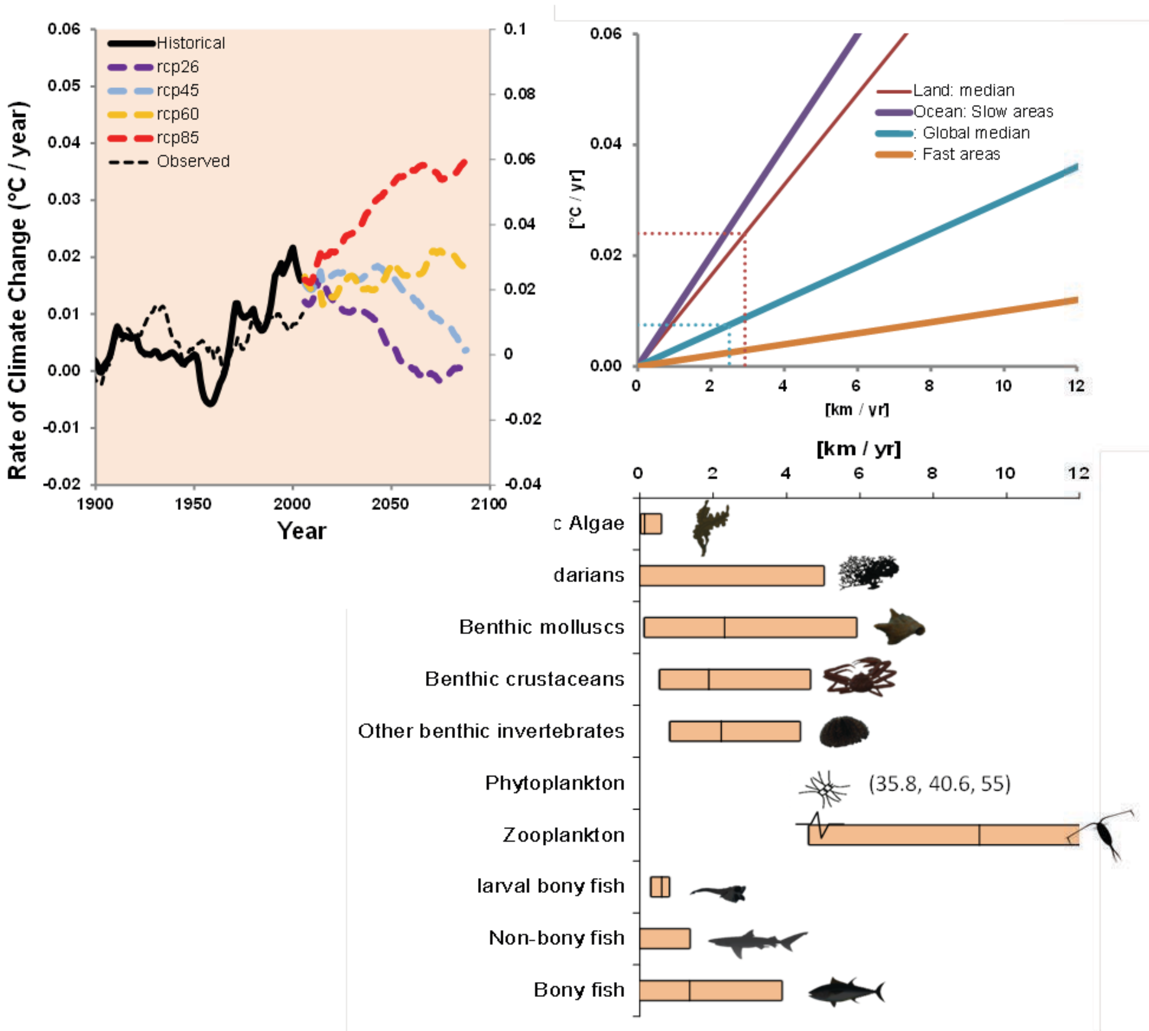

Figure MB-3. A. Rate of climate change for the Ocean (sea surface temperature (SST) °C); B. corresponding climate velocities for the Ocean and median velocity from land (adapted from Burrows et al., 2011); and C. observed rates of displacement of marine taxonomic groups over several decades until 2010. The thin dotted red arrows give an example of interpretation. Rates of climate change of 0.008 °C yr^{-1} correspond to ca. 2.4 km yr^{-1}median climate velocity in the Ocean. When compared to observed rates of displacement, many marine taxonomic groups have been able to track these velocities, except phyto- and zooplankton where rates of displacement greatly exceed climate velocity. All values are calculated for ocean surface with the exclusion of polar seas (Figure 30-1a). (A) Observed rates of climate change for Ocean SST (Black dotted line) are derived from HadISST1.1 data set, all other rates are calculated based on the average of the CMIP5 climate model ensembles (Table S30-3) for the historical period and for the future based on the four RCP emissions scenarios. Data were smoothed using a 20-year sliding window. (B) Median climate velocity calculated from HadISST1.1 dataset over 1960–2010 using the methods of Burrows et al., 2011. The three axes represent estimated median climate velocities are representative of areas of slow velocities such as Pacific subtropical gyre (STG) system (Purple line), the global Ocean surface (excluding polar seas, Blue line), and areas of high velocities such as the Coral Triangle and North Sea (Orange line). Figure 30-3 shows climate velocities over the ocean surface calculated over 1960–2010. The Red line corresponds to the median rate over global land surface calculated using historical surface temperatures from the CMIP5 model ensemble (Table S30-3). (C) Rates of displacement for marine taxonomic groups estimated by Poloczanska et al. 2013 using published studies (Figure MB-2 Black data set). Note the displacement rates for phytoplankton exceed the axis, so values are given. **[Illustration to be redrawn to conform to IPCC publication specifications.]**

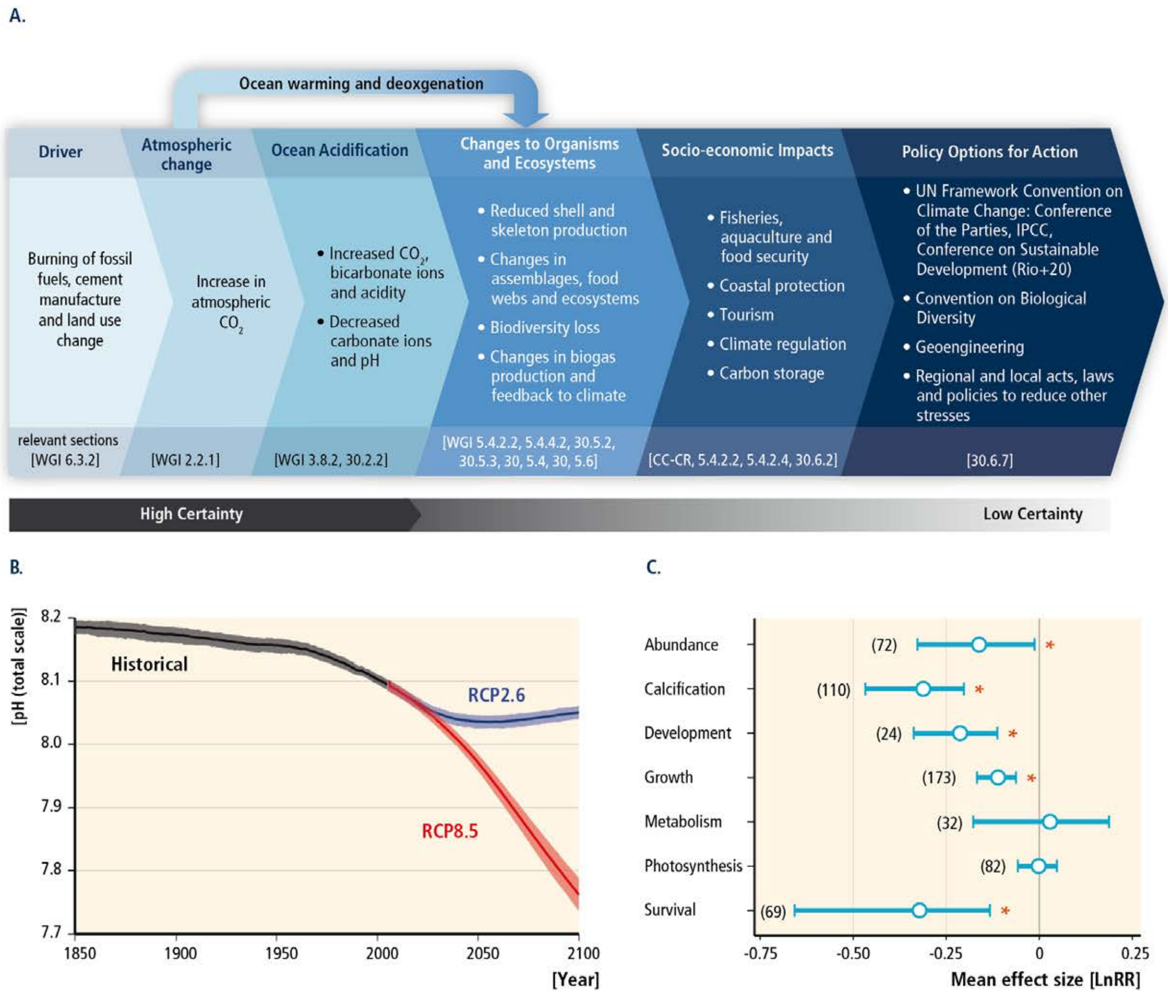

Figure OA-1: A: Overview of the chemical, biological, socio-economic impacts of ocean acidification and of policy options (adapted from Turley and Gattuso, 2012). B: Multi-model simulated time series of global mean ocean surface pH (on the total scale) from CMIP5 climate model simulations from 1850 to 2100. Projections are shown for emission scenarios RCP2.6 (blue) and RCP8.5 (red) for the multi-model mean (solid lines) and range across the distribution of individual model simulations (shading). Black (grey shading) is the modelled historical evolution using historical reconstructed forcings. The models that are included are those from CMIP5 that simulate the global carbon cycle while being driven by prescribed atmospheric CO_2 concentrations. The number of CMIP5 models to calculate the multi-model mean is indicated for each time period/scenario (WGI AR5 Figure 6.28). C: Effect of near future acidification (seawater pH reduction of 0.5 unit or less) on major response variables estimated using weighted random effects meta-analyses, with the exception of survival which is not weighted (Kroeker et al., 2013). The log-transformed response ratio (LnRR) is the ratio of the mean effect in the acidification treatment to the mean effect in a control group. It indicates which process is most uniformly affected by ocean acidification but large variability exists between species. Significance is determined when the 95% bootstrapped confidence interval does not cross zero. The number of experiments used in the analyses is shown in parentheses. * denotes a statistically significant effect.

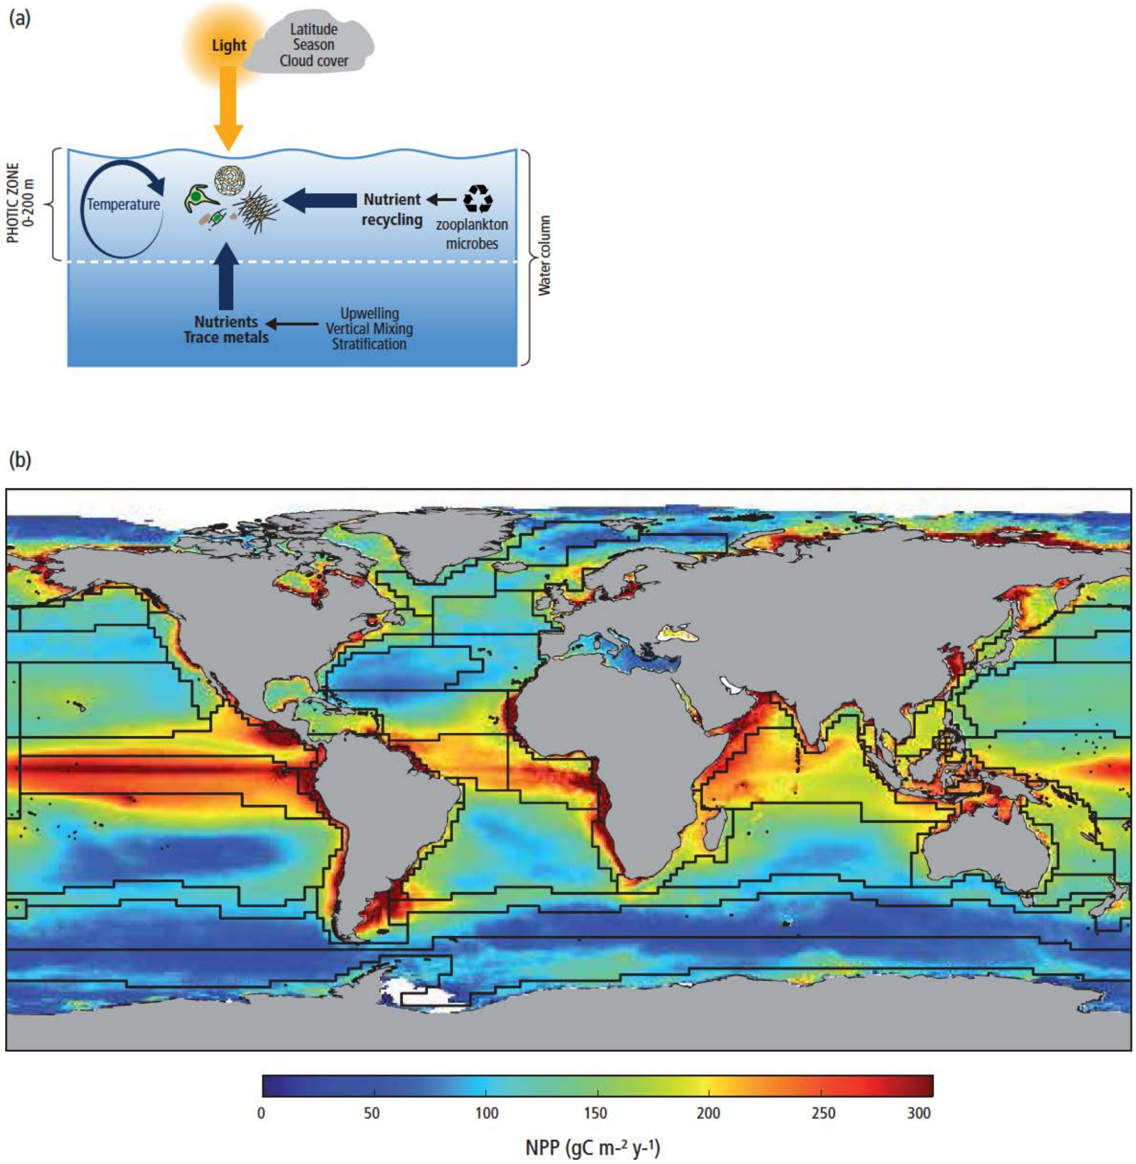

Figure PP-1: A) Environmental factors controlling Net Primary Production (NPP). NPP is mainly controlled by three basic processes: 1) Light conditions in the surface ocean, i.e. the photic zone where photosynthesis occurs, 2) upward flux of nutrients and micronutrients from underlying waters into the photic zone, 3) Regeneration of nutrients and micronutrients via the breakdown and recycling of organic material before it sinks out of the photic zone. All three processes are influenced by physical, chemical and biological processes and vary across regional ecosystems. In addition, water temperature strongly influences the upper rate of photosynthesis for cells that are resource-replete. Predictions of alteration of primary productivity under climate change depend on correct parameterizations and simulations of each of these variables and processes for each region. B) Annual composite map of global areal NPP rates (derived from MODIS Aqua satellite climatology from 2003-2012; NPP was calculated with the Carbon-based Production Model (CbPM, Westberry *et al*., 2008)). Overlaid is a grid of (thin black lines) that represent 51 distinct global ocean biogeographical provinces (after Longhurst, 1998 and based on Boyd and Doney, 2002). The characteristics and boundaries of each province are primarily set by the underlying regional ocean physics and chemistry. Figure courtesy of Toby Westberry (OSU) and Ivan Lima (WHOI), satellite data courtesy of NASA Ocean Biology Processing Group.

Figure UP-1: Upper panel: Schematic hypothetic mechanism of increasing coastal wind-driven upwelling at eastern boundary systems, where differential warming rates between land and ocean results in increased land-ocean pressure gradients (1) that produce stronger alongshore winds (2) and offshore movement of surface water through Ekman transport (3), and increased upwelling of deep cold nutrient rich waters to replace it (4). Lower panel: potential consequences of climate change in upwelling systems. Increasing stratification and uncertainty in wind stress trends result in uncertain trends in upwelling. Increasing upwelling may result in higher input of nutrients to the euphotic zone, and increased primary production, which in turn may enhance pelagic fisheries, but also decreased coastal fisheries due to an augmented exposure of coastal fauna to hypoxic, low pH waters. Decreased upwelling may result in lower primary production in these systems with direct impacts on pelagic fisheries productivity.
