Climate Change 2014: Impacts, Adaptation, and Vulnerability

SUMMARY FOR POLICYMAKERS

Drafting Authors

Christopher Field (USA), Vicente Barros (Argentina), Michael Mastrandrea (USA), Katharine Mach (USA), Mohamed Abdrabo (Egypt), Neil Adger (UK), Yury Anokhin (Russian Federation), Oleg Anisimov (Russian Federation), Douglas Arent (USA), Jonathon Barnett (Australia), Virginia Burkett (USA), Rongshuo Cai (China), Monalisa Chatterjee (USA/India), Stewart Cohen (Canada), Wolfgang Cramer (Germany/France), Purnamita Dasgupta (India), Debra Davidson (Canada), Fatima Denton (Gambia), Petra Döll (Germany), Kirstin Dow (USA), Yasuaki Hijioka (Japan), Ove Hoegh-Guldberg (Australia), Richard Jones (UK), Roger Jones (Australia), Roger Kitching (Australia), Sari Kovats (UK), Patricia Romero Lankao (Mexico), Joan Nymand Larsen (Iceland), Erda Lin (China), David Lobell (USA), Iñigo Losada (Spain), Graciela Magrin (Argentina), José Marengo (Brazil), Anil Markandya (Spain), Bruce McCarl (USA), Roger McLean (Australia), Linda Mearns (USA), Guy Midgley (South Africa), Nobuo Mimura (Japan), John Morton (UK), Isabelle Niang (Senegal), Ian Noble (Australia), Leonard Nurse (Barbados), Karen O'Brien (Norway), Taikan Oki (Japan), Lennart Olsson (Sweden), Michael Oppenheimer (USA), Jonathan Overpeck (USA), Joy Pereira (Malaysia), Elvira Poloczanska (Australia), John Porter (Denmark), Hans-O. Pörtner (Germany), Michael Prather (USA), Roger Pulwarty (USA), Andy Reisinger (New Zealand), Aromar Revi (India), Oliver Ruppel (Namibia), David Satterthwaite (UK), Daniela Schmidt (UK), Josef Settele (Germany), Kirk Smith (USA), Dáithí Stone (Canada/South Africa/USA), Avelino Suarez (Cuba), Petra Tschakert (USA), Riccardo Valentini (Italy), Alicia Villamizar (Venezuela), Rachel Warren (UK), Thomas Wilbanks (USA), Poh Poh Wong (Singapore), Alistair Woodward (New Zealand), Gary Yohe (USA)

CONTENTS OF THE SUMMARY FOR POLICYMAKERS

INTRODUCTION

Human interference with the climate system is occurring,[1] and climate change poses risks for human and natural systems (Figure SPM.1). The assessment of impacts, adaptation, and vulnerability in the Working Group II contribution to the IPCC's Fifth Assessment Report (WGII AR5) evaluates how patterns of risks and potential benefits are shifting due to climate change and how risks can be reduced through mitigation and adaptation.

Compared to past WGII reports, the WGII AR5 assesses a substantially larger knowledge base of relevant scientific, technical, and socioeconomic literature. Increased literature from all regions has facilitated comprehensive assessment across a broader set of topics and sectors, with expanded treatment of human systems, adaptation, and the ocean. [1.1, Figure 1-1]

Section A of this summary characterizes observed impacts, vulnerability and exposure, and responses to date. Section B examines the range of future risks and potential benefits. Section C considers principles for effective adaptation and the broader interactions among adaptation, mitigation, and sustainable development. Box SPM.1 defines central concepts, and Box SPM.2 introduces terms used to convey the degree of certainty in key findings. Chapter references in square brackets and in footnotes indicate support for findings, paragraphs of findings, figures, and tables in this summary.

Figure SPM.1: Climate-related hazards, exposure, and vulnerability interact to produce risk. Changes in both the climate system (left) and development processes including adaptation and mitigation (right) are drivers of hazards, exposure, and vulnerability. [19.2, Figure 19-1]

Boxes SPM.1 and SPM.2 are included at the end of the SPM text.

A) IMPACTS, VULNERABILITY, AND ADAPTATION IN A COMPLEX AND CHANGING WORLD

A-1. Observed Impacts, Vulnerability, and Exposure

Observed impacts of climate change are widespread and consequential. Recent changes in climate have caused impacts on natural and human systems on all continents and across the oceans.[2] Evidence of climate change impacts is strongest and most comprehensive for natural systems, although some impacts in human systems have also been attributed to climate change. See Figure SPM.2 for a summary of observed impacts and indicators of a changing climate, illustrating broader trends presented in this section.[3]

Figure SPM.2: Widespread indicators of a changing climate. (A) Global patterns of observed climate change impacts, at regional, subregional, and more local scales. For categories of attributed impacts, symbols indicate affected systems and sectors, the relative contribution of climate change (major or minor) to the observed change, and confidence in attribution. (B) Glacier mass budgets from all published measurements for Himalayan glaciers, also showing global average glacier mass budget estimates from WGI AR5 4.3 with shading indicating ±1 standard deviation. The blue box for each Himalaya measurement has a height of ±1 standard deviation centered on its average (and ±1 standard error for multi-annual measurements). Himalaya-wide measurement (red) was made by satellite laser altimetry. (C) Locations of substantial drought- and heat-induced tree mortality around the globe over 1970-2011. (D) Average rates of change in distribution (km per decade) for marine taxonomic groups based on observations over 1900-2010. Positive distribution changes are consistent with warming (moving into previously cooler waters, generally poleward). The number of responses analyzed is given for each category. (E) Summary of estimated impacts of observed climate changes on yields over 1960-2013 for four major crops in temperate and tropical regions, with the number of data points analyzed given for each category. [Figures 3-3, 4-7, 7-2, 18-3, and MB-2]

[1] WGI AR5 2.2, 6.3, 10.3-6, 10.9
[2] Attribution of observed impacts in the WGII AR5 links responses of natural and human systems to climate change, not to anthropogenic climate change, unless explicitly indicated.
[3] 18.1, 18.3-6

In response to ongoing climate change, terrestrial and marine species have shifted their ranges, seasonal activities, migration patterns, and abundance, and have demonstrated altered species interactions (*high confidence*). Increased tree mortality, observed in many places worldwide, has been attributed to climate change in some regions. While recent warming contributed to the extinction of many species of Central American amphibians (*medium confidence*), most recent observed terrestrial-species extinctions have not been attributed to recent climate change, despite some speculative efforts (*high confidence*). Natural climate change at rates much slower than current anthropogenic change has led to significant ecosystem shifts, including species emergences and extinctions, in the past millions of years.[4]

In many regions, changing precipitation or melting snow and ice are altering hydrological systems, affecting water resources and quality (*medium confidence*). Glaciers continue to shrink in many regions due to climate change (*high confidence*). Climate change has caused permafrost warming and thawing in high-latitude and high-elevation mountain regions.[5]

Negative impacts of climate change on crop and terrestrial food production have been more common than positive impacts, which are evident in some high-latitude regions (*high confidence*). Recent periods of rapid food and cereal price increases have indicated that current markets in key producing regions are sensitive to climate extremes.[6]

In recent decades, climate change has *likely* contributed to human ill-health although the present world-wide burden of ill-health from climate change is relatively small compared with effects of other stressors and is not well quantified. There has been increased heat-related mortality and decreased cold-related mortality in some regions as a result of warming (*medium confidence*).[7]

Vulnerability and exposure

Differences in vulnerability and exposure arise from non-climatic stressors and multidimensional inequalities, which shape differential risks from climate change (*very high confidence*). See Box SPM.3.[8]

Impacts from recent extreme climatic events, such as heat waves, droughts, floods, and wildfires, demonstrate significant vulnerability and exposure of some ecosystems and many human systems to climate variability (*very high confidence*). These experiences are consistent with a significant adaptation deficit in developing and developed countries for some sectors and regions.[9]

Climate-related hazards constitute an additional burden to people living in poverty, acting as a threat multiplier often with negative outcomes for livelihoods (*high confidence*). Climate-related hazards affect poor people's lives directly through impacts on livelihoods, such as reductions in crop yields or destruction of homes, and indirectly through increased food prices and food insecurity. Limited positive observed impacts on poor people include isolated cases of social asset accumulation, agricultural diversification, disaster preparedness, and collective action.[10]

Violent conflict strongly influences vulnerability to climate change impacts for people living in affected places (*medium evidence, high agreement*). Large-scale violent conflict harms assets that facilitate adaptation, including infrastructure, institutions, natural capital, social capital, and livelihood opportunities.[11]

Box SPM.3. Multidimensional Inequality and Vulnerability to Climate Change

[4] 4.2-4, 5.3-5, 6.1, 6.3-5, 18.3, 18.5, 22.3, 24.4, 25.6, 28.2, 30.4-5, Boxes 4-2, 4-3, 25-3, CC-CR, and CC-MB
[5] 3.2, 4.3, 18.3, 18.5, 24.4, 26.2, 28.2, Tables 3-1 and 25-1, Figures 18-2 and 26-1
[6] 7.3, 18.4, 22.3, 24.4, 26.5, Figures 7-2, 7-3, and 7-7
[7] 11.4-6, 18.4, 22.3, 24.4, 25.8, 26.6, 28.2
[8] 8.2, 9.3, 12.2, 13.1-2, 14.1-3, 19.6, 26.8, Box CC-GC
[9] 3.2, 4.2-3, 8.1, 9.3, 10.7, 11.3, 11.7, 13.2, 14.1, 18.6, 22.3, 25.6-8, 26.6-7, 28.4, 30.5, 30.7, Tables 18-3 and 23-1, Figure 26-2, Boxes 4-3, 4-4, 25-5, 25-6, 25-8, and CC-CR
[10] 8.2-3, 9.3, 11.3, 13.1-3, 22.3, 24.4, 26.8
[11] 12.5, 19.4, 19.6

People who are socially, economically, culturally, politically, institutionally, or otherwise marginalized are often highly vulnerable to climate change and climate change responses (*medium evidence*, *high agreement*). This heightened vulnerability is rarely due to a single cause. Rather, it is the product of intersecting social processes that result in inequalities in socioeconomic status, income, and exposure, including, for example, discrimination on the basis of gender, class, ethnicity, age, and (dis)ability. The full spectrum of these processes and their context-specific interactions shape multidimensional vulnerability and differential capacities and opportunities of individuals, households, and communities.[12]

A-2. Adaptation Experience

Adaptive human responses can be motivated by observed and projected climate change impacts and by broader vulnerability-reduction and development objectives.

Adaptation is already occurring and is becoming embedded in some planning processes (*high confidence*). Engineered and technological adaptation options are the most commonly implemented adaptive responses. There is increasing recognition of the value of ecosystem-based, institutional, and social measures, including provision of social protection measures, and of linkages with disaster risk reduction. Selection of adaptation options continues to emphasize incremental adjustments and co-benefits and is starting to emphasize flexibility and learning (*medium evidence, medium agreement*). Most evaluations of adaptation have been restricted to impacts, vulnerability, and adaptation planning, with very few assessing the processes of implementation or actual adaptation actions (*medium evidence, high agreement*).[13]

Governments at various scales are starting to develop adaptation plans and policies, and adaptation experience is accumulating across regions (*high confidence*).

- In Africa, most national governments are initiating governance systems for adaptation, and in predominantly isolated efforts, disaster risk management, adjustments in technologies and infrastructure, ecosystem-based approaches, conservation agriculture, and livelihood diversification are reducing vulnerability.[14]
- In Europe, adaptation policy has been developed across scales, with some adaptation planning integrated into coastal and water management and into disaster risk management.[15]
- In Asia, adaptation practices have sometimes provided livelihood benefits, and adaptation has been facilitated through integrated water resource management.[16]
- In Australasia, planning for sea-level rise and, in southern Australia, for reduced water availability is becoming widely adopted, although implementation faces major constraints, especially for transformational responses at local and community levels.[17]
- In North America, governments are engaging in incremental adaptation assessment and planning, particularly at the municipal level, with some proactive adaptation anticipating future impacts for longer-term investments in energy and public infrastructure.[18]
- In Central and South America, ecosystem-based adaptation including protected areas, conservation agreements, and community management of natural areas is increasingly common, with benefits for improvements in livelihoods and preservation of traditional cultures.[19]
- In the Arctic, residents have a history of adapting to change, but the rate of climate change and complex inter-linkages with societal, economic, and political factors represent unprecedented challenges for northern communities.[20]
- In small islands, diverse physical and human attributes and their sensitivity to climate-related drivers have been inconsistently integrated into adaptation planning.[21]

A-3. The Decision-making Context

Responding to climate-related risks involves making decisions and taking actions in the face of continuing uncertainty about the extent of climate change and the severity of impacts in a changing world, with potential limits to the effectiveness of incremental approaches (*high confidence*). Iterative risk management is a useful framework for decision-making in situations characterized by large potential consequences, persistent uncertainties, long timeframes, potential for learning, and multiple influences changing over time, such as climate and non-climatic stressors. See Figure SPM.3. Assessment of the full range of potential future impacts, including low-probability outcomes with large consequences, is central to understanding future risks and the benefits and tradeoffs of alternative risk management actions. The increasing complexity of adaptation actions across scales and contexts means that institutional learning and monitoring are important components of effective adaptation.[22]

Figure SPM.3: Illustration of iterative risk management. [Figure 2-1]

The benefits of mitigation and adaptation occur over different timeframes (*high confidence*). Figure SPM.4 illustrates projected climate futures under scenarios RCP2.6 and 8.5, along with observed temperature changes. Projected global temperature increase over the next few decades is similar across emission scenarios (Figure SPM.4B).[23] During this near-term era of committed climate change, risks will evolve as socioeconomic trends interact with the changing climate. Societal responses, particularly adaptations, will influence near-term outcomes. In the second half of the 21st century and beyond, global temperature increase diverges across emission scenarios (Figure SPM.4B and 4C).[24] For this longer-term era of climate options, near-term and longer-term mitigation and adaptation, as well as development pathways, will determine the risks of climate change. Near-term choices thus affect the risks of climate change throughout the 21st century.[25]

Figure SPM.4: Observed and projected changes in annual average temperature. (A) Observed temperature trends from 1901-2012 determined by linear regression. Trends have been calculated where sufficient data permit a robust estimate (i.e., only for grid boxes with greater than 70% complete records and more than 20% data availability in the first and last 10% of the time period). Other areas are white. Solid colors indicate areas where change is significant at the 10% level. Diagonal lines indicate areas where change is not significant. Observed data (range of grid-point values: -0.53 to 2.50°C over period) are from WGI AR5 Figures SPM.1 and 2.21. (B) Observed and simulated variations in past and projected future global annual average temperature relative to 1986-2005. Black lines show the GISTEMP, NCDC-MLOST, and HadCRUT4.2 estimates from observational measurements. Blue and red shading denotes the ±1.64 standard deviation range based on simulations from 32 models for RCP2.6 and 39 models for RCP8.5; blue and red lines denote the ensemble mean for each scenario. For future projections, light-gray vertical bands specify an indicative timeframe (2030-2040) for the near-term era of committed climate change and an indicative timeframe (2080-2100) for the longer-term era of climate options. [Box CC-RC; WGI AR5 Figures SPM.1 and SPM.7] (C) CMIP5 multi-model mean projections of annual average temperature changes for 2081-2100 under RCP2.6 and 8.5, relative to 1986-2005. Solid colors indicate areas with very strong agreement, where the multi-model mean change is greater than twice the baseline variability and >90% of models agree on sign of change. Colors with white dots indicate areas with strong agreement, where >66% of models show change greater than the baseline variability and >66% of models agree on sign of change. Gray indicates areas with divergent changes, where >66% of models show change greater than the baseline variability, but <66% agree on sign of change. Colors with diagonal lines indicate areas with little or no change, where >66% of models show change less than the baseline variability, although there may be significant change at shorter timescales such as seasons, months, or days. Analysis uses model data (range of grid-point values across RCP2.6 and 8.5: 0.06 to 11.71°C) from WGI AR5 Figure SPM.8, with full description of methods in Box CC-RC. See also Annex I of WGI AR5. [Boxes 21-2 and CC-RC]

Adaptation planning and implementation at a range of scales are contingent on values, objectives, and risk perceptions (*high confidence*). Some types of adaptation options, such as insurance or large-scale infrastructure

[22] 2.1-4, 3.6, 14.1-3, 15.2-3, 15.5, 16.2-4, 17.2, 20.6, 22.4, 25.4, 25.10, Figure 1-5, Boxes 16-1 and 25-2
[23] WGI AR5 11.3
[24] WGI AR5 12.4 and Table SPM.2
[25] 2.5, 21.2-3, 21.5, Box CC-RC

projects, may differentially affect stakeholders. Recognition of diverse interests, values, and expectations, including local and indigenous knowledge, can benefit decision-making processes.[26]

Decision support is most effective when it is sensitive to context, taking into account the diversity of different types of decisions, decision processes, and constituencies (*robust evidence, high agreement*). Organizations bridging science and policy play an important role in the communication and transfer of climate-related knowledge, such as information on risks combining physical climate science and assessments of impacts, adaptation, and vulnerability (*medium evidence, high agreement*).[27]

Scenarios are useful tools for characterizing possible future socioeconomic pathways, climate change and its risks, and policy implications (*high confidence*). Climate change risks vary substantially across plausible alternative development pathways, and the relative importance of development and climate change varies by sector, region, and time period. Both development and climate change are important determinants of possible outcomes. Modeled future impacts assessed in this report are generally based on climate-model projections using the Representative Concentration Pathway (RCP) and the older IPCC Special Report on Emission Scenarios (SRES) scenarios.[28]

Uncertainties about future vulnerability, exposure, and responses of human and natural systems can be larger than uncertainties in regional climate projections, and they are beginning to be incorporated in assessments of future risks (*high confidence*). Understanding future vulnerability, as well as exposure, of interlinked human and natural systems is challenging due to the number of relevant socioeconomic factors, which have been incompletely considered to date. These factors include wealth and its distribution across society, patterns of aging, access to technology and information, labor force participation, the quality of adaptive responses, societal values, and mechanisms and institutions to resolve conflicts. Cross-regional phenomena are also important for understanding the ramifications of climate change at regional scales.[29]

B) FUTURE RISKS AND OPPORTUNITIES FOR ADAPTATION

This section presents future risks and more limited potential benefits across sectors and regions, examining how they are affected by the magnitude and rate of climate change and by development choices. It also points to opportunities for reducing risks through mitigation and adaptation. The section describes risks and potential benefits over the next few decades, the near-term era of committed climate change, and in the second half of the 21st century and beyond, the longer-term era of climate options.

B-1. Key Risks across Sectors and Regions

Many risks of climate change warrant consideration. Key risks, in particular, are potentially severe impacts relevant to “dangerous anthropogenic interference with the climate system,” as described in Article 2 of the United Nations Framework Convention on Climate Change. Key risks can involve potentially large or irreversible consequences, high probability of consequences, and/or limited adaptive capacity. Key risks are integrated into five overarching reasons for concern (RFCs) in Box SPM.4.

Key risks that span sectors and regions (*high confidence*) include the following, each of which contributes to one or more RFC.[30]

i. Risk of death, injury, and disrupted livelihoods in low-lying coastal zones and small island developing states, due to sea-level rise, coastal flooding, and storm surges.[31] [RFC 1-5]
ii. Risk of food insecurity linked to warming, drought, and precipitation variability, particularly for poorer populations.[32] [RFC 2-4]

[27] 2.1-4, 8.4, 14.4, 16.2-3, 16.5, 21.2-3, 21.5, 22.4, Box 9-4
[28] 1.1, 1.3, 2.2-3, 19.6, 20.2, 21.3, 21.5, 26.2, Box CC-RC; WGI AR5 Box SPM.1
[29] 11.3, 21.3-5, 25.3-4, 25.11, 26.2
[30] 19.2-4, 19.6, Table 19-4, Boxes 19-2 and CC-KR
[31] 5.4, 8.1-2, 13.1-2, 19.2-4, 19.6-7, 24.4-5, 26.7-8, 29.3, 30.3, Tables 19-4 and 26-1, Figures 7-4 and 26-2, Boxes 25-1, 25-7, and CC-KR
[32] 3.5, 7.4-5, 11.3, 11.6, 13.2, 19.3-4, 19.6, 22.3, 24.4, 25.5, 25.7, 26.5, 26.8, 27.3, Table 19-4, Boxes CC-KR and CC-VW

iii. Risk of severe harm for large urban populations due to inland flooding.[33] [RFC 2 and 3]
iv. Risk of loss of rural livelihoods and income due to insufficient access to drinking and irrigation water and reduced agricultural productivity, particularly for farmers and pastoralists with minimal capital in semi-arid regions.[34] [RFC 2 and 3]
v. Systemic risks due to extreme events leading to breakdown of infrastructure networks and critical services.[35] [RFC 2-4]
vi. Risk of loss of marine ecosystems and the services they provide for coastal livelihoods, especially for fishing communities in the tropics and the Arctic.[36] [RFC 1-5]
vii. Risk of loss of terrestrial ecosystems and the services they provide for terrestrial livelihoods.[37] [RFC 1, 3, and 4]
viii. Risk of mortality, morbidity, and other harms during periods of extreme heat, particularly for vulnerable urban populations.[38] [RFC 2 and 3]

Mitigation of greenhouse gas emissions over the next few decades can substantially reduce risks of climate change in the second half of the 21st century (*high confidence*). Examples include reduced risk of negative agricultural yield impacts, of water scarcity, of major challenges to urban settlements and infrastructure from sea-level rise, and of adverse impacts from heat extremes, floods, and droughts in areas where increased occurrence of these extremes are projected. Under all assessed scenarios for mitigation and adaptation, some risk from residual damages is unavoidable (*very high confidence*).[39]

Large magnitudes of warming increase the likelihood of severe, pervasive, and challenging impacts. Risks associated with global temperature rise in excess of 4°C relative to preindustrial levels include potential adverse impacts on agricultural production worldwide, potentially extensive ecosystem impacts, and increasing species extinction risk (*high confidence*), as well as possible crossing of thresholds that lead to disproportionately large earth system responses (*low confidence*). The precise levels of climate change sufficient to trigger tipping points (critical thresholds) remain uncertain, but the likelihood of crossing tipping points in the earth system or interlinked human and natural systems decreases with reduced greenhouse gas emissions (*medium confidence*).[40]

Box SPM.4. Human Interference with the Climate System

Human interference with the climate system is occurring, yet determining whether this interference is dangerous, as relevant to Article 2 of the UNFCCC, involves both risk assessment and value judgments. This report assesses risks across contexts and through time, providing a basis for value judgments about the level of climate change at which risks become dangerous.

Five integrative reasons for concern (RFCs) provide a framework for summarizing key risks across sectors and regions. First identified in the IPCC Third Assessment Report, the reasons for concern illustrate the implications of warming and of adaptation limits for people, economies, and ecosystems. They provide one starting point for evaluating dangerous anthropogenic interference with the climate system. An updated assessment of risks for each reason for concern is presented below and in Box SPM.4 Figure 1. All temperature changes are given relative to 1986-2005 ("recent").[41]

(1) ***Unique and threatened systems:*** Some unique and threatened systems, including ecosystems and cultures, are at risk from climate change at recent temperatures. The number of such systems at risk of severe consequences increases at warming of 1°C. Many species and systems with limited adaptive capacity are subject to very high risks at warming of 2°C, particularly Arctic sea ice systems and coral reefs (*high confidence*).

(2) ***Extreme weather events:*** Climate-change-related risks from extreme events, such as heat waves, extreme precipitation, and coastal flooding, are moderate at recent temperatures (*high confidence*) and high at 1°C warming (*medium confidence*).

[33] 3.2, 3.4-5, 8.1-2, 13.2, 19.6, 25.10, 26.3, 26.7-8, 27.3, Tables 19-4 and 26-1, Boxes 25-8 and CC-KR
[34] 3.2, 3.4-5, 8.2, 9.3, 12.2, 13.2, 19.3, 19.6, 24.4, 25.7, 26.8, Table 19-4, Boxes 25-5 and CC-KR
[35] 8.1-2, 10.2-3, 12.6, 19.6, 23.9, 25.10, 26.7-8, 28.3, Table 19-4, Boxes CC-KR and CC-HS
[36] 5.4, 6.3, 7.4, 9.3, 19.5-6, 22.3, 25.6, 27.3, 28.2-3, 29.3, 30.5-7, Table 19-4, Boxes CC-OA, CC-CR, CC-KR, and CC-HS
[37] 4.3, 19.3-6, 22.3, 25.6, 27.3, 28.2-3, Tables 19-4 and 23-2, Boxes CC-KR and CC-WE
[38] 8.1-2, 11.3-4, 13.2, 19.3, 19.6, 23.5, 24.4, 25.8, 26.6, 26.8, Tables 19-4 and 26-1, Boxes CC-KR and CC-HS
[39] 3.4-5, 16.3, 16.6, 17.2, 19.7, 20.3, 25.10, Tables 3-2, 8-3, and 8-5, Boxes 13-2, 16-3, and 25-1
[40] 4.2-3, 11.8, 19.5, 19.7, 26.5, Box CC-HS
[41] 18.6, 19.6

(3) ***Distribution of impacts:*** Risks for disproportionately affected people and communities are generally greatest in low-latitude, less-developed areas, and are moderate at recent temperatures because of regionally differentiated climate-change impacts on food production (*medium* to *high confidence*). Developed countries also have highly vulnerable populations. Based on risks for regional crop production and water resources in some countries, risks become high for warming above 2°C (*medium confidence*).

(4) ***Global aggregate impacts:*** Risks to the overall global economy and Earth's biodiversity become moderate for warming between 1-2°C (*medium confidence*) and high around 3°C, reflecting warming-dependent increases in risks of economic impacts (*low confidence*) and extensive biodiversity loss with concomitant loss of ecosystem services (*high confidence*).

(5) ***Large-scale singular events:*** With increasing warming, some physical systems or ecosystems may be at risk of abrupt and drastic changes. Risks of such tipping points become moderate between 0-1°C, due to early warning signs that both coral reef and Arctic systems are already experiencing irreversible regime shifts. Risks become high between 1-4°C, with a disproportionate increase in risks as temperature increases between 1-2°C, due to the potential for commitment to a large and irreversible sea-level rise from ice sheet loss (*medium confidence*).

Box SPM.4 Figure 1: (Right panel) The dependence of risks associated with reasons for concern on the level of climate change, updated based on assessment of the literature and expert judgments. Purple shading, introduced in this assessment, indicates very high risk of severe impacts and the presence of significant irreversibilities combined with limited adaptive capacity. [Figure 19-4] (Left panel) Observed and simulated variations in past and projected future global annual average temperature relative to 1986-2005, as in Figure SPM.4. [Figure RC-1, Box CC-RC; WGI AR5 Figures SPM.1 and SPM.7]

B-2. Sectoral Risks and Potential for Adaptation

Climate change will amplify climate-related risks to natural and human systems. Some of these risks will be limited to a particular sector or region, and others will have cascading effects. To a lesser extent, climate change will also reduce some climate-related risks and have some potential benefits.

Freshwater resources

Freshwater-related risks of climate change increase significantly with increasing greenhouse gas emissions (*robust evidence, high agreement*). By the end of the 21st century, the number of people exposed annually to a 20th-century 100-year river flood is projected to be three times greater for RCP8.5 than for RCP2.6. In presently dry regions, drought frequency will *likely* increase by the end of this century under RCP8.5 (*medium confidence*).[42]

Climate change will reduce renewable surface water and groundwater resources significantly in most dry subtropical regions, exacerbating competition for water among sectors (*robust evidence, high agreement*). In contrast, water resources will increase at high latitudes. Each degree of warming is projected to decrease renewable water resources by at least 20% for an additional 7% of the global population. Climate change is projected to reduce raw water quality and pose risks to drinking water quality, due to interacting factors: increased temperature; increased sediment, nutrient, and pollutant loadings from heavy rainfall; reduced dilution of pollutants during droughts; and disruption of treatment facilities during floods (*medium evidence, high agreement*). Adaptive water management techniques, including scenario planning, learning-based approaches, and flexible and low-regret solutions, can address uncertainty due to climate change (*limited evidence, high agreement*).[43]

Terrestrial and freshwater ecosystems

A large fraction of terrestrial and freshwater species faces increased extinction risk under projected climate change during and beyond the 21st century, especially as climate change interacts with other pressures, such as habitat modification, over-exploitation, pollution, and invasive species (*high confidence*). Extinction risk is increased under all RCP scenarios, with risk increasing with both magnitude and rate of climate change. Many species will be unable to move fast enough during the 21st century to track suitable climates under mid- and high-

[42] 3.4-5, 26.3, Tables 3-2 and 25-1, Box 25-8; WGI AR5 12.4
[43] 3.2, 3.4-6, 22.3, 25.5, 26.3, Table 3-2, Boxes 25-2 and CC-WE

range rates of climate change (i.e., RCP4.5, 6.0, and 8.5) (*medium confidence*). See Figure SPM.5. Management actions can reduce, but not eliminate, risks to ecosystems and can increase ecosystem adaptability, for example through reduction of other stresses and habitat fragmentation, maintenance of genetic diversity, assisted translocation, and manipulation of disturbance regimes (*high confidence*).[44]

Within this century, magnitudes and rates of climate change associated with RCP4.5, 6.0, and 8.5 pose high risk of abrupt and irreversible regional-scale change in the composition, structure, and function of terrestrial and freshwater ecosystems, for example in the boreal-tundra Arctic system and the Amazon forest, leading to substantial additional climate change (*medium confidence*). Carbon stored in the terrestrial biosphere is vulnerable to loss to the atmosphere as a result of climate change, deforestation, and ecosystem degradation (*high confidence*). Tree mortality and associated forest dieback will occur in many regions in the next one to three decades (*medium confidence*), with forest dieback posing risks for carbon storage, biodiversity, wood production, water quality, amenity, and economic activity.[45]

Figure SPM.5: Rates of displacement of several terrestrial and freshwater species groups in the absence of human intervention, indicating climate velocities for temperature. White boxes with black bars indicate medians and ranges of observed rates of displacement for trees, plants, mammals, birds, plant-feeding insects, and freshwater mollusks. For RCP2.6, 4.5, 6.0, and 8.5 for 2050-2090, horizontal lines show climate velocity for the global-land-area average and for large flat regions. Species groups with displacement rates below each line are projected to be unable to track climate in the absence of human intervention. [Figure 4-5]

Coastal systems and low-lying areas

Due to sea-level rise throughout the 21st century and beyond, coastal systems and low-lying areas will increasingly experience adverse impacts such as submergence, coastal flooding, and coastal erosion (*very high confidence*). The population and assets exposed to coastal risks as well as human pressures on coastal ecosystems will increase significantly in the coming decades due to population growth, economic development, and urbanization (*high confidence*).[46]

By 2100, due to climate change and development patterns and without adaptation, hundreds of millions of people will be affected by coastal flooding and displaced due to land loss (*high confidence*). The majority affected will be in East, Southeast, and South Asia. The relative costs of adaptation vary strongly among and within regions and countries for the 21st century (*high confidence*). Some low-lying developing countries and small island states are expected to face very high impacts and associated annual damage and adaptation costs of several percentage points of GDP.[47]

Marine systems

By mid 21st century, spatial shifts of marine species will cause species richness to increase at mid and high latitudes (*high confidence*) and to decrease at tropical latitudes (*medium confidence*), resulting in global redistribution of catch potential for fishes and invertebrates, with implications for food security (*medium confidence*). See Figure SPM.6A. Animal displacements are projected to lead to high-latitude invasions and high local-extinction rates in the tropics and semi-enclosed seas. Open-ocean net primary production is projected to redistribute and to fall globally by 2100 under RCP8.5. Climate change adds to the threats of over-fishing and other non-climatic stressors, thus complicating marine management regimes (*high confidence*).[48]

Ocean acidification poses risks to ecosystems, especially polar ecosystems and coral reefs, associated with impacts on the physiology, behavior, and population dynamics of individual species (*medium* to *high confidence*). Highly calcified mollusks, echinoderms, and reef-building corals are more sensitive than crustaceans (*high confidence*) and fishes (*low confidence*), with potential consequences for fisheries and livelihoods. See Figure SPM.6B. Ocean acidification occurs in combination with other environmental changes, both globally (e.g.,

[44] 4.3-4, 25.6, 26.4, Box CC-RF
[45] 4.2-3, 25.6, Figure 4-8, Boxes 4-2, 4-3, and 4-4
[46] 5.3-5, 22.3, 24.4, 25.6, 26.3, 26.8, Table 26-1, Box 25-1
[47] 5.3-5, 24.4
[48] 6.3-5, 7.4, 25.6, 28.3, 30.6-7, Boxes CC-MB and CC-PP

warming, decreasing oxygen levels) and locally (e.g., pollution, eutrophication) (*high confidence*). Simultaneous environmental drivers, such as warming and ocean acidification, can lead to interactive, complex, and amplified impacts for species.[49]

Figure SPM.6: Climate change risks for fisheries. (A) For 2°C increase from preindustrial levels using SRES A1B (≈RCP6.0), projected global redistribution of maximum catch potential of 1000 species of exploited fishes and invertebrates, comparing the 10-year averages 2001-2010 and 2051-2060, without analysis of potential impacts of overfishing. (B) Marine mollusk and crustacean fisheries (estimated catch rates ≥0.005 tonnes per sq. km) and known locations of warm- and cold-water corals, depicted on a global map showing the distribution of ocean acidification in 2100 under RCP8.5. [WGI AR5 Figure SPM.8] The bottom panel compares sensitivity to ocean acidification across corals, mollusks, and crustaceans, vulnerable animal phyla with socioeconomic relevance (e.g., for coastal protection and fisheries). The number of species analyzed across studies is given for each category of elevated CO_2. For 2100, RCP scenarios falling within each pCO_2 category are as follows: RCP4.5 for 500-650 μatm, RCP6.0 for 651-850 μatm, and RCP8.5 for 851-1370 μatm. [6.1, 6.3, 30.5, Figures 6-10 and 6-14; WGI AR5 Box SPM.1]

Food production systems and food security

Without adaptation, local temperature increases of 1°C or more above preindustrial levels are projected to negatively impact yields for the major crops (wheat, rice, and maize) in tropical and temperate regions, although individual locations may benefit (*medium confidence*). With or without adaptation, climate change will reduce median yields by 0 to 2% per decade for the rest of the century, as compared to a baseline without climate change. These projected impacts will occur in the context of rising crop demand, projected to increase by about 14% per decade until 2050. See Figure SPM.7 for a summary of projected changes in crop yields over the 21st century. Risks are greatest for tropical countries, given projected impacts that exceed adaptive capacity and higher poverty rates compared with temperate regions. Climate change will progressively increase inter-annual variability of crop yields in many regions.[50]

On average, adaptation improves yields by the equivalent of ~15-18% of current yields, but the effectiveness of adaptation is highly variable (*medium confidence*). Positive and negative yield impacts projected for local temperature increases of about 2°C above preindustrial levels maintain possibilities for effective adaptation in crop production (*high confidence*). For local warming of about 4°C or more, differences between crop production and population-driven demand will become increasingly large in many regions, posing significant risks to food security even with adaptation.[51]

Figure SPM.7: Summary of projected changes in crop yield as a function of time with and without adaptation, across studies for all regions. Data (n=1090) are plotted in the 20-year period on the horizontal axis that includes the midpoint of each future projection period. [Figure 7-5]

Urban areas

Heat stress, extreme precipitation, inland and coastal flooding, and drought and water scarcity pose risks in urban areas for people, assets, economies, and ecosystems, with risks amplified for those lacking essential infrastructure and services or living in exposed areas (*very high confidence*). Reducing basic service deficits and building resilient infrastructure systems could significantly reduce exposure and vulnerability in cities and urban areas. Urban adaptation benefits from effective multi-level urban risk governance, alignment of policies and incentives, strengthened local government and community adaptation capacity, synergies with the private sector, appropriate financing and institutional development, and increased capacity of low-income groups and vulnerable communities and their partnerships with local governments (*medium confidence*).[52]

Rural areas

[49] 5.4, 6.3, 6.5, 22.3, 25.6, 28.3, 30.5, Boxes CC-CR, CC-OA, and TS.7
[50] 7.4, 22.3, 24.4, 25.7, 26.5, Figures 7-4, 7-5, 7-6, and 7-7
[51] 7.5, 22.3, 25.7, 26.5, Tables 7-2 and 11-3, Figures 7-4, 7-5, 7-7, and 7-8
[52] 3.5, 8.2-4, 22.3, 24.4-5, 26.8, Boxes 25-9 and CC-HS

Major future rural impacts will be felt in the near-term and beyond through impacts on water supply, food security, and agricultural incomes, including shifts in production of food and non-food crops in many areas of the world (*high confidence*). Price rises, which may be induced by climate shocks as well as other factors, have a disproportionate impact on the welfare of the poor in rural areas, such as female-headed households and those with limited access to modern agricultural inputs, infrastructure, and education. Options exist for adaptations within international agricultural trade (*medium confidence*).[53]

Key economic sectors and services

For most economic sectors, the impacts of drivers such as changes in population, age structure, income, technology, relative prices, lifestyle, regulation, and governance will be large relative to the impacts of climate change (*medium evidence, high agreement*). Climate change will reduce energy demand for heating and increase energy demand for cooling in the residential and commercial sectors (*robust evidence, high agreement*). Climate change will affect energy sources and technologies differently, depending on resources (e.g., water flow, wind, insolation), technological processes (e.g., cooling), or locations (e.g., coastal regions, floodplains) involved. More frequent and/or severe weather disasters for some regions and/or hazards will increase losses and loss variability in various regions and challenge insurance systems to offer affordable coverage while raising more risk-based capital, particularly in low- and middle-income countries. Large-scale public-private risk prevention initiatives and government insurance of the non-diversifiable portion of risk offer example mechanisms for adaptation.[54]

Global mean temperature increase of 2.5°C above preindustrial levels may lead to global aggregate economic losses between 0.2 and 2.0% of income (*medium evidence, medium agreement*). Losses increase with greater warming, but little is known about aggregate economic impacts above 3°C. Impact estimates are incomplete and depend on a large number of assumptions, many of which are disputable, and aggregate impacts hide large differences between and within countries. The incremental economic impact of emitting a tonne of carbon dioxide lies between a few dollars and several hundreds of dollars per tonne of carbon (*robust evidence, medium agreement*). Estimates vary strongly with the assumed discount rate, with larger ranges for lower discount rates.[55]

Human health

Until mid-century, climate change will impact human health mainly by exacerbating health problems that already exist (*very high confidence*), and climate change throughout the 21st century will lead to increases in ill-health in many regions, as compared to a baseline without climate change (*high confidence*). Examples include greater likelihood of injury, disease, and death due to more intense heat waves and fires; increased likelihood of under-nutrition resulting from diminished food production in poor regions; risks from lost work capacity and reduced labor productivity in vulnerable populations; and increased risks from food- and water-borne diseases. Positive effects will include modest improvements in cold-related mortality and morbidity in some areas due to fewer cold extremes, shifts in food production, and reduced capacity of disease-carrying vectors (*medium confidence*), but globally, positive impacts will be outweighed by the magnitude and severity of negative impacts (*high confidence*). The most effective adaptation measures for health in the near-term are programs that implement basic public health measures such as provision of clean water and sanitation, secure essential health care including vaccination and child health services, increase capacity for disaster preparedness and response, and alleviate poverty (*very high confidence*). For RCP8.5 by 2100, the combination of high temperature and humidity in some areas for parts of the year will compromise normal human activities, including growing food or working outdoors (*high confidence*).[56]

Human security

Climate change over the 21st century will have significant impacts on forms of migration that compromise human security (*medium evidence, high agreement*). Populations that lack the resources for mobility and

[53] 9.3, 25.9, 26.8, Box 25-5
[54] 3.5, 10.2, 10.7, 10.10, 25.7, 26.7, Box 25-7
[55] 10.9
[56] 8.2, 11.3-8, 19.3, 22.3, 25.8, 26.6, Figure 25-5, Box CC-HS

migration often experience higher exposure to weather-related extremes, in both rural and urban areas, particularly in low-income countries. Expanding opportunities for mobility can reduce vulnerability, but altered migration flows can also create risks as well as potential benefits for migrants and for sending and receiving regions and states.[57]

Climate change indirectly increases risks from violent conflict in the form of civil war, inter-group violence, and violent protests by exacerbating well-established drivers of these conflicts such as poverty and economic shocks (*medium confidence*). Statistical studies show that climate variability is significantly related to these forms of conflict. Poorly designed adaptation and mitigation strategies can increase risks from violent conflict.[58]

Climate change over the 21st century will lead to new challenges to states and will increasingly shape national security policies (*medium evidence, medium agreement*). Small-island states and other states highly vulnerable to sea-level rise face major challenges to their territorial integrity. Some transboundary impacts of climate change, such as changes in sea ice, shared water resources, and migration of fish stocks, have the potential to increase rivalry among states. The presence of robust institutions can manage many of these rivalries to reduce conflict risks.[59]

Livelihoods and poverty

Throughout the 21st century, climate change impacts will slow down economic growth and poverty reduction, further erode food security, and trigger new poverty traps, the latter particularly in urban areas and emerging hotspots of hunger (*medium confidence*). Climate change will exacerbate poverty in low and lower-middle income countries and create new poverty pockets in upper-middle- to high-income countries with increasing inequality. In urban and rural areas, wage-labor-dependent poor households that are net buyers of food will be particularly affected due to food price increases, including in regions with high food insecurity and high inequality (particularly Africa), although the agricultural self-employed could benefit. Insurance programs, social protection measures, and disaster risk management may enhance long-term livelihood resilience among poor and marginalized people, if policies address multidimensional poverty.[60]

B-3. Regional Key Risks and Potential for Adaptation

Risks will vary across regions and populations, through space and time, dependent on myriad factors including the extent of mitigation and adaptation. Key regional risks identified with *medium* to *high confidence* are presented in Table SPM.1. Projected changes in climate and increasing atmospheric CO_2 will have positive effects for some sectors in some locations. For extended summary of regional risks and the more limited potential benefits, see Technical Summary section B-3 and Chapters 21-30.

Table SPM.1: Key regional risks from climate change and the potential for reducing risks through mitigation and adaptation. Risks have been identified based on assessment of the relevant scientific, technical, and socioeconomic literature, as detailed in supporting chapter sections. Each key risk is characterized as very low to very high for three timeframes: the present, near-term (here, assessed over 2030-2040), and longer-term (here, assessed over 2080-2100). Assessed risk levels integrate probability and consequence over the full range of possible outcomes, acknowledging the importance of differences in values and objectives in interpretation of the assessed risk levels. For the near-term era of committed climate change, projected levels of global mean temperature increase do not diverge substantially across emission scenarios. For the longer-term era of climate options, risk levels are presented for global mean temperature increase of 2°C and 4°C above preindustrial levels, illustrating the potential role of mitigation in reducing risks. For the present, risk levels are estimated for current adaptation and a hypothetical highly adapted state, identifying where current adaptation deficits exist. For the future, risk levels are estimated for a continuation of current adaptation and for a highly adapted state, representing the potential for and limits to adaptation. Relevant climate variables are indicated by icons. Risk levels are not necessarily comparable, especially across regions, because the assessment considers potential impacts and adaptation in different physical, biological, and human systems across diverse regional contexts.

C) MANAGING FUTURE RISKS AND BUILDING RESILIENCE

Managing the risks of climate change involves decisions with implications for future societies, economies, environment, and climate. This section evaluates adaptation as a means to build resilience, as well as limits to adaptation, the role of transformation, and climate-resilient pathways. Figure SPM.8 provides an overview of responses for addressing climate change.

Figure SPM.8: An overview of overlapping entry points and approaches, as well as core considerations, in responding to climate change, as assessed in the WGII AR5. Bracketed references indicate sections of this summary with corresponding assessment findings.

C-1. Principles for Effective Adaptation

Adaptation is highly regionally and context specific, with no single approach for reducing risks appropriate across all settings (*medium confidence*). Effective risk reduction and adaptation strategies consider the dynamics of vulnerability and exposure and their linkages with development and climate change (*high confidence*). Specific examples of responses to climate change are presented in Table SPM.2.[61]

Table SPM.2: Managing the risks of climate change: entry points, strategies, and adaptation options. These approaches should be considered overlapping rather than discrete, and they are often pursued simultaneously. Examples given can be relevant to more than one category. [14.2-3, Table 14-1]

From individuals to governments, actors across scales and regions have complementary roles in enabling adaptation planning and implementation (*high confidence*), for example through increasing awareness of climate change risks, learning from experience with climate variability, and achieving synergies with disaster risk reduction. Local government and the private sector are increasingly recognized as critical to progress in adaptation, given their roles in scaling up adaptation of communities and households and in managing risk information and financing (*medium evidence, high agreement*). National governments can coordinate adaptation by local and subnational governments, creating legal frameworks, protecting vulnerable groups, and providing information, policy frameworks, and financial support (*robust evidence, high agreement*). Public action can influence the degree to which private parties undertake adaptation actions.[62]

In many cases, a first step towards adaptation to future climate change is reducing vulnerability and exposure to present climate through low-regrets measures and actions emphasizing co-benefits (*high confidence*). Available strategies and actions can increase resilience across a range of possible future climates while helping to improve human livelihoods, social and economic well-being, and environmental quality. See Table SPM.2. Integration of adaptation into planning and decision-making can promote synergies with development.[63]

Multiple simultaneous constraints can interact to impede adaptation planning and implementation (*high confidence*). Common constraints on implementation arise from the following: uncertainty about projected impacts; limited financial and human resources; limited integration or coordination of different levels of governance; different perceptions of risks; inadequate responses from political institutions; competing values; absence of adaptation leaders and champions; and limited tools to monitor adaptation effectiveness. Underestimating the complexity of adaptation as a social process can create unrealistic expectations.[64]

Poor planning, overemphasizing short-term outcomes, or discounting or failing to consider all consequences can result in maladaptation (*medium evidence, high agreement*). Maladaptation can increase the vulnerability or exposure of the target group in the future, or the vulnerability of other locations or sectors.[65]

[65] 14.6, 15.5, 17.2-3, 22.4

Existing and emerging economic instruments can foster adaptation by providing incentives for anticipating and reducing impacts (*medium confidence*). Instruments include risk sharing and transfer mechanisms, loans, public-private finance partnerships, payments for environmental services, improved resource pricing (e.g., water markets), charges and subsidies including taxes, norms and regulations, and behavioral approaches. Risk financing mechanisms across scales, such as insurance and risk pools, contribute to increasing resilience to climate extremes and climate variability, but can also provide disincentives, cause market failure, and decrease equity. The public sector often plays a key role as regulator, provider, or insurer of last resort.[66]

Global adaptation cost estimates are substantially greater than current adaptation funding and investment, particularly in developing countries, suggesting a funding gap and a growing adaptation deficit (*medium confidence*). The most recent global adaptation cost estimates suggest a range from 70 to 100 US$ billion per year in developing countries from 2010 to 2050 (*low confidence*). Important omissions and shortcomings in data and methods render these estimates highly preliminary (*high confidence*).[67]

C-2. Climate-resilient Pathways and Transformation

Climate-resilient pathways are sustainable-development trajectories that combine adaptation and mitigation to reduce climate change and its impacts. They include iterative processes to ensure that effective risk management can be implemented and sustained (*high confidence*). Prospects for climate-resilient development pathways are related fundamentally to what the world accomplishes with climate change mitigation.[68]

Greater rates and magnitude of climate change increase the likelihood of exceeding adaptation limits that emerge from the interaction among climate change and biophysical and socioeconomic constraints (*high confidence*). Opportunities to take advantage of positive synergies between adaptation and mitigation may decrease with time, particularly if limits to adaptation are exceeded. In some parts of the world, current failures to address emerging impacts are already eroding the basis for sustainable development.[69]

Significant co-benefits, synergies, and tradeoffs exist between mitigation and adaptation and between alternative adaptation responses; interactions occur both within and across regions (*very high confidence*). Increasing efforts to mitigate and adapt to climate change imply an increasing complexity of interactions, particularly at the intersections among water, energy, land use, and biodiversity, but tools to understand and manage these interactions remain limited. For instance, increasing bioenergy crop cultivation poses risks to ecosystems and biodiversity, although contributions of biomass energy to mitigation reduce climate-related risks (*high confidence*). Examples of mitigation actions with adaptation co-benefits include (i) improved energy efficiency and cleaner energy sources, leading to reduced local emissions of health-damaging climate-altering air pollutants, and (ii) reduced energy and water consumption in urban areas through greening cities and recycling water.[70]

Transformations in political, economic, and technological systems resulting from changes in paradigms and goals can facilitate adaptation and mitigation and promote sustainable development (*high confidence*). Transformational adaptation is an important consideration for decisions involving long life- or lead-times, and it can be a response to adaptation limits. It includes adaptation at greater scale or magnitude, introduction of new technologies or practices, formation of new structures or systems of governance, or shifts in the location of activities. Societal debates over risks from forced and reactive transformations as opposed to deliberate transitions to sustainability may place new and increased demands on governance structures to reconcile conflicting goals and visions for the future.[71]

Box SPM.1. Terms Critical for Understanding the Summary[72]

Climate change: Climate change refers to a change in the state of the climate that can be identified (e.g., by using statistical tests) by changes in the mean and/or the variability of its properties, and that persists for an extended period, typically decades or longer. Climate change may be due to natural internal processes or external forcings such as modulations of the solar cycles, volcanic eruptions, and persistent anthropogenic changes in the composition of the atmosphere or in land use. Note that the Framework Convention on Climate Change (UNFCCC), in its Article 1, defines climate change as: 'a change of climate which is attributed directly or indirectly to human activity that alters the composition of the global atmosphere and which is in addition to natural climate variability observed over comparable time periods.' The UNFCCC thus makes a distinction between climate change attributable to human activities altering the atmospheric composition, and climate variability attributable to natural causes.

Exposure: The presence of people, livelihoods, species or ecosystems, environmental services and resources, infrastructure, or economic, social, or cultural assets in places that could be adversely affected.

Vulnerability: The propensity or predisposition to be adversely affected. Vulnerability encompasses a variety of concepts including sensitivity or susceptibility to harm and lack of capacity to cope and adapt.

Impacts: Effects on natural and human systems. In this report, the term *impacts* is used primarily to refer to the effects on natural and human systems of extreme weather and climate events and of climate change. Impacts generally refer to effects on lives, livelihoods, health status, ecosystems, economic, social, and cultural assets, services (including environmental), and infrastructure due to the interaction of climate changes or hazardous climate events occurring within a specific time period and the vulnerability of an exposed society or system. Impacts are also referred to as *consequences* and *outcomes*. The impacts of climate change on geophysical systems, including floods, droughts, and sea-level rise, are a subset of impacts called physical impacts.

Risk: The potential for consequences where something of human value (including humans themselves) is at stake and where the outcome is uncertain. Risk is often represented as probability of occurrence of hazardous events or trends multiplied by the consequences if these events occur. This report assesses climate-related risks.

Adaptation: The process of adjustment to actual or expected climate and its effects. In human systems, adaptation seeks to moderate harm or exploit beneficial opportunities. In natural systems, human intervention may facilitate adjustment to expected climate and its effects.

Transformation: A change in the fundamental attributes of a system, often based on altered paradigms, goals, or values. Transformations can occur in technological or biological systems, financial structures, and regulatory, legislative, or administrative regimes.

Box SPM.2. Communication of the Degree of Certainty in Assessment Findings

The degree of certainty in each key finding of the assessment is based on the type, amount, quality, and consistency of evidence (e.g., data, mechanistic understanding, theory, models, expert judgment) and the degree of agreement. The summary terms to describe evidence are: *limited*, *medium*, or *robust*; and agreement: *low*, *medium*, or *high*.

Confidence in the validity of a finding synthesizes the evaluation of evidence and agreement. Levels of confidence include five qualifiers: *very low*, *low*, *medium*, *high*, and *very high*.

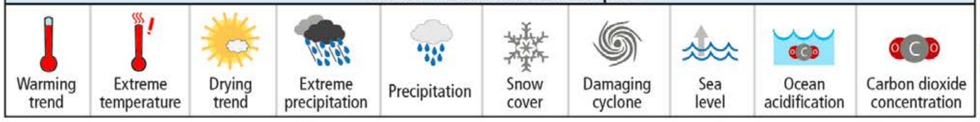
The likelihood, or probability, of some well-defined outcome having occurred or occurring in the future can be described quantitatively through the following terms: v*irtually certain*, 99–100% probability; *extremely likely*, 95–100%; *very likely*, 90–100%; *likely*, 66–100%; *more likely than not*, >50–100%; *about as likely as not*, 33–66%; *unlikely*, 0–33%; *very unlikely*, 0–10%; *extremely unlikely*, 0–5%; and *exceptionally unlikely*, 0–1%. Unless otherwise indicated, findings assigned a likelihood term are associated with *high* or *very high* confidence. Where appropriate, findings are also formulated as statements of fact without using uncertainty qualifiers.

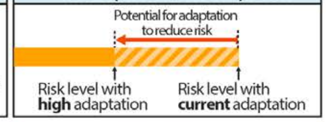
[72] Reflecting progress in science, some definitions differ in breadth and focus from the definitions used in the AR4 and other IPCC reports.

Within paragraphs of this summary, the confidence, evidence, and agreement terms given for a bold key finding apply to subsequent statements in the paragraph, unless additional terms are provided.

[1.1, Box 1-1]

Table SPM.1.

Climate-related drivers of impacts	Risk & potential for adaptation
	




Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
Africa					
Compounded stress on water resources facing significant strain from overexploitation and degradation at present and increased demand in the future (*high confidence*)	• Reducing non-climate stressors on water resources • Strengthening institutional capacities for demand management, groundwater assessment, integrated water-wastewater planning, and integrated land and water governance		22.3-4	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Reduced crop productivity with strong adverse effects on regional, national, and household food security, also given increased pest and disease damage and flood impacts on food system infrastructure (*high confidence*)	• Technological adaptation responses (e.g., stress-tolerant crop varieties, irrigation) • Enhancing smallholder access to credit and other critical production resources and diversifying livelihoods • Strengthening institutions at local to regional levels to support agriculture and gender-oriented policy support		22.3-4	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Changes in the incidence and geographic range of vector- and water-borne diseases due to changes in the mean and variability of temperature and precipitation, particularly along the edges of their distribution (*medium confidence*)	• Achieving development goals, particularly improved access to safe water and improved sanitation, and enhancement of public health functions such as surveillance • Vulnerability mapping and early warning systems • Coordination across sectors		22.3	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	
Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
Europe					
Increased economic losses and people affected by flooding in river basins and coasts, driven by increasing urbanization and by increasing sea levels and peak river discharges (*high confidence*)	Adaptation can prevent most of the projected damages (*high confidence*). • Significant experience in hard flood-protection technologies • High costs for increasing flood protection • Potential barriers to implementation: demand for land in Europe and environmental and landscape concerns		23.2-3, 23.7	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Increased water restrictions. Significant reduction in water availability from river abstraction and from groundwater resources, combined with increased water demand (e.g., for irrigation, energy and industry, domestic use) and with reduced water drainage and runoff as a result of increased evaporative demand (*high confidence*)	• Proven adaptation potential from adoption of more water-efficient technologies and of water-saving strategies (e.g., for irrigation, crop species, land cover, industries, domestic use) • Further adaptation possible through solar desalinization with mitigation co-benefits		23.4, 23.7	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Increased economic losses and people affected by extreme heat events: impacts on health and well-being, labor productivity, crop production, and air quality (*medium confidence*)	• Implementation of warning systems • Adaptation of dwellings and workplaces and of transport and energy infratructure • Reductions in emissions to improve air quality • Improved wildfire management		23.3, 23.5-7	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	
Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
Asia					
Increased flooding leading to widespread damage to infrastructure and settlements in Asia (*medium confidence*)	• Exposure reduction via effective land-use planning, selective relocation, and structural measures • Reduction in the vulnerability of lifeline infrastructure and services (e.g., water, energy, waste management, food, biomass, mobility, local ecosystems, telecommunications) • Assistance to vulnerable sectors and households		24.4	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	
Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
		Asia (continued)			
Increased risk of heat-related mortality (*high confidence*)	• Heat health warning systems • Urban planning to reduce heat islands • Improvement of the built environment		24.4	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Increased risk of drought-related water and food shortage causing malnutrition (*high confidence*)	• Disaster preparedness including early-warning systems and local response strategies		24.4	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	
Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
		Australasia			
Significant change in community composition and structure of coral reefs and montane ecosystems and risk of loss of some native species in Australia (*high confidence*)	• Ability to adapt naturally is limited especially for species that occupy narrow climatic ranges and fragmented habitats. • Main human adaptation options are to reduce other pressures (e.g., pollution, runoff, fishing, tourism, introduced predators and pests) and improve early warning systems. Assisted colonization and other direct interventions such as shading of reefs have been proposed but remain untested at scale.		25.6, 25.10	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Increased frequency and intensity of flood damage to infrastructure and settlements in Australia and New Zealand (*high confidence*)	• Significant adaptation deficit in some regions to current flood risk. • Effective adaptation includes land-use controls and relocation as well as protection and accommodation of increased risk to ensure flexibility.		Table 25-1, Boxes 25-8 and 25-9	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Increasing risks to coastal infrastructure and low-lying ecosystems in Australia and New Zealand, with widespread damage towards the upper end of projected sea-level-rise ranges (*high confidence*)	• Adaptation deficit in some locations to current coastal erosion and flood risk. Successive building and protection cycles constrain flexible responses. • Effective adaptation includes land-use controls and ultimately relocation as well as protection and accommodation.		25.6, 25.10, Box 25-1	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	
Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
		North America			
Loss of ecosystem integrity, property loss, human morbidity, and mortality due to wildfires (*high confidence*)	• Some ecosystems are more fire-adapted than others. Forest managers and municipal planners are increasingly incorporating fire protection measures (e.g., prescribed burning, introduction of resilient vegetation). Institutional capacity to support ecosystem adaptation is limited. • Adaptation of human settlements is constrained by rapid private property development in high-risk areas and by limited household-level adaptive capacity.		26.4, 26.8, Box 26-2	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Heat-related human mortality (*high confidence*)	• Residential air conditioning (A/C) can effectively reduce risk. However, availability and usage of A/C is often limited among the most vulnerable individuals and is subject to complete loss during power failures. Vulnerable populations include athletes and outdoor workers for whom A/C is not available. • Community- and household-scale adaptations have the potential to reduce exposure to heat extremes via family support, heat warnings, cooling centers, greening, and high albedo surfaces.		26.6, 26.8	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Property and infrastructure damage; supply chain, ecosystem, and social system disruption; public health impacts; and water quality impairment from river and coastal urban floods (*high confidence*)	• Implementing management of urban drainage is expensive and disruptive to urban areas. • Low-regret strategies with co-benefits include less impervious surfaces leading to more groundwater recharge, green infrastructure, and rooftop gardens. • Sea-level rise increases water elevations in coastal outfalls, which impedes drainage. In many cases, older rainfall design standards are being used that need to be updated to reflect current climate conditions.		26.2-4, 26.8	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	
Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
Central and South America					
Water availability in semi-arid and glacier-melt-dependent regions and flooding in urban areas due to extreme precipitation (*high confidence*)	• Water-supply deficit replacement and improved land use • Urban flood management (including infrastructure), early warning systems, better weather and runoff forecasts, and infectious disease control		27.3	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Very low / Medium / Very high
Decreased food production and food quality (*medium confidence*)	• Development of new crop varieties more adapted to changes in CO_2, temperature, and drought • Offsetting of human and animal health impacts of reduced food quality • Offsetting of economic impacts of land use change		27.3	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Very low / Medium / Very high

Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
Small Islands					
Loss of livelihoods, coastal settlements, and infrastructure in small islands (*high confidence*)	• Significant potential exists for adaptation in islands, but additional external resources and technologies will enhance response. • Efficacy of traditional community coping strategies is expected to be substantially reduced in the future.		Figure 29-4	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Very low / Medium / Very high
The interaction of rising global mean sea level in the 21st century with high-water-level events will threaten low-lying coastal areas in small islands (*high confidence*)	• High ratio of coastal area to land mass will make adaptation a significant financial and resource challenge for islands. • Adaptation options include maintenance and restoration of coastal landforms and ecosystems, improved management of soils and freshwater resources, and appropriate building codes and settlement patterns.		29.4, Table 29-1; WGI AR5 13.5, Table 13.5	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Very low / Medium / Very high

Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
The Ocean					
Distributional shift in fish and invertebrate species, and decrease in fishery catch potential at low latitudes, e.g., in equatorial upwelling and coastal boundary systems and sub-tropical gyres (*high confidence*)	• Evolutionary adaptation potential of fish and invertebrate species to warming is limited as indicated by their ongoing latitudinal shifts. • Human adaptation options: Large-scale translocation of industrial fishing activities following the regional decreases (low latitude) vs. possibly transient increases (high latitude) in catch potential; Flexible management that can react to variability and change; Improvement of fish resilience to thermal stress by reducing other stressors such as pollution and eutrophication; Expansion of aquaculture.		6.3, Box CC-MB	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Very low / Medium / Very high
Reduced biodiversity, fisheries abundance, and coastal protection by coral reefs due to heat-induced mass coral bleaching and mortality increases, e.g., in coastal boundary systems and sub-tropical gyres (*high confidence*)	• Evidence of rapid evolution by corals is very limited. Some corals may migrate to higher latitudes, but entire reef systems are not expected to be able to track the high rates of temperature shifts. • Human adaptation options are limited to reducing other stresses, mainly by enhancing water quality, and limiting pressures from tourism and fishing. These options will delay human impacts of climate change by a few decades, but their efficacy will be severely reduced as thermal stress increases.		5.4, 6.4, 30.3, 30.5, Box CC-CR	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Very low / Medium / Very high
Coastal inundation and habitat loss due to sea-level rise and intensified precipitation events, e.g., in coastal boundary systems and sub-tropical gyres (*medium* to *high confidence*)	• Human adaptation options are limited to reducing other stresses, mainly by reducing pollution and limiting pressures from tourism, fishing, and aquaculture. • Loss of ecosystems such as sea grass, mangroves, and coral reefs can be reduced by reducing deforestation and increasing reforestation of river catchments and coastal areas to retain sediments and nutrients.		5.5, 30.5-6, Box CC-CR	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Very low / Medium / Very high

Table SPM.2.

Overlapping Entry Points	Category	Examples	Chapter Reference(s)
Vulnerability reduction through development & planning ***Including many low-regrets measures***	**Human development**	Improved access to education, nutrition, health facilities, energy, safe settlement structures, & social support structures; Reduced gender inequality & marginalization in other forms.	8.3, 9.3, 13.1-3, 14.2-3, 22.4
	Poverty alleviation	Insurance schemes; Social safety nets & social protection; Disaster risk reduction; Improved access to & control of local resources, land tenure, & storage facilities.	8.3, 9.3, 13.1-3, Box 8-4
	Livelihood security	Income, asset, & livelihood diversification; Improved infrastructure; Access to technology & decision-making fora; Enhanced agency; Changed cropping, livestock, & aquaculture practices; Reliance on social networks.	7.5, 13.1-3, 22.3-4, 23.4, 26.5, 27.3, 29.6, Table 24-7
	Disaster risk management	Early warning systems; Hazard & vulnerability mapping; Improved drainage; Flood & cyclone shelters; Building codes; Storm & wastewater management; Transport & road infrastructure improvements.	8.2-4, 11.7, 14.3, 15.3-4, 22.4, 24.4, 25.4, 26.6, 28.4
	Ecosystem management	Maintaining wetlands & urban green spaces; Coastal afforestation; Dam management; Reduction of other stressors on ecosystems & of habitat fragmentation; Maintenance of genetic diversity; Assisted translocation; Manipulation of disturbance regimes; Community-based natural resource management.	4.3-4, 8.3, 22.4, Table 3-3, Boxes 4-2, 4-3, 8-2, 15-1, 25-8, 25-9, & CC-EA
	Spatial or land-use planning	Provisioning of adequate housing, infrastructure, & services; Managing development in flood prone & other high risk areas; Urban upgrading programs; Land zoning laws; Easements; Protected areas.	4.4, 8.1, 8.3-4, 22.4, 23.7-8, 27.3, Box 25-8
Adaptation ***Including incremental & transformational adjustments***	**Structural/ physical**	***Engineered & built-environment options:*** Sea walls & coastal protection structures; Flood levees; Water storage; Improved drainage; Flood & cyclone shelters; Building codes; Storm & wastewater management; Transport & road infrastructure improvements; Floating houses; Power plant & electricity grid adjustments.	3.5-6, 5.5, 8.2-3, 10.2, 11.7, 23.3, 24.4, 25.7, 26.3, 26.8, Boxes 15-1, 25-1, 25-2, & 25-8
		Technological options: New crop & animal varieties; Traditional technologies & methods; Efficient irrigation; Water-saving technologies; Conservation agriculture; Food storage & preservation facilities; Hazard mapping & monitoring; Early warning systems; Building insulation; Mechanical & passive cooling.	7.5, 8.3, 9.4, 10.3, 15.3-4, 22.4, 24.4, 26.3, 26.5, 27.3, 28.2, 28.4, 29.6-7, Table 25-2, Boxes 20-5 & 25-2
		Ecosystem-based options: Ecological restoration; Afforestation & reforestation; Mangrove conservation & replanting; Green infrastructure (e.g., shade trees, green roofs); Controlling overfishing; Fisheries co-management; Assisted migration or managed translocation; Ecological corridors; Ex situ conservation & seed banks; Community-based natural resource management.	4.4, 5.5, 8.3, 9.4, 11.7, 15.3-4, 22.4, 23.6-7, 24.4, 25.6, 26.4, 27.3, 28.2, 29.7, 30.6, Boxes 15-1, 22-2, 25-9, 26-2, & CC-EA
		Services: Social safety nets & social protection; Food banks & distribution of food surplus; Municipal services including water & sanitation; Vaccination programs; Essential public health services; Enhanced emergency medical services.	3.5-6, 8.3, 9.3-4, 11.7, 11.9, 22.4, 29.6, Box 13-2
	Institutional	***Economic options:*** Financial incentives including taxes & subsidies; Insurance; Catastrophe bonds; Payments for ecosystem services; Water tariffs; Microfinance; Disaster contingency funds; Cash transfers.	8.3-4, 9.4, 10.7, 11.7, 13.3, 15.4, 17.5, 22.4, 26.7, 27.6, 29.6, Box 25-7
		Laws & regulations: Land zoning laws; Building standards; Easements; Water regulations & agreements; Laws to support disaster risk reduction; Laws to encourage insurance purchasing; Defined property rights & land tenure security; Protected areas; Fishing quotas; Patent pools & technology transfer.	4.4, 8.3, 9.3, 10.5, 10.7, 15.2, 15.4, 17.5, 22.4, 23.4, 23.7-8, 24.4, 25.4, 26.3, 27.3, Table 25-2, Box CC-CR
		Government policies & programs: National & regional adaptation plans including mainstreaming; Sub-national & local adaptation plans; Urban upgrading programs; Municipal water management programs; Disaster planning & preparedness; Integrated water resource management; Integrated coastal zone management; Ecosystem-based management; Community-based adaptation.	2.2-4, 3.6, 4.4, 5.5, 6.4, 7.5, 8.3, 11.7, 15.2-4, 22.4, 23.7, 25.4, 25.8, 26.8-9, 27.3-4, 29.6, 30.6, Boxes 25-1, 25-2, & 25-9
	Social	***Educational options:*** Awareness raising & integrating into education; Gender equity in education; Extension services; Sharing local & traditional knowledge; Participatory action research & social learning; Knowledge-sharing & learning platforms.	8.3-4, 9.4, 11.7, 12.3, 15.2-4, 22.4, 25.4, 28.4, 29.6, Table 25-2
		Informational options: Hazard & vulnerability mapping; Early warning & response systems; Systematic monitoring & remote sensing; Climate services; Use of indigenous climate observations; Participatory scenario development.	2.4, 5.5, 8.3-4, 9.4, 11.7, 15.2-4, 22.4, 23.5, 24.4, 25.8, 26.6, 26.8, 27.3, 28.2, 28.5, Table 25-2, Box 26-3
		Behavioral options: Household preparation & evacuation planning; Migration; Soil & water conservation; Storm drain clearance; Livelihood diversification; Changed cropping, livestock, & aquaculture practices; Reliance on social networks.	5.5, 7.5, 9.4, 11.7, 12.4, 22.3-4, 23.4, 23.7, 25.7, 26.5, 27.3, 29.6, Table SM24-7, Box 25-5
Transformation	**Spheres of change**	***Practical:*** Social & technical innovations, behavioral shifts, or institutional & managerial changes that produce substantial shifts in outcomes.	8.3, 20.5, Box 25-5
		Political: Changes in the political, social, cultural, & ecological systems or structures that currently contribute to risk & vulnerability or impede practical transformations.	14.2-3, 20.5, 25.4, Table 14-1
		Personal: Changes in individual & collective assumptions, beliefs, values, & worldviews that influence climate change responses.	14.2-3, 20.5, 25.4, Table 14-1

CONTENTS OF THE TECHNICAL SUMMARY

INTRODUCTION

Human interference with the climate system is occurring. [WGI AR5 2.2, 6.3, 10.3-6, 10.9] Climate change poses risks for human and natural systems (Figure TS.1). The assessment of impacts, adaptation, and vulnerability in the Working Group II contribution to the IPCC's Fifth Assessment Report (WGII AR5) evaluates how patterns of risks and potential benefits are shifting due to climate change and how risks can be reduced through mitigation and adaptation. It recognizes that risks of climate change will vary across regions and populations, through space and time, dependent on myriad factors including the extent of mitigation and adaptation.

[INSERT FIGURE TS.1 HERE
Figure TS.1: Climate-related hazards, exposure, and vulnerability interact to produce risk. Changes in both the climate system (left) and development processes including adaptation and mitigation (right) are drivers of hazards, exposure, and vulnerability. [19.2, Figure 19-1]]

Section A of this summary characterizes observed impacts, vulnerability and exposure, and responses to date. Section B examines the range of future risks and potential benefits across sectors and regions, highlighting where choices matter for reducing risks through mitigation and adaptation. Section C considers principles for effective adaptation and the broader interactions among adaptation, mitigation, and sustainable development.

Box TS.1 introduces the context of the WGII AR5, and Box TS.2 defines central concepts. To accurately convey the degree of certainty in key findings, the report relies on the consistent use of calibrated uncertainty language, introduced in Box TS.3. Chapter references in square brackets indicate support for findings, paragraphs of findings, figures, and tables in this summary.

_____ START BOX TS.1 HERE _____

Box TS.1. Context for the Assessment

For the past two decades, IPCC's Working Group II has developed assessments of climate change impacts, adaptation, and vulnerability. The WGII AR5 builds from the WGII contribution to the IPCC's Fourth Assessment Report (WGII AR4), published in 2007, and the Special Report on Managing the Risks of Extreme Events and Disasters to Advance Climate Change Adaptation (SREX), published in 2012. The WGII AR5 is presented in two volumes, reflecting an expanded literature basis and multidisciplinary approach, increased focus on societal impacts and responses, and continued comprehensive regional coverage. [1.1]

The number of scientific publications available for assessing climate change impacts, adaptation, and vulnerability more than doubled between 2005 and 2010, allowing for a more robust assessment that supports policymaking (*high confidence*). The diversity of the topics and regions covered has similarly expanded, as has the geographic distribution of the authors contributing to the knowledge base for climate change assessments (Box TS.1 Figure 1). Authorship of climate-change publications from developing countries has increased, although it still represents a small fraction of the total. The unequal distribution of publications presents a challenge to the production of a comprehensive and balanced global assessment. [1.1, Figure 1-1]

[INSERT BOX TS.1 FIGURE 1 HERE
Box TS.1 Figure 1: Number of climate-change publications listed in the Scopus bibliographic database. (A) Number of climate-change publications in English (as of July 2011) summed by country affiliation of all authors of the publications and sorted by region. Each publication can be counted multiple times (i.e., the number of different countries in the author affiliation list). (B) Number of climate-change publications in English with individual countries mentioned in title, abstract, or key words (as of July 2011) sorted by region for the decades 1981-1990, 1991-2000, and 2001-2010. Each publication can be counted multiple times if more than one country is listed. [Figure 1-1]]

Adaptation has emerged as a central area in climate change research, in country-level planning, and in implementation of climate change strategies (*high confidence*). The body of literature, including government and private sector reports, shows an increased focus on adaptation opportunities and the interrelations between adaptation, mitigation, and alternative sustainable pathways. The literature shows an emergence of studies on transformative processes that take advantage of synergies between adaptation planning, development strategies, social protection, and disaster risk reduction and management. [1.1]

As a core feature and innovation of IPCC assessment, major findings are presented with defined, calibrated language that communicates the strength of scientific understanding, including uncertainties and areas of disagreement (Box TS.3). Each finding is supported by a traceable account of the evaluation of evidence and agreement. [1.1, Box 1-1]

Box TS.2. Terms Critical for Understanding the Summary

Core concepts defined in the WGII AR5 glossary and used throughout the report include the following terms. Reflecting progress in science, some definitions differ in breadth and focus from the definitions used in the AR4 and other IPCC reports.

Climate change: Climate change refers to a change in the state of the climate that can be identified (e.g., by using statistical tests) by changes in the mean and/or the variability of its properties, and that persists for an extended period, typically decades or longer. Climate change may be due to natural internal processes or external forcings such as modulations of the solar cycles, volcanic eruptions, and persistent anthropogenic changes in the composition of the atmosphere or in land use. Note that the Framework Convention on Climate Change (UNFCCC), in its Article 1, defines climate change as: ‘a change of climate which is attributed directly or indirectly to human activity that alters the composition of the global atmosphere and which is in addition to natural climate variability observed over comparable time periods.’ The UNFCCC thus makes a distinction between climate change attributable to human activities altering the atmospheric composition, and climate variability attributable to natural causes.

Exposure: The presence of people, livelihoods, species or ecosystems, environmental services and resources, infrastructure, or economic, social, or cultural assets in places that could be adversely affected.

Vulnerability: The propensity or predisposition to be adversely affected. Vulnerability encompasses a variety of concepts including sensitivity or susceptibility to harm and lack of capacity to cope and adapt.

Impacts: Effects on natural and human systems. In this report, the term *impacts* is used primarily to refer to the effects on natural and human systems of extreme weather and climate events and of climate change. Impacts generally refer to effects on lives, livelihoods, health status, ecosystems, economic, social, and cultural assets, services (including environmental), and infrastructure due to the interaction of climate changes or hazardous climate events occurring within a specific time period and the vulnerability of an exposed society or system. Impacts are also referred to as *consequences* and *outcomes*. The impacts of climate change on geophysical systems, including floods, droughts, and sea-level rise, are a subset of impacts called physical impacts.

Risk: The potential for consequences where something of human value (including humans themselves) is at stake and where the outcome is uncertain. Risk is often represented as probability of occurrence of hazardous events or trends multiplied by the consequences if these events occur. This report assesses climate-related risks.

Adaptation: The process of adjustment to actual or expected climate and its effects. In human systems, adaptation seeks to moderate harm or exploit beneficial opportunities. In natural systems, human intervention may facilitate adjustment to expected climate and its effects.

> ***Incremental adaptation:*** Adaptation actions where the central aim is to maintain the essence and integrity of a system or process at a given scale.
>
> ***Transformational adaptation:*** Adaptation that changes the fundamental attributes of a system in response to climate and its effects.

Transformation: A change in the fundamental attributes of a system, often based on altered paradigms, goals, or values. Transformations can occur in technological or biological systems, financial structures, and regulatory, legislative, or administrative regimes.

Resilience: The capacity of a social-ecological system to cope with a hazardous event or disturbance, responding or reorganizing in ways that maintain its essential function, identity, and structure, while also maintaining the capacity for adaptation, learning, and transformation.

_____ START BOX TS.3 HERE _____

Box TS.3. Communication of the Degree of Certainty in Assessment Findings

Based on the Guidance Note for Lead Authors of the IPCC Fifth Assessment Report on Consistent Treatment of Uncertainties, the WGII AR5 relies on two metrics for communicating the degree of certainty in key findings:

- Confidence in the validity of a finding, based on the type, amount, quality, and consistency of evidence (e.g., data, mechanistic understanding, theory, models, expert judgment) and the degree of agreement. Confidence is expressed qualitatively.
- Quantified measures of uncertainty in a finding expressed probabilistically (based on statistical analysis of observations or model results, or both, and expert judgment).

Each finding has its foundation in evaluation of associated evidence and agreement. The summary terms to describe evidence are: *limited*, *medium*, or *robust*; and agreement: *low*, *medium*, or *high*. These terms are presented with some key findings. In many cases, assessment authors additionally evaluate their confidence about the validity of a finding, providing a synthesis of the evaluation of evidence and agreement. Levels of confidence include five qualifiers: *very low*, *low*, *medium*, *high*, and *very high*. Box TS.3 Figure 1 illustrates the flexible relationship between the summary terms for evidence and agreement and the confidence metric. For a given evidence and agreement statement, different confidence levels could be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence.

[INSERT BOX TS.3 FIGURE 1 HERE
Box TS.3 Figure 1: Evidence and agreement statements and their relationship to confidence. The shading increasing towards the top right corner indicates increasing confidence. Generally, evidence is most robust when there are multiple, consistent independent lines of high-quality evidence. [Figure 1-3]]

When assessment authors evaluate the likelihood, or probability, of some well-defined outcome having occurred or occurring in the future, a finding can include likelihood terms (see below) or a more precise presentation of probability. Use of likelihood is not an alternative to use of confidence. Unless otherwise indicated, findings assigned a likelihood term are associated with *high* or *very high* confidence.

Term	**Likelihood of the outcome**
Virtually certain	99–100% probability
Extremely likely	95– 100% probability
Very likely	90–100% probability
Likely	66–100% probability
More likely than not	>50–100% probability
About as likely as not	33–66% probability
Unlikely	0–33% probability
Very unlikely	0–10% probability
Extremely unlikely	0–5% probability
Exceptionally unlikely	0–1% probability

Where appropriate, findings are also formulated as statements of fact without using uncertainty qualifiers.

Within paragraphs of this summary, the confidence, evidence, and agreement terms given for a bold key finding apply to subsequent statements in the paragraph, unless additional terms are provided.

[1.1, Box 1-1]

_____ END BOX TS.3 HERE _____

A) IMPACTS, VULNERABILITY, AND ADAPTATION IN A COMPLEX AND CHANGING WORLD

This section presents observed effects of climate change, building from understanding of vulnerability, exposure, and climate-related hazards as determinants of impacts. The section considers the factors, including development and non-climatic stressors, that influence vulnerability and exposure, evaluating the sensitivity of systems to climate change. The section also identifies challenges and options based on adaptation experience, looking at what has motivated previous adaptation actions in the context of climate change and broader objectives. It examines current understanding of decision-making as relevant to climate change.

A-1. Observed Impacts, Vulnerability, and Exposure

Observed impacts of climate change are widespread and consequential. Recent changes in climate have caused impacts on natural and human systems on all continents and across the oceans.[1] This conclusion is strengthened by more numerous and improved observations and analyses since the AR4. For many natural systems on land and in the ocean, new or stronger evidence exists for substantial and wide-ranging climate change impacts. For human systems, effects of changing social and economic factors have often been larger than climate-change-related impacts, but despite this, some impacts in human systems have also been attributed to climate change. In many regions, impacts on natural and human systems are now detected even in the presence of strong confounding factors such as pollution or land use change. See Table TS.1 and Figure TS.2 for a summary of observed impacts and indicators of a changing climate, illustrating broader trends presented in this section. Most reported impacts of climate change are attributed to warming and/or to shifts in precipitation patterns. There is also emerging evidence of impacts of ocean acidification. Few robust attribution studies and meta-analyses have linked impacts in physical and biological systems to anthropogenic climate change. [18.1, 18.3-6]

[INSERT TABLE TS.1 HERE
Table TS.1: Examples of observed impacts attributed to climate change with *medium* (M) or *high* (H) confidence, indicating the relative contribution of climate change (major [C] or minor [c]) to the observed change, for natural and human systems across eight major world regions over the past several decades. [Tables 18-5, 18-6, 18-7, 18-8, and 18-9]]

[INSERT FIGURE TS.2 HERE
Figure TS.2: Widespread indicators of a changing climate. (A) Global patterns of observed climate change impacts, at regional, subregional, and more local scales. For categories of attributed impacts, symbols indicate affected systems and sectors, the relative contribution of climate change (major or minor) to the observed change, and confidence in attribution. (B) Glacier mass budgets from all published measurements for Himalayan glaciers, also showing global average glacier mass budget estimates from WGI AR5 4.3 with shading indicating ±1 standard deviation. The blue box for each Himalaya measurement has a height of ±1 standard deviation centered on its average (and ±1 standard error for multi-annual measurements). Himalaya-wide measurement (red) was made by satellite laser altimetry. (C) Locations of substantial drought- and heat-induced tree mortality around the globe over 1970-2011. (D) Average rates of change in distribution (km per decade) for marine taxonomic groups based on observations over 1900-2010. Positive distribution changes are consistent with warming (moving into previously cooler waters, generally poleward). The number of responses analyzed is given for each category. (E) Summary of estimated impacts of observed climate changes on yields over 1960-2013 for four major crops in temperate and tropical regions, with the number of data points analyzed given for each category. [Figures 3-3, 4-7, 7-2, 18-3, and MB-2]]

Differences in vulnerability and exposure arise from non-climatic stressors and multidimensional inequalities, which shape differential risks from climate change (*very high confidence*). See Box TS.4. Vulnerability and exposure vary over time and across geographic contexts. Changes in poverty or socioeconomic status, ethnic composition, age structure, and governance have had a significant influence on the outcome of past crises associated with climate-related hazards. [8.2, 9.3, 12.2, 13.1-2, 14.1-3, 19.6, 26.8, Box CC-GC]

[1] Attribution of observed impacts in the WGII AR5 links responses of natural and human systems to climate change, not to anthropogenic climate change, unless explicitly indicated.

Impacts from recent extreme climatic events, such as heat waves, droughts, floods, and wildfires, show significant vulnerability and exposure of some ecosystems and many human systems to climate variability (*very high confidence*). Impacts include the alteration of ecosystems and of food production, damage to infrastructure and settlements, morbidity and mortality, and consequences for mental health and human well-being. These experiences are consistent with a significant adaptation deficit in developing and developed countries for some sectors and regions. The following examples illustrate impacts of extreme weather and climate events experienced across regional contexts.

- In Africa, extreme weather and climate events including droughts and floods have significant impacts on economic sectors, natural resources, ecosystems, livelihoods, and human health. The floods of the Zambezi River in Mozambique in 2008, for example, displaced 90,000 people, and along the Zambezi River Valley, with approximately 1 million people living in the flood-affected areas, temporary displacement is taking on permanent characteristics. [22.3-4, 22.6]
- Recent floods in Australia and New Zealand caused severe damage to infrastructure and settlements and 35 deaths in Queensland alone (2011). The Victorian heat wave (2009) increased heat-related morbidity and was associated with more than 300 excess deaths, while intense bushfires destroyed over 2,000 buildings and led to 173 deaths. Widespread drought in south-east Australia (1997-2009) and many parts of New Zealand (2007-2009; 2012-13) resulted in economic losses (e.g., regional GDP in the southern Murray-Darling Basin was below forecast by about 5.7% in 2007/08, and New Zealand lost about NZ$3.6b in direct and off-farm output in 2007-09). [3.2, 13.2, 25.6, 25.8, Table 25-1, Boxes 25-5, 25-6, 25-8]
- In Europe, extreme weather events currently have significant impacts in multiple economic sectors as well as adverse social and health effects (*high confidence*). [Table 23-1]
- In North America, most economic sectors and human systems have been affected by and have responded to extreme weather, including hurricanes, flooding, and intense rainfall (*high confidence*). Extreme heat events currently result in increases in mortality and morbidity (*very high confidence*), with impacts that vary by age, location, and socioeconomic factors (*high confidence*). Extreme coastal storm events have caused excess mortality and morbidity, particularly along the east coast of the United States, and the gulf coast of both Mexico and the United States. Much North American infrastructure is currently vulnerable to extreme weather events (*medium confidence*), with deteriorating water-resource and transportation infrastructure particularly vulnerable (*high confidence*). [3.2, 26.6-7, Figure 26-2]
- In the Arctic, extreme weather events have had direct and indirect adverse health effects for residents (*high confidence*). [28.2]

_____ START BOX TS.4 HERE _____

Box TS.4. Multidimensional Inequality and Vulnerability to Climate Change

People who are socially, economically, culturally, politically, institutionally, or otherwise marginalized in society are often highly vulnerable to climate change and climate change responses (*medium evidence, high agreement*). This heightened vulnerability is rarely due to a single cause. Rather, it is the product of intersecting social processes that result in inequalities in socioeconomic status, income, and exposure, including, for example, discrimination on the basis of gender, class, race/ethnicity, age, and (dis)ability. See Box TS.4 Figure 1. Understanding differential capacities and opportunities of individuals, households, and communities requires knowledge of these intersecting social drivers, which may be context-specific and clustered in diverse ways (e.g., class and ethnicity in one case, gender and age in another). Few studies depict the full spectrum of these intersecting social processes and the ways in which they shape multidimensional vulnerability to climate change.

Examples of inequality-driven impacts and risks of climate change and climate change responses (*medium evidence, high agreement*):

- Privileged members of society can benefit from climate change impacts and response strategies, due to their flexibility in mobilizing and accessing resources and positions of power, often to the detriment of others. [13.2-3, 22.4, 26.8]
- Differential impacts on men and women arise from distinct roles in society, the way these roles are enhanced or constrained by other dimensions of inequality, risk perceptions, and the nature of response to hazards. [8.2, 9.3, 11.3, 12.2, 13.2, 18.4, 22.4, Box CC-GC]

- Both male and female deaths are recorded after flooding, affected by socioeconomic disadvantage, occupation, and culturally imposed expectations to save lives. While women are generally more sensitive to heat stress, more male workers are reported to have died largely due to responsibilities related to outdoor and indoor work. [11.3, 13.2, Box CC-GC]
- Women often experience additional duties as laborers and caregivers as a result of extreme weather events and climate change, as well as responses (e.g., male outmigration), while facing more psychological and emotional distress, reduced food intake, adverse mental health outcomes due to displacement, and in some cases increasing incidences of domestic violence. [9.3-4, 12.4, 13.2, Box CC-GC]
- Children and the elderly are often at higher risk due to narrow mobility, susceptibility to infectious diseases, reduced caloric intake, and social isolation. While adults and older children are more severely affected by some climate-sensitive vector-borne diseases such as dengue, young children are more likely to die from or be severely compromised by diarrheal diseases and floods. The elderly face disproportional physical harm and death from heat stress, droughts, and wildfires. [8.2, 10.9, 11.1, 11.4-5, 13.2, 22.4, 23.5, 26.6]
- In most urban areas, low-income groups, including migrants, face large climate change risks because of poor-quality, insecure, and clustered housing, inadequate infrastructure, and lack of provision for health care, emergency services, flood exposure, and measures for disaster risk reduction. [8.1-2, 8.4-5, 12.4, 22.3, 26.8]
- People disadvantaged by race or ethnicity, especially in high-income countries, experience more harm from heat stress, often due to low economic status and poor health conditions, and displacement after extreme events. [11.3, 12.4, 13.2]
- Livelihoods and lifestyles of indigenous peoples, pastoralists, and fisherfolk, often dependent on natural resources, are highly sensitive to climate change and climate change policies, especially those that marginalize their knowledge, values, and activities. [9.3, 11.3, 12.3, 14.2, 22.4, 25.8, 26.8, 28.2]
- Disadvantaged groups without access to land and labor, including female-headed households, tend to benefit less from climate change response mechanisms (e.g., CDM, REDD+, large-scale land acquisition for biofuels, and planned agricultural adaptation projects). [9.3, 12.2, 12.5, 13.3, 22.4, 22.6]

[INSERT BOX TS.4 FIGURE 1 HERE
Box TS.4 Figure 1: Multidimensional vulnerability driven by intersecting dimensions of inequality. Vulnerability increases when people’s capacities and opportunities to adapt to climate change and adjust to climate change responses are diminished. [Figure 13-5]]

_____ END BOX TS.4 HERE _____

Freshwater resources

In many regions, changing precipitation or melting snow and ice are altering hydrological systems, affecting water resources and quality (*medium confidence*). Glaciers continue to shrink in many regions due to climate change (*high confidence*) (Figure TS.2B). Climate change has caused permafrost warming and thawing in high-latitude and high-elevation mountain regions. There is no evidence that surface water and groundwater drought frequency has changed over the last few decades, although impacts of drought have increased mostly due to increased water demand. [3.2, 4.3, 18.3, 18.5, 24.4, 25.5, 26.2, 28.2, Tables 3-1 and 25-1, Figures 18-2 and 26-1]

Terrestrial and freshwater ecosystems

Many terrestrial plant and animal species have shifted their ranges and seasonal activities and altered their abundance in response to past climate change, and they are doing so now in many regions (*high confidence*). Increased tree mortality, observed in many places worldwide, has been attributed to climate change in some regions (Figure TS.2C). Increases in the frequency or intensity of ecosystem disturbances such as droughts, wind-storms, fires, and pest outbreaks have been detected in many parts of the world and in some cases are attributed to climate change (*medium confidence*). While recent warming contributed to the extinction of many species of Central American amphibians (*medium confidence*), most recent observed terrestrial-species extinctions have not been attributed to recent climate change, despite some speculative efforts (*high confidence*). [4.2-4, 18.3, 18.5, 22.3, 25.6, 26.4, 28.2, Figure 4-10, Boxes 4-2, 4-3, 4-4, and 25-3]

Coastal systems and low-lying areas

Coastal systems are particularly sensitive to changes in sea level and ocean temperature and to ocean acidification (*very high confidence*). Coral bleaching and species range shifts have been attributed to changes in ocean temperature. For many other coastal changes, the impacts of climate change are difficult to identify given other human-related drivers (e.g. land-use change, coastal development, pollution) (*robust evidence, high agreement*). [5.3-5, 18.3, 25.6, 26.4, Box 25-3]

Marine systems

Warming has caused and will continue to cause shifts in the abundance, geographic distribution, migration patterns, and timing of seasonal activities of species (*very high confidence*), paralleled by reduction in maximum body sizes in warming waters (*medium confidence*). This has resulted and will further result in changing interactions between species, including competition and predator-prey dynamics (*high confidence*). Numerous observations over the last decades in all ocean basins show global-scale changes including large-scale distribution shifts of species (*very high confidence*) and altered ecosystem composition (*high confidence*) on multidecadal time scales, tracking climate trends. Many fishes, invertebrates, and phytoplankton have shifted their distribution and/or abundance poleward and/or to deeper, cooler waters (Figure TS.2D). Some warm-water corals and their reefs have responded to warming with species replacement, bleaching, and decreased coral cover causing habitat loss. Few field observations to date demonstrate biological responses attributable to anthropogenic ocean acidification, as in many places these responses are not yet outside their natural variability and may be influenced by confounding local or regional factors. See also Box TS.7. Natural climate change at rates slower than current anthropogenic change has led to significant ecosystem shifts, including species emergences and extinctions, in the past millions of years. [5.4, 6.1, 6.3-5, 18.3, 18.5, 22.3, 25.6, 26.4, 30.4-5, Boxes 25-3, CC-OA, CC-CR, and CC-MB]

Vulnerability of most marine organisms to warming is set by their physiology which defines their limited temperature ranges and hence their thermal sensitivity (*high confidence*). See Figure TS.3. Temperature defines the geographic distribution of many species and their responses to climate change. Shifting temperature means and extremes alter habitat (e.g., sea ice and coastal habitat), and cause changes in abundance through local extinctions and latitudinal expansions or shifts of up to hundreds of kilometers per decade (*very high confidence*). Although genetic adaptation occurs (*medium confidence*), the capacity of fauna and flora to compensate for or keep up with the rate of ongoing thermal change is limited (*low confidence*). [6.3, 6.5]

Oxygen minimum zones are progressively expanding in the tropical Pacific, Atlantic, and Indian Oceans, due to reduced ventilation and O_2 solubilities in more stratified oceans at higher temperatures (*high confidence*). In combination with human activities that increase the productivity of coastal systems, hypoxic areas (“dead zones”) are increasing in number and size. Regional exacerbation of hypoxia causes shifts to hypoxia-tolerant biota and reduces habitat for commercially relevant species, with implications for fisheries. [6.1, 6.3, 30.3, 30.5-6; WGI AR5 3.8]

[INSERT FIGURE TS.3 HERE
Figure TS.3: Temperature specialization of species (A), which is influenced by other factors such as oxygen, causes warming-induced distribution shifts (B), for example, the northward expansion of warm-temperate species in the Northeast Atlantic (C). These distribution changes depend on species-specific physiology and ecology. Detailed introduction of each panel follows: (A) The temperature tolerance range and performance levels of an organism are described by its performance curve. Each performance (e.g., exercise, growth, reproduction) is highest at optimum temperature (T_{opt}) and lower at cooler or warmer temperatures. Surpassing temperature thresholds (T_p) means going into time-limited tolerance, and more extreme temperature changes lead to exceedance of thresholds that cause metabolic disturbances (T_c) and ultimately onset of cell damage (T_d). These thresholds for an individual can shift (horizontal arrows), within limits, between summer and winter (seasonal acclimatization) or when the species adapts to a cooler or warmer climate over generations (evolutionary adaptation). Under elevated CO_2 levels (ocean acidification) or low oxygen, thermal windows narrow (dashed grey curves). (B) During climate warming, a species follows its normal temperatures as it moves or is displaced, typically resulting in a poleward shift of the biogeographic range (exemplified for the northern hemisphere). The polygon delineates the distribution range in space and seasonal time; the level of grey denotes abundance. (C) Long-term changes in the mean number of warm-temperate pseudo-oceanic copepod species in the Northeast Atlantic from 1958 to 2005. [Figures 6-5, 6-7, and 6-8]]

Food production systems and food security

Negative impacts of climate change on crop and terrestrial food production have been more common than positive impacts, which are evident in some high-latitude regions (*high confidence*). Production of wheat and maize globally and in many regional systems has been impacted by climate change over the past several decades (*medium confidence*). The impacts of climate change on rice and soybean have been small in major production regions and globally. See Figure TS.2E. Recent periods of rapid food and cereal price increases have indicated that current markets in key producing regions are sensitive to climate extremes (*high confidence*). Crop yields have a large negative sensitivity to extreme daytime temperatures around 30°C, throughout the growing season. CO_2 has stimulatory effects on crop yields in most cases, and elevated tropospheric ozone has damaging effects. Interactions among CO_2 and ozone, mean temperature, extremes, water, and nitrogen are non-linear and difficult to predict (*medium confidence*). [7.3, 18.4, 22.3, 24.4, 26.5, Figures 7-2, 7-3, and 7-7, Box 25-3]

Urban areas

Urban areas hold more than half the world's population and most of its built assets and economic activities. A high proportion of the population and economic activities at risk from climate change are in urban areas, and a high proportion of global greenhouse gas emissions are generated by urban-based activities and residents. Cities are composed of complex inter-dependent systems that can be leveraged to support climate change adaptation via effective city governments supported by cooperative multi-level governance (*medium confidence*). This can enable synergies with infrastructure investment and maintenance, land-use management, livelihood creation, and ecosystem services protection. [8.1, 8.3-4]

Rapid urbanization and growth of large cities in low- and middle-income countries have been accompanied by expansion of highly vulnerable urban communities living in informal settlements, many of which are on land exposed to extreme weather (*medium confidence*). [8.2-3]

Rural areas

Climate change in rural areas will take place in the context of many important economic, social, and land-use trends (*very high confidence*). In different regions, absolute rural populations have peaked or will peak in the next few decades. The proportion of the rural population depending on agriculture is varied across regions, but declining everywhere. Poverty rates in rural areas are higher than overall poverty rates, but also falling more sharply, and the proportions of population in extreme poverty accounted for by rural people are also falling: in both cases with the exception of Sub-Saharan Africa, where these rates are rising. Accelerating globalization, through migration, labor linkages, regional and international trade, and new information and communication technologies, is bringing about economic transformation in rural areas of both developing and developed countries. [9.3, Figure 9-2]

For rural households and communities, access to land and natural resources, flexible local institutions, knowledge and information, and livelihood strategies can contribute to resilience to climate change (*high confidence*). **Especially in developing countries, rural people are subject to multiple non-climatic stressors, including under-investment in agriculture, problems with land and natural resource policy, and processes of environmental degradation (*very high confidence*).** In developed countries, there are important shifts towards multiple uses of rural areas, especially leisure uses, and new rural policies based on the collaboration of multiple stakeholders, the targeting of multiple sectors, and a change from subsidy-based to investment-based policy. [9.3, 22.4, Table 9-3]

Key economic sectors and services

Economic losses due to extreme weather events have increased globally, mostly due to increase in wealth and exposure, with a possible influence of climate change (*low confidence* in attribution to climate change). Flooding can have major economic costs, both in term of impacts (e.g., capital destruction, disruption) and adaptation (e.g., construction, defensive investment) (*robust evidence, high agreement*). Since the mid-20th century, socioeconomic losses from flooding have increased mainly due to greater exposure and vulnerability (*high confidence*). [3.2, 3.4, 10.3, 18.4, 23.2-3, 26.7, Figure 26-2, Box 25-7]

Human health

In recent decades, climate change has *likely* contributed to human ill-health although the present world-wide burden of ill-health from climate change is relatively small compared with effects of other stressors and is not well quantified. There has been increased heat-related mortality and decreased cold-related mortality in some regions as a result of warming (*medium confidence*). Local changes in temperature and rainfall have altered distribution of some water-borne illnesses and disease vectors and have reduced food production for some vulnerable populations (*medium confidence*). [11.4-6, 18.4, 22.3, 24.4, 25.8, 26.6, 28.2]

The health of human populations is sensitive to shifts in weather patterns and other aspects of climate change (*very high confidence*). These effects occur directly, due to changes in temperature and precipitation and in the occurrence of heat waves, floods, droughts, and fires. Health may be damaged indirectly by climate-change-related ecological disruptions, such as crop failures or shifting patterns of disease vectors, or by social responses to climate change, such as displacement of populations following prolonged drought. Variability in temperatures is a risk factor in its own right, over and above the influence of average temperatures on heat-related deaths. [11.4, 28.2]

Human security

Challenges for vulnerability reduction and adaptation actions are particularly high in regions that have shown severe difficulties in governance (*high confidence*). Violent conflict strongly influences vulnerability to climate change impacts for people living in affected places (*medium evidence, high agreement*). Large-scale violent conflict harms assets that facilitate adaptation, including infrastructure, institutions, natural capital, social capital, and livelihood opportunities. [12.5, 19.4, 19.6]

Livelihoods and poverty

Climate-related hazards constitute an additional burden to people living in poverty, acting as a threat multiplier often with negative outcomes for livelihoods (*high confidence*). Climate-related hazards affect poor people's lives directly through impacts on livelihoods, such as reductions in crop yields or destruction of homes, and indirectly through increased food prices and food insecurity. Urban and rural transient poor who face multiple deprivations can slide into chronic poverty as a result of extreme events, or a series of events, when unable to rebuild their eroded assets (*limited evidence, high agreement*). Limited positive observed impacts on poor people include isolated cases of social asset accumulation, agricultural diversification, disaster preparedness, and collective action. [9.3, 11.3, 13.1-3, 22.4, 24.4, 26.8]

Livelihoods of indigenous peoples in the Arctic have been altered by climate change, through impacts on food security and traditional and cultural values (*medium confidence*). There is emerging evidence of climate change impacts on livelihoods of indigenous people in other regions. [18.4, Table 18-9, Box 18-5]

A-2. Adaptation Experience

This section focuses on adaptive human responses to climate change and its impacts. People cope with climate variability, extremes, and change, and they manage risks through adaptation. Adaptive human responses can be motivated by observed and projected climate change impacts and by broader vulnerability-reduction and development objectives, such as reducing existing adaptation deficits to current climate.

Adaptation is already occurring and is becoming embedded in some planning processes (*high confidence*). Engineered and technological adaptation options are the most commonly implemented adaptive responses. There is increasing recognition of the value of ecosystem-based, institutional, and social measures, including provision of social protection measures, and of linkages with disaster risk reduction. Governments at various scales are starting to develop adaptation plans and policies. Selection of adaptation options continues to emphasize incremental adjustments and co-benefits and is starting to emphasize flexibility and learning (*medium evidence, medium agreement*). [4.4, 5.5, 6.4, 8.3, 9.4, 11.7, 14.1, 14.3, 15.2-4, 17.2-3, 22.3-5, 23.7, 25.4, 25.10, 26.8-9, 27.3, 30.6, Boxes 25-1, 25-2, 25-9, and CC-EA]

Most evaluations of adaptation have been restricted to impacts, vulnerability, and adaptation planning, with very few assessing the processes of implementation or actual adaptation actions (*medium evidence, high agreement*). Vulnerability indicators define, quantify, and weight aspects of vulnerability across regional units, but methods of constructing indices are subjective, often lack transparency, and can be difficult to interpret. There are conflicting views on the choice of adaptation metrics, given differing values placed on needs and outcomes, many of which cannot be captured in a comparable way by metrics. Indicators proving most useful for policy learning are those that track not just process and implementation, but also the extent to which targeted outcomes are occurring. Multi-metric evaluations including risk and uncertainty are increasingly used, an evolution from a previous focus on cost-benefit analysis and identification of "best economic adaptations" (*high confidence*). Adaptation assessments best suited to delivering effective adaptation measures often include both top-down assessments of biophysical climate changes and bottom-up assessments of vulnerability targeted towards local solutions to globally derived risks and towards particular decisions. [4.4, 14.4-5, 15.2-3, 17.2-3, 21.3, 21.5, 22.4, 25.4, 25.10, 26.8-9, Box CC-EA]

Specific examples of adaptation actions across regions and contexts include the following:

- Urban adaptation has emphasized city-based disaster risk management such as early warning systems and infrastructure investments; ecosystem-based adaptation and green roofs; enhanced storm and wastewater management; urban and peri-urban agriculture improving food security; enhanced social protection; and good-quality, affordable, and well-located housing (*high confidence*). [8.3-4, 15.4, 26.8, Boxes 25-9, CC-UR, and CC-EA]
- There is a growing body of literature on adaptation practices in both developed- and developing-country rural areas, including documentation of practical experience in agriculture, water, forestry, and biodiversity and, to a lesser extent, fisheries (*very high confidence*). Public policies supporting decision-making for adaptation in rural areas exist in developed and, increasingly, developing countries, and there are also examples of private adaptations led by individuals, companies, and NGOs (*high confidence*). Adaptation constraints, particularly pronounced in developing countries, result from lack of access to credit, land, water, technology, markets, information, and perceptions of the need to change. [9.4, 17.3, Tables 9-7 and 9-8]
- In Africa, most national governments are initiating governance systems for adaptation (*high confidence*). Progress on national and sub-national policies and strategies has initiated the mainstreaming of adaptation into sectoral planning, but evolving institutional frameworks cannot yet effectively co-ordinate the range of adaptation initiatives being implemented. Disaster risk management, social protection, adjustments in technologies and infrastructure, ecosystem-based approaches, conservation agriculture, and livelihood diversification are reducing vulnerability, but largely in isolated initiatives. [11.7, 22.4, Box CC-EA]
- In Europe, adaptation policy has been developed at international (EU), national, and local government levels, with limited systematic information on current implementation or effectiveness (*high confidence*). Some adaptation planning has been integrated into coastal and water management and into disaster risk management, but there is *limited evidence* of adaptation planning in rural development or land-use planning. [11.7, 23.7, Box 23-3]
- In Asia, community-based approaches are a means to address poverty and livelihoods as well as facilitate integration of disaster risk reduction, development, and climate change adaptation (*limited evidence, high agreement*). Adaptation practices have sometimes provided unexpected livelihood benefits, as with the introduction of traditional flood mitigation measures in China, which have led to reductions in the physical and economic vulnerabilities of communities. Adaptation has also been expedited though integrated water resource management. [11.7, 24.4]
- In Australasia, planning for sea-level rise and, in southern Australia, for reduced water availability is becoming widely adopted, although implementation of specific policies remains piecemeal, subject to political changes, and open to legal challenges (*high confidence*). Adaptive capacity is generally high in many human systems, but implementation faces major constraints especially for transformational responses at local and community levels. [25.4, 25.10, Table 25-2, Boxes 25-1, 25-2, and 25-9]
- In North America, governments are engaging in incremental adaptation assessment and planning, particularly at the municipal level, with some proactive adaptation anticipating future impacts for longer-term investments in energy and public infrastructure (*high confidence*). [26.8-9]
- In Central and South America, ecosystem-based adaptation practices, such as adaptive management and establishment of protected areas, conservation agreements, and community management of natural areas, are

increasingly common, with potential for balancing biodiversity conservation, improving livelihoods, and preserving traditional cultures (*high confidence*). [27.3]

- In the Arctic, residents have a history of adapting to change, but the rate of climate change and complex inter-linkages with societal, economic, and political factors represent unprecedented challenges for northern communities (*high confidence*). [28.2, 28.4]
- In small islands, diverse physical and human attributes and their sensitivity to climate-related drivers have been inconsistently integrated into adaptation planning (*high confidence*). [Table 29-3, Figure 29-1]
- Observed coastal adaptation includes major projects (e.g., Thames Estuary, Venice Lagoon, Delta Works) and specific practices in some countries (e.g., Netherlands, Australia, Bangladesh) (*high confidence*). [5.5, 7.3, 15.4, Box CC-EA]
- Ocean adaptation strategies beyond coastal areas are generally poorly developed (*high confidence*). [30.6]

Table TS.2 presents examples of how climate extremes and change, as well as exposure and vulnerability at the scale of risk management, shape adaptation actions and approaches to reducing vulnerability and enhancing resilience.

[INSERT TABLE TS.2 HERE
Table TS.2: Illustrative examples of adaptation experience, as well as approaches to reducing vulnerability and enhancing resilience. Adaptation actions can be influenced by climate variability, extremes, and change, and by exposure and vulnerability at the scale of risk management. Many examples and case studies demonstrate complexity at the level of communities or specific regions within a country. It is at this spatial scale that complex interactions between vulnerability, exposure, and climate change come to the fore. [Table 21-4]]

A-3. The Decision-making Context

Responding to climate-related risks involves making decisions and taking actions in the face of continuing uncertainty about the extent of climate change and the severity of impacts in a changing world, with potential limits to the effectiveness of incremental approaches (*high confidence*). Iterative risk management is a useful framework for decision-making in situations characterized by large potential consequences, persistent uncertainties, long timeframes, potential for learning, and multiple influences changing over time, such as climate and non-climatic stressors. See Figure TS.4. Assessment of the full range of potential future impacts, including low-probability outcomes with large consequences, is central to understanding future risks and the benefits and tradeoffs of alternative risk management actions. The increasing complexity of adaptation actions across scales and contexts means that institutional learning and monitoring are important components of effective adaptation. [2.1-4, 3.6, 14.1-5, 15.2-3, 15.5, 16.2-4, 17.2, 20.6, 22.4, 25.4, 25.10, Figure 1-5, Boxes 16-1 and 25-2]

[INSERT FIGURE TS.4 HERE
Figure TS.4: Illustration of iterative risk management. [Figure 2-1]]

The benefits of mitigation and adaptation occur over different timeframes (*high confidence*). Figure TS.5 illustrates projected climate futures under scenarios RCP2.6 and 8.5, along with observed temperature and precipitation changes. Projected global temperature increase over the next few decades is similar across emission scenarios. [WGI AR5 11.3] During this near-term era of committed climate change, risks will evolve as socioeconomic trends interact with the changing climate. Societal responses, particularly adaptations, will influence near-term outcomes. In the second half of the 21st century and beyond, global temperature increase diverges across emission scenarios. [WGI AR5 12.4 and Table SPM.2] For this longer-term era of climate options, near-term and ongoing mitigation and adaptation, as well as development pathways, will determine the risks of climate change. Present-day choices thus affect the risks of climate change throughout the 21st century. [2.5, 21.2-3, 21.5, Box CC-RC]

[INSERT FIGURE TS.5 HERE
Figure TS.5: Observed and projected changes in annual average temperature (A) and precipitation (B). (A, top panel) Observed temperature trends from 1901-2012 determined by linear regression. [WGI AR5 Figures SPM.1 and 2.21] (B, top panel) Observed precipitation change from 1951-2010 determined by linear regression. [WGI AR5 Figure SPM.2] For observed temperature and precipitation, trends have been calculated where sufficient data permit a robust estimate (i.e., only for grid boxes with greater than 70% complete records and more than 20% data

availability in the first and last 10% of the time period). Other areas are white. Solid colors indicate areas where change is significant at the 10% level. Diagonal lines indicate areas where change is not significant. (A, middle panel) Observed and simulated variations in past and projected future global annual average temperature relative to 1986-2005. Black lines show the GISTEMP, NCDC-MLOST, and HadCRUT4.2 estimates from observational measurements. Blue and red shading denotes the ±1.64 standard deviation range based on simulations from 32 models for RCP2.6 and 39 models for RCP8.5; blue and red lines denote the ensemble mean for each scenario. For future projections, light-gray vertical bands specify an indicative timeframe (2030-2040) for the near-term era of committed climate change and an indicative timeframe (2080-2100) for the longer-term era of climate options. [Box CC-RC; WGI AR5 Figures SPM.1 and SPM.7] (A and B, bottom panel) CMIP5 multi-model mean projections of annual average temperature changes (A) and average percent change in annual mean precipitation (B) for 2081-2100 under RCP2.6 and 8.5, relative to 1986-2005. Solid colors indicate areas with very strong agreement, where the multi-model mean change is greater than twice the baseline variability and >90% of models agree on sign of change. Colors with white dots indicate areas with strong agreement, where >66% of models show change greater than the baseline variability and >66% of models agree on sign of change. Gray indicates areas with divergent changes, where >66% of models show change greater than the baseline variability, but <66% agree on sign of change. Colors with diagonal lines indicate areas with little or no change, where >66% of models show change less than the baseline variability, although there may be significant change at shorter timescales such as seasons, months, or days. Analysis uses model data from WGI AR5 Figure SPM.8, with full description of methods in Box CC-RC. See also Annex I of WGI AR5. [Boxes 21-2 and CC-RC]]

Adaptation planning and implementation at a range of scales are contingent on values, objectives, and risk perceptions (*high confidence*). Some types of adaptation options, such as insurance or large-scale infrastructure projects, may differentially affect stakeholders. Awareness that climate change may exceed the adaptive capacity of some people and ecosystems may have ethical implications for mitigation decisions and investments. Recognition of diverse interests, values, and expectations, including local and indigenous knowledge, can benefit decision-making processes. Economic analysis of adaptation is moving away from a unique emphasis on efficiency, market solutions, and benefit/cost analysis to include consideration of non-monetary and non-market measures, risks, inequities, behavioral biases, barriers and limits, and consideration of ancillary benefits and costs. [2.2-4, 12.3, 15.2, 16.2-4, 16.6-7, 17.2-3, 21.3, 22.4, 25.4, 25.8, 26.7, 26.9, Table 15-1, Boxes 16-1, 16-4, and 25-7]

Decision support is most effective when it is sensitive to context, taking into account the diversity of different types of decisions, decision processes, and constituencies (*robust evidence, high agreement*). Organizations bridging science and policy play an important role in the communication and transfer of climate-related knowledge, such as information on risks combining physical climate science and assessments of impacts, adaptation, and vulnerability (*medium evidence, high agreement*). [2.1-4, 8.4, 14.4, 16.2-3, 16.5, 21.2-3, 21.5, 22.4, Box 9-4]

Scenarios are useful tools for characterizing possible future socioeconomic pathways, climate change and its risks, and policy implications (*high confidence*). Climate change risks vary substantially across plausible alternative development pathways, and the relative importance of development and climate change varies by sector, region, and time period. Both development and climate change are important determinants of possible outcomes. Modeled future impacts assessed in this report are generally based on climate-model projections using the Representative Concentration Pathway (RCP) and the older IPCC Special Report on Emission Scenarios (SRES) scenarios. [1.1, 1.3, 2.2-3, 19.6, 20.2, 21.3, 21.5, 26.2, Box CC-RC; WGI AR5 Box SPM.1]

Scenarios can be divided into those that explore how futures may unfold under various drivers (problem exploration) and those that test how various interventions may play out (solution exploration) (*robust evidence, high agreement*). Adaptation approaches address uncertainties associated with future climate and socioeconomic conditions and with the diversity of specific contexts (*medium evidence, high agreement*). Although many national studies identify a variety of strategies and approaches for adaptation, they can be classified into two broad categories: 'top-down' and 'bottom-up' approaches. The top-down approach is a scenario-impact approach, consisting of downscaled climate projections, impact assessments, and formulation of strategies and options. The bottom-up approach is a vulnerability-threshold approach, starting with identification of vulnerabilities, sensitivities, and thresholds for specific sectors or communities. Iterative assessments of impacts and adaptation in the top-down approach and building adaptive capacity of local communities are typical strategies for responding to uncertainties. [2.2-3, 15.3]

Uncertainties about future vulnerability, exposure, and responses of human and natural systems can be larger than uncertainties in regional climate projections, and they are beginning to be incorporated in assessments of future risks (*high confidence*). Understanding future vulnerability, as well as exposure, of interlinked human and natural systems is challenging due to the number of relevant socioeconomic factors, which have been incompletely considered to date. These factors include wealth and its distribution across society, patterns of aging, access to technology and information, labor force participation, the quality of adaptive responses, societal values, and mechanisms and institutions to resolve conflicts. Cross-regional phenomena are also important for understanding the ramifications of climate change at regional scales. [11.3, 21.3-5, 25.3-4, 25.11, 26.2]

B) FUTURE RISKS AND OPPORTUNITIES FOR ADAPTATION

This section presents future risks and more limited potential benefits across sectors and regions, examining how they are affected by the magnitude and rate of climate change and by development choices. It also points to opportunities for reducing risks through mitigation and adaptation. The section examines the distribution of risks across populations with contrasting vulnerability and adaptive capacity, across sectors where metrics for quantifying impacts may be quite different, and across regions with varying traditions and resources. The assessment features interactions across sectors and regions and among climate change and other stressors. The section describes risks and potential benefits over the next few decades, the near-term era of committed climate change. Over this timeframe, magnitude of projected climate change is similar across high and low emission scenarios. The section also provides information on risks and potential benefits in the second half of the 21st century and beyond, the longer-term era of climate options. Over this longer term, magnitude of climate change diverges across high and low emission scenarios, and the assessment distinguishes potential outcomes for 2°C and 4°C global mean temperature increase above preindustrial levels. The section elucidates how and when choices matter in reducing future risks, highlighting the differing timeframes for mitigation and adaptation benefits.

B-1. Key Risks across Sectors and Regions

Many risks of climate change warrant consideration. Key risks, in particular, are potentially severe impacts relevant to "dangerous anthropogenic interference with the climate system," as described in Article 2 of the United Nations Framework Convention on Climate Change. Key risks can involve potentially large or irreversible consequences, high probability of consequences, and/or limited adaptive capacity. Key risks are integrated into five overarching reasons for concern (RFCs) in Box TS.5.

Key risks that span sectors and regions (*high confidence*) include the following, each of which contributes to one or more RFC. Roman numerals correspond to entries in Table TS.3, which further illustrates relevant examples and interactions. [19.2-4, 19.6, Table 19-4, Boxes 19-2 and CC-KR]

i. Risk of death, injury, and disruption to livelihoods, food supplies, and drinking water, in addition to loss of common-pool resources, sense of place, and identity, due to sea-level rise, coastal flooding, and storm surges affecting high concentrations of people, economic activity, biodiversity, and critical infrastructure in low-lying coastal zones and small island developing states. See RFC 1-5. [5.4, 8.1-2, 13.1-2, 19.2-4, 19.6-7, 24.4-5, 26.7-8, 29.3, 30.3, Tables 19-4 and 26-1, Figure 26-2, Boxes 25-1, 25-7, and CC-KR]
ii. Risk of food insecurity and breakdown of food systems linked to warming, drought, and precipitation variability, particularly in regions with poorer populations. See RFC 2-4. [3.5, 7.4-5, 11.3, 11.6, 13.2, 19.3-4, 19.6, 22.3, 24.4, 25.5, 25.7, 26.5, 26.8, 27.3, Table 19-4, Figure 7-4, Boxes CC-KR and CC-VW]
iii. Risk of severe harm due to inland flooding and limited coping and adaptive capacities of large urban populations. See RFC 2 and 3. [3.2, 3.4-5, 8.1-2, 13.2, 19.6, 25.10, 26.3, 26.7-8, 27.3, Tables 19-4 and 26-1, Boxes 25-8 and CC-KR]
iv. Risk of loss of rural livelihoods and income of rural residents due to insufficient access to drinking and irrigation water and reduced agricultural productivity, as well as risk of food insecurity, particularly for farmers and pastoralists with minimal capital in semi-arid regions. See RFC 2 and 3. [3.2, 3.4-5, 8.2, 9.3, 12.3, 13.2, 19.3, 19.6, 24.4, 25.7, 26.8, Table 19-4, Boxes 25-5 and CC-KR]
v. Systemic risks due to multiple interacting hazards affecting infrastructure networks in combination with a high dependency of people on critical services (e.g., electricity, water supply, and health and emergency services) that may break down during extreme events. See RFC 2-4. [8.1-2, 10.2-3, 12.6, 19.6, 23.9, 25.10, 26.7-8, 28.3, Table 19-4, Boxes CC-KR and CC-HS]
vi. Risk of loss of marine ecosystems and the services they provide for coastal livelihoods. Biodiversity and coastal ecosystem services important for fishing communities in the tropics and the Arctic are especially at risk due to rising water temperature, increased stratification, and ocean acidification. See RFC 1-5. [5.4, 6.3, 7.4, 9.3, 19.5-6, 22.3, 25.6, 27.3, 28.2-3, 29.3, 30.5-7, Table 19-4, Boxes CC-OA, CC-CR, CC-KR, and CC-HS]
vii. Risk of loss of terrestrial ecosystems and the services they provide for terrestrial livelihoods. These services are at risk due to rising temperatures, changes in precipitation patterns, and extreme weather events. Risks are high for communities whose livelihoods depend on provisioning services. See RFC 1, 3, and 4. [4.3, 19.3-6, 22.3-4, 25.6, 27.3, 28.2-3, Tables 19-4 and 23-2, Boxes CC-KR and CC-WE]

viii. Risk of mortality, morbidity, and other harms during periods of extreme heat, particularly for urban populations of the elderly, infants, people with chronic ill-health, and expectant mothers. Increasing frequency and intensity of extreme heat (including exposure to the urban heat island effect and air pollution) interacts with an inability of some local organizations that provide health, emergency, and social services to adapt to new risk levels for vulnerable groups. See RFC 2 and 3. [8.1-2, 11.3-4, 13.2, 19.3, 19.6, 23.5, 24.4, 25.8, 26.6, 26.8, Tables 19-4 and 26-1, Boxes CC-KR and CC-HS]

[INSERT TABLE TS.3 HERE
Table TS.3: A selection of the hazards, key vulnerabilities, key risks, and emergent risks identified in chapters of this report. The examples underscore the complexity of risks determined by various interacting climate-related hazards, non-climatic stressors, and multifaceted vulnerabilities (see also Figure TS.1). Vulnerabilities identified as key arise when exposure to hazards combines with social, institutional, economic, or environmental vulnerability, as indicated by icons in the table. Emergent risks arise from complex-system interactions. Roman numerals correspond with key risks listed in section B-1. [19.6, Table 19-4]]

Mitigation of greenhouse gas emissions can substantially reduce risks of climate change in the second half of the 21st century (*high confidence*). Examples include reduced risk of negative agricultural yield impacts, of water scarcity, of major challenges to urban settlements and infrastructure from sea-level rise, and of adverse impacts from heat extremes, floods, and droughts in areas where increased occurrence of these extremes are projected. Under all assessed scenarios for mitigation and adaptation, some risk from residual damages is unavoidable (*very high confidence*). Since mitigation reduces the rate as well as the magnitude of warming, it also increases the time available for adaptation to a particular level of climate change, potentially by several decades, but adaptation cannot generally overcome all climate change effects. In addition to biophysical limits to adaptation for example under high temperatures, some adaptation options will be too costly or resource intensive or will be cost ineffective until climate change effects grow to merit investment costs (*high confidence*). Some mitigation or adaptation options also pose risks. [3.4-5, 4.2, 4.4, 16.3, 16.6, 17.2, 19.7, 20.3, 22.4-5, 25.10, Tables 3-2, 8-3, and 8-5, Boxes 13-2, 16-3, and 25-1]

Large magnitudes of warming increase the likelihood of severe, pervasive, and challenging impacts. Risks associated with global temperature rise in excess of 4°C relative to preindustrial levels include potential adverse impacts on agricultural production worldwide, potentially extensive ecosystem impacts, and increasing species extinction risk (*high confidence*), as well as possible crossing of thresholds that lead to disproportionately large earth system responses (*low confidence*). The precise levels of climate change sufficient to trigger tipping points (critical thresholds) remain uncertain, but the likelihood of crossing tipping points in the earth system or interlinked human and natural systems decreases with reduced greenhouse gas emissions (*medium confidence*). [4.2-3, 11.8, 19.5, 19.7, 26.5, Box CC-HS]

_____ START BOX TS.5 HERE _____

Box TS.5. Human Interference with the Climate System

Human interference with the climate system is occurring, yet determining whether this interference is dangerous, as relevant to Article 2 of the UNFCCC, involves both risk assessment and value judgments. Scientific assessment can characterize risks based on the likelihood, magnitude, and scope of potential consequences of climate change. Science can also evaluate risks varying spatially and temporally across alternative development pathways, which affect vulnerability, exposure, and level of climate change. Interpreting the potential danger of risks, however, also requires value judgments by people with differing goals and worldviews. Judgments about the risks of climate change depend on the relative importance ascribed to economic vs. ecosystem assets, to the present vs. the future, and to the distribution vs. aggregation of impacts. From some perspectives, isolated or infrequent impacts from climate change may not rise to the level of dangerous anthropogenic interference, but accumulation of the same kinds of impacts could, as they become more widespread, more frequent, or more severe. The rate of climate change can also influence risks. This report assesses risks across contexts and through time, providing a basis for value judgments about the level of climate change at which risks become dangerous.

Five integrative reasons for concern (RFCs) provide a framework for summarizing key risks across sectors and regions. First identified in the IPCC Third Assessment Report, the reasons for concern illustrate the implications of warming and of adaptation limits for people, economies, and ecosystems. They provide one starting point for evaluating dangerous anthropogenic interference with the climate system. An updated assessment of risks for each reason for concern is presented below and in Box TS.5 Figure 1. All temperature changes are given relative to 1986-2005 ("recent"). [18.6, 19.6]

(1) ***Unique and threatened systems:*** Some unique and threatened systems, including ecosystems and cultures, are at risk from climate change at recent temperatures. The number of such systems at risk of severe consequences increases at warming of 1°C. Many species and systems with limited adaptive capacity are subject to very high risks at warming of 2°C, particularly Arctic sea ice systems and coral reefs (*high confidence*).
(2) ***Extreme weather events:*** Climate-change-related risks from extreme events, such as heat waves, extreme precipitation, and coastal flooding, are moderate at recent temperatures (*high confidence*) and high at 1°C warming (*medium confidence*).
(3) ***Distribution of impacts:*** Risks for disproportionately affected people and communities are generally greatest in low-latitude, less-developed areas, and are moderate at recent temperatures because of regionally differentiated climate-change impacts on food production (*medium* to *high confidence*). Developed countries also have highly vulnerable populations. Based on risks for regional crop production and water resources in some countries, risks become high for warming above 2°C (*medium confidence*).
(4) ***Global aggregate impacts:*** Risks to the overall global economy and Earth's biodiversity become moderate for warming between 1-2°C (*medium confidence*) and high around 3°C, reflecting warming-dependent increases in risks of economic impacts (*low confidence*) and extensive biodiversity loss with concomitant loss of ecosystem services (*high confidence*).
(5) ***Large-scale singular events:*** With increasing warming, some physical systems or ecosystems may be at risk of abrupt and drastic changes. Risks of such tipping points become moderate between 0-1°C, due to early warning signs that both coral reef and Arctic systems are already experiencing irreversible regime shifts. Risks become high between 1-4°C, with a disproportionate increase in risks as temperature increases between 1-2°C, due to the potential for commitment to a large and irreversible sea-level rise from ice sheet loss (*medium confidence*).

[INSERT BOX TS.5 FIGURE 1 HERE
Box TS.5 Figure 1: (Right panel) The dependence of risks associated with reasons for concern on the level of climate change, updated based on assessment of the literature and expert judgments. Purple shading, introduced in this assessment, indicates very high risk of severe impacts and the presence of significant irreversibilities combined with limited adaptive capacity. [Figure 19-4] (Left panel) Observed and simulated variations in past and projected future global annual average temperature relative to 1986-2005, as in Figure TS.5. [Figure RC-1, Box CC-RC; WGI AR5 Figures SPM.1 and SPM.7]]

_____ END BOX TS.5 HERE _____

_____ START BOX TS.6 HERE _____

Box TS.6. Consequences of Large Temperature Increase

This box provides a selection of salient climate change impacts projected for large temperature rise. Warming levels described here (e.g., 4°C warming) refer to global mean temperature increase above preindustrial levels.

With 4°C warming, climate change is projected to become the dominant driver of impacts on ecosystems, superseding drivers such as land-use change. [4.2.4, 19.5.1, 26.3] A number of studies project large increases in water stress, groundwater supplies, and drought in a number of regions with >4°C warming, and decreases in others, generally placing already arid regions at greater water stress. [19.5.1, Box 26-1]

Risks of large-scale singular events such as ice sheet disintegration, methane release from clathrates, and onset of long-term droughts in areas such as southwest North America [Box 26-1; WGI AR5 12.4.5, 12.5.5, 13.4], as well as regime shifts in ecosystems and substantial species loss [4.3.2, 19.6.3], are higher with increased warming. Sustained warming greater than some threshold would lead to the near-complete loss of the Greenland ice sheet over a millennium or more, causing a global mean sea-level rise of up to 7 m (*high confidence*); current estimates indicate that the threshold is greater than about 1°C (*low confidence*) but less than about 4°C (*medium confidence*) global mean warming. [WGI AR5 5.8, 13.4-5] Abrupt and irreversible ice loss from a potential instability of marine-based areas of the Antarctic ice sheet in response to climate forcing is possible, but current evidence and understanding is insufficient to make a quantitative assessment. [19.6.3; WGI AR5 5.8, 13.4-5] Sea-level rise of 0.45-0.82 m (mean 0.63m) is *likely* by 2081-2100 under RCP8.5 (*medium confidence*) [WGI AR5 Table 13.5], with sea level continuing to rise beyond 2100.

The Atlantic Meridional Overturning Circulation (AMOC) is considered *very likely* to weaken over the 21st century, with a best estimate of 34% loss (range 12-54%) under RCP8.5. [WGI AR5 12.4] The release of CO_2 or CH_4 to the atmosphere from thawing permafrost carbon stocks over the 21st century is assessed to be in the range of 180 to 910 $GtCO_2$ for RCP8.5 (*low confidence*). [WGI AR5 6.4] A nearly ice-free Arctic Ocean in September before mid-century is *likely* under RCP8.5 (*medium confidence*). [WGI AR5 11.3, 12.4-5]

For RCP8.5 by 2100, the combination of high temperatures and high humidity in some areas for parts of the year will compromise normal human activities, including growing food or working outdoors (*high confidence*). [11.8.1] Above 4°C local warming, risks for food security become very significant (*high confidence*). [7.5, Table 7-3, Figure 7-7]

Under 4°C warming, some models project large increases in fire risk in parts of the world. [4.3.3, Figure 4-6] 4°C warming implies a substantial increase in extinction risk for terrestrial and freshwater species, although there is *low agreement* concerning the fraction of species at risk. [4.3.2] Widespread coral reef mortality is expected with significant impacts on coral reef ecosystems (*high confidence*). [5.4.2, Box CC-CR] Assessments of potential ecological impacts at and above 4°C warming imply a high risk of extensive loss of biodiversity with concomitant loss of ecosystem services (*high confidence*). [4.3.2, 4.3.4, 19.3.2, Box 25-6]

Projected large increases in exposure to water stress, fluvial and coastal flooding, negative impacts on crop yields, and disruption of ecosystem function and services would represent large, potentially compounding impacts of climate change on society generally and on the global economy. [19.4.3, 19.5.1, 19.6.3, 26.3, 26.7, 26.8, Figure 7-4]

_____ END BOX TS.6 HERE _____

B-2. Sectoral Risks and Potential for Adaptation

For the near-term era of committed climate change (the next few decades) and the longer-term era of climate options (the second half of the 21st century), climate change will amplify climate-related risks to natural and human systems, dependent on the magnitude and rate of climate change and on the vulnerability and exposure of interlinked human and natural systems. Some of these risks will be limited to a particular sector or region, and others will have cascading effects. To a lesser extent, climate change will also reduce some climate-related risks and have some potential benefits. Key sectoral risks identified with *medium* to *high confidence* are presented in Table TS.4. For extended summary of sectoral risks and the more limited potential benefits, see introductory overviews for each sector below and also Chapters 3-13.

[INSERT TABLE TS.4 HERE
Table TS.4: Key sectoral risks from climate change and the potential for reducing risks through mitigation and adaptation. Risks have been identified based on assessment of the relevant scientific, technical, and socioeconomic literature, as detailed in supporting chapter sections. Each key risk is characterized as very low to very high for three timeframes: the present, near-term (here, assessed over 2030-2040), and longer-term (here, assessed over 2080-2100). Assessed risk levels integrate probability and consequence over the full range of possible outcomes, acknowledging the importance of differences in values and objectives in interpretation of the assessed risk levels. For the near-term era of committed climate change, projected levels of global mean temperature increase do not diverge substantially across emission scenarios. For the longer-term era of climate options, risk levels are presented for global mean temperature increase of 2°C and 4°C above preindustrial levels, illustrating the potential role of mitigation in reducing risks. For the present, risk levels are estimated for current adaptation and a hypothetical highly adapted state, identifying where current adaptation deficits exist. For the future, risk levels are estimated for a continuation of current adaptation and for a highly adapted state, representing the potential for and limits to adaptation. Relevant climate variables are indicated by icons. Risk levels are not necessarily comparable across sectors because the assessment considers potential impacts and adaptation across diverse physical, biological, and human systems.]

Freshwater resources

Freshwater-related risks of climate change increase significantly with increasing greenhouse gas emissions (*robust evidence, high agreement*). By the end of the 21st century, the number of people exposed annually to a 20th-century 100-year river flood is projected to be three times greater for RCP8.5 than for RCP2.6. See Figure TS.6. In presently dry regions, drought frequency will *likely* increase by the end of this century under RCP8.5 (*medium confidence*). [3.4-5, 26.3, Tables 3-2 and 25-1, Box 25-8; WGI AR5 12.4.5]

Climate change will reduce renewable surface water and groundwater resources significantly in most dry subtropical regions, exacerbating competition for water among sectors (*robust evidence, high agreement*). In contrast, water resources will increase at high latitudes. Each degree of warming is projected to decrease renewable water resources by at least 20% for an additional 7% of the global population. Climate change is projected to reduce raw water quality and pose risks to drinking water quality, due to interacting factors: increased temperature; increased sediment, nutrient, and pollutant loadings from heavy rainfall; reduced dilution of pollutants during droughts; and disruption of treatment facilities during floods (*medium evidence, high agreement*). [3.2, 3.4-5, 22.3, 25.5, 26.3, Table 3-2, Boxes 25-10 and CC-WE]

Adaptive water management techniques, including scenario planning, learning-based approaches, and flexible and low-regret solutions, can address uncertainty due to climate change (*limited evidence, high agreement*). Barriers to progress include lack of human and institutional capacity, financial resources, awareness, and communication. [3.6, Box 25-2]

[INSERT FIGURE TS.6 HERE
Figure TS.6: Projected change in river flood return period and exposure, based on one hydrological model driven by 11 CMIP5 GCMs and on global population in 2005. (A) In the 2080s under RCP8.5, multi-model median return period (years) for the 20th-century 100-year flood. (B) Global exposure to the 20th-century 100-year flood in millions of people. Left: ensemble means of historical (black line) and future simulations (colored lines) for each scenario. Shading denotes ±1 standard deviation. Right: maximum and minimum (whiskers), mean (horizontal lines within each bar), ±1 standard deviation (box), and projections of each GCM (colored symbols) averaged over the 21st century. [Figure 3-6]]

Terrestrial and freshwater ecosystems

Climate change is projected to be a powerful stressor on terrestrial and freshwater ecosystems in the second half of the 21st century, especially under high-warming scenarios such as RCP6.0 and 8.5 (*high confidence*). Through to 2040 globally, direct human impacts such as land-use change, pollution, and water resource development will continue to dominate threats to most freshwater ecosystems (*high confidence*) and most terrestrial ecosystems (*medium confidence*). Many species will be unable to move fast enough during the 21st century to track suitable climates under mid- and high-range rates of climate change (i.e., RCP4.5, 6.0, and 8.5) (*medium confidence*). See Figure TS.7. Tree mortality and associated forest dieback will occur in many regions in the next one to three decades (*medium confidence*), with forest dieback posing risks for carbon storage, biodiversity, wood production, water quality, amenity, and economic activity. Management actions can reduce, but not eliminate, risks to ecosystems and can increase ecosystem adaptability, for example through reduction of other stresses and habitat fragmentation, maintenance of genetic diversity, assisted translocation, and manipulation of disturbance regimes (*high confidence*). [4.3-4, 25.6, 26.4, Boxes 4-2, 4-3, and CC-RF]

A large fraction of terrestrial and freshwater species faces increased extinction risk under projected climate change during and beyond the 21st century, especially as climate change interacts with other pressures, such as habitat modification, over-exploitation, pollution, and invasive species (*high confidence*). Extinction risk is increased under all RCP scenarios, with risk increasing with both magnitude and rate of climate change. Models project that the risk of species extinctions will increase in the future due to climate change, but there is *low agreement* concerning the fraction of species at increased risk, the regional and taxonomic distribution of such extinctions, and the timeframe over which extinctions could occur. Some aspects leading to uncertainty in the quantitative projections of extinction risks were not taken into account in previous models; as more realistic details are included, it has been shown that the extinction risks may be either underestimated or overestimated when based on simpler models. [4.3, 25.6]

Within this century, magnitudes and rates of climate change associated with RCP4.5, 6.0, and 8.5 pose high risk of abrupt and irreversible regional-scale change in the composition, structure, and function of terrestrial and freshwater ecosystems, for example in the boreal-tundra Arctic system and the Amazon forest, leading to substantial additional climate change (*medium confidence*). For the boreal-tundra system, continued climate change will transform the species composition, land cover, drainage, and permafrost extent of the boreal-tundra system, leading to decreased albedo and the release of greenhouse gases (*medium confidence*), with adaptation measures unable to prevent substantial change (*high confidence*). Increased severe drought together with land-use change and forest fire would cause much of the Amazon forest to transform to less-dense drought- and fire-adapted ecosystems, increasing risk for biodiversity while decreasing net carbon uptake from the atmosphere (*medium confidence*). Large reductions in deforestation, as well as wider application of effective wildfire management, will lower the risk of abrupt change in the Amazon, as well as potential negative impacts of that change (*medium confidence*). [4.2-3, Figure 4-8, Boxes 4-3 and 4-4]

The natural carbon sink provided by terrestrial ecosystems is partially offset at the decadal timescale by carbon released through the conversion of natural ecosystems (principally forests) to farm and grazing land and through ecosystem degradation (*high confidence*). Carbon stored in the terrestrial biosphere is vulnerable to loss to the atmosphere as a result of climate change, deforestation, and ecosystem degradation. [4.2-3, Box 4-3]

[INSERT FIGURE TS.7 HERE
Figure TS.7: Rates of climate change (A), corresponding climate velocities (B), and rates of displacement of several terrestrial and freshwater species groups in the absence of human intervention (C). Horizontal and vertical pink bands provide a guide to interpretation of the figure. Species groups with displacement rates left of each band (in C) are projected to be unable to track climate in the absence of human intervention. Extended introduction of each panel follows: (A) Observed rates of climate change for global land areas are derived from CRUTEM4 climate data reanalysis; all other rates are calculated based on the average of CMIP5 climate model ensembles for the historical period (grey shading indicates model uncertainty) and for the future based on the four RCPs. Data were smoothed using a 20-year sliding window, and rates are means of between 17 and 30 models using one member per model. (B) Estimates of climate velocity for temperature were synthesized from historical and projected future relationships between rates of temperature change and climate velocity. The three scalars are climate velocities representative of mountainous areas (left), the global-land-area average (center), and large flat regions (right). (C) Rates of displacement for trees, plants, mammals, birds, plant-feeding insects, and freshwater mollusks. [Figure 4-5]]

Coastal systems and low-lying areas

Due to sea-level rise throughout the 21st century and beyond, coastal systems and low-lying areas will increasingly experience adverse impacts such as submergence, coastal flooding, and coastal erosion (*very high confidence*). The population and assets exposed to coastal risks as well as human pressures on coastal ecosystems will increase significantly in the coming decades due to population growth, economic development, and urbanization (*high confidence*). [5.3-5, 22.3, 24.4, 25.6, 26.3, 26.8, Table 26-1, Box 25-1]

By 2100, due to climate change and development patterns and without adaptation, hundreds of millions of people will be affected by coastal flooding and displaced due to land loss (*high confidence*). The majority affected will be in East, Southeast, and South Asia. The relative costs of adaptation vary strongly among and within regions and countries for the 21st century (*high confidence*). Some low-lying developing countries and small island states are expected to face very high impacts and associated annual damage and adaptation costs of several percentage points of GDP. [5.3-5, 24.4, 25.6, Box 25-1]

Marine systems

By mid 21st century, spatial shifts of marine species will cause species richness to increase at mid and high latitudes (*high confidence*) and to decrease at tropical latitudes (*medium confidence*), resulting in global redistribution of catch potential for fishes and invertebrates, with implications for food security (*medium confidence*). Species displacements are projected to lead to high-latitude invasions and high local-extinction rates in the tropics and semi-enclosed seas. Animal displacements will cause a 30-70% increase in the fisheries yield of some high-latitude regions by 2055 (relative to 2005), a redistribution at mid latitudes, and a drop of 40-60% in some of the tropics and the Antarctic, for 2°C warming above preindustrial levels (*medium confidence* for direction of fisheries' yield trends, *low confidence* for the precise magnitudes of yield change). See Figure TS.8A. Open-ocean net primary production is projected to redistribute and to fall globally by 2100 under RCP8.5 (*medium confidence*). [6.3-5, 25.6, 28.3, 30.4-6, Boxes CC-MB and CC-PP]

The progressive redistribution of species and the reduction in marine biodiversity in sensitive regions and habitats puts the sustained provision of fisheries productivity and other ecosystem services at risk, which will increase due to warming by 1°C or more by 2100 compared to the present, with limited adaptive capacity of human societies (*high confidence*). Socioeconomic vulnerability is highest in developing tropical countries, leading to risks from reduced supplies, income, and employment from marine fisheries. [6.4-5]

Ocean acidification poses risks to ecosystems, especially polar ecosystems and coral reefs, associated with impacts on the physiology, behavior, and population dynamics of individual species (*medium* to *high confidence*). See Box TS.7. Highly calcified mollusks, echinoderms, and reef-building corals are more sensitive than crustaceans (*high confidence*) and fishes (*low confidence*), with potential consequences for fisheries and livelihoods (Figure TS.8B). Ocean acidification occurs in combination with other environmental changes, both globally (e.g., warming, decreasing oxygen levels) and locally (e.g., pollution, eutrophication) (*high confidence*). Simultaneous environmental drivers, such as warming and ocean acidification, can lead to interactive, complex, and amplified impacts for species. [5.3-4, 6.3, 6.5, 22.3, 25.6, 28.2-3, 30.4-5, Boxes CC-CR and CC-OA]

Climate change adds to the threats of over-fishing and other non-climatic stressors, thus complicating marine management regimes (*high confidence*). In the short term, strategies including climate forecasting and early warning systems can reduce risks from ocean warming and acidification for some fisheries and aquaculture industries. Fisheries and aquaculture industries with high-technology and/or large investments, as well as marine shipping and oil and gas industries, have high capacities for adaptation due to greater development of environmental monitoring, modeling, and resource assessments. For smaller-scale fisheries and developing nations, building social resilience, alternative livelihoods, and occupational flexibility represent important strategies for reducing the vulnerability of ocean-dependent human communities. [6.4, 7.3-4, 25.6, 29.4, 30.6-7]

[INSERT FIGURE TS.8 HERE
Figure TS.8: Climate change risks for fisheries. (A) For 2°C increase from preindustrial levels using SRES A1B (≈RCP6.0), projected global redistribution of maximum catch potential of 1000 species of exploited fishes and invertebrates, comparing the 10-year averages 2001-2010 and 2051-2060, without analysis of potential impacts of overfishing. (B) Marine mollusk and crustacean fisheries (estimated catch rates ≥0.005 tonnes per sq. km) and known locations of warm- and cold-water corals, depicted on a global map showing the distribution of ocean acidification in 2100 under RCP8.5. [WGI AR5 Figure SPM.8] The bottom panel compares sensitivity to ocean acidification across corals, mollusks, and crustaceans, vulnerable animal phyla with socioeconomic relevance (e.g., for coastal protection and fisheries). The number of species analyzed across studies is given for each category of elevated CO_2. For 2100, RCP scenarios falling within each pCO_2 category are as follows: RCP4.5 for 500-650 μatm, RCP6.0 for 651-850 μatm, and RCP8.5 for 851-1370 μatm. [6.1, 6.3, 30.5, Figures 6-10 and 6-14; WGI AR5 Box SPM.1]]

Food production systems and food security

Without adaptation, local temperature increases of 1°C or more above preindustrial levels are projected to negatively impact yields for the major crops (wheat, rice, and maize) in tropical and temperate regions, although individual locations may benefit (*medium confidence*). With or without adaptation, climate change will reduce median yields by 0 to 2% per decade for the rest of the century, as compared to a baseline without climate change. These projected impacts will occur in the context of rising crop demand, projected to increase by about 14% per decade until 2050. See Figure TS.9 for a summary of projected changes in crop yields over the 21st century. Risks are greatest for tropical countries, given projected impacts that exceed adaptive capacity and higher poverty rates compared with temperate regions. Climate change will progressively increase inter-annual variability of crop yields in many regions. [7.4, 22.3, 24.4, 25.7, 26.5, Figures 7-4, 7-5, 7-6, and 7-7]

On average, adaptation improves yields by the equivalent of ~15-18% of current yields, but the effectiveness of adaptation is highly variable (*medium confidence*). Positive and negative yield impacts projected for local temperature increases of about 2^{o}C above preindustrial levels maintain possibilities for effective adaptation in crop production (*high confidence*). For local warming of about 4^{o}C or more, differences between crop production and population-driven demand will become increasingly large in many regions, posing significant risks to food security even with adaptation. [7.5, 22.3, 25.7, 26.5, Table 7-2, Figures 7-4, 7-5, 7-7, and 7-8]

[INSERT FIGURE TS.9 HERE
Figure TS.9: Summary of projected changes in crop yield as a function of time with and without adaptation, across studies for all regions. Data (n=1090) are plotted in the 20-year period on the horizontal axis that includes the midpoint of each future projection period. [Figure 7-5]]

Urban areas

Rising sea levels and storm surges, heat stress, extreme precipitation, inland and coastal flooding, drought and water scarcity, and air pollution pose widespread negative risks for people, health, livelihoods, assets, local and national economies, and ecosystems (*very high confidence*). These risks are amplified for those who lack essential infrastructure and services or who live in exposed areas. [3.5, 8.2-3, 22.3, 24.4, 24.5, 26.8, Box CC-HS]

Reducing basic service deficits and building resilient infrastructure systems (e.g., for water supply, sanitation, storm and waste water drains, electricity, transportation and telecommunication, health care, education, and emergency response) could significantly reduce hazard exposure and vulnerability to climate change, especially for those who are most at risk or vulnerable (*very high confidence*). Urban adaptation provides opportunities for incremental and transformational adjustments towards resilience and sustainable development via effective multi-level urban risk governance, alignment of policies and incentives, strengthened local government and community adaptation capacity, synergies with the private sector, or appropriate financing and institutional development (*medium confidence*). Enabling the capacity of low-income groups and vulnerable communities and their partnerships with local governments can also be an effective urban adaptation strategy. [8.3-4, 24.4, 24.5, 26.8, Table 11-3, Box 25-9]

Rural areas

Major future rural impacts will be felt in the near-term and beyond through impacts on water supply, food security, and agricultural incomes, including shifts in production of food and non-food crops in many areas of the world (*high confidence*). Price rises, which may be induced by climate shocks as well as other factors, have a disproportionate impact on the welfare of the poor in rural areas, such as female-headed households and those with limited access to modern agricultural inputs, infrastructure, and education. Climate change will increase international agricultural trade volumes in both physical and value terms (*limited evidence, medium agreement*). Importing food can help countries adjust to climate-change-induced domestic productivity shocks while short-term food deficits in low-income countries may have to be met through food aid. Valuation of non-marketed ecosystem services and limitations of economic valuation models that aggregate across contexts pose challenges for valuing rural impacts. [9.3, 26.8, Box 25-5]

Options exist for adaptations within international agricultural trade (*medium confidence*). Deepening agricultural markets and improving the predictability and the reliability of the world trading system through trade reform could result in reduced market volatility and manage food supply shortages caused by climate change. Investing in the production of small-scale farms in developing countries also provides benefits. [9.3, 25.9]

Key economic sectors and services

For most economic sectors, the impacts of drivers such as changes in population, age structure, income, technology, relative prices, lifestyle, regulation, and governance will be large relative to the impacts of climate change (*medium evidence, high agreement*). Climate change will reduce energy demand for heating and increase energy demand for cooling in the residential and commercial sectors (*robust evidence, high agreement*). Climate change will affect energy sources and technologies differently, depending on resources (e.g., water flow, wind, insolation), technological processes (e.g., cooling), or locations (e.g., coastal regions, floodplains) involved. More frequent and/or severe weather disasters for some regions and/or hazards will increase losses and loss variability in various regions and challenge insurance systems to offer affordable coverage while raising more risk-based capital, particularly in low- and middle-income countries. Large-scale public-private risk prevention initiatives and government insurance of the non-diversifiable portion of risk offer example mechanisms for adaptation. [3.5, 10.2, 10.7, 10.10, 25.7, 26.7, Box 25-7]

Climate change may influence the integrity and reliability of pipelines and electricity grids (*medium evidence, medium agreement*). Climate change may require changes in design standards for the construction and operation of pipelines and of power transmission and distribution lines. Adopting existing technology from other geographical and climatic conditions may reduce the cost of adapting new infrastructure as well as the cost of retrofitting existing pipelines and grids. Climate change may negatively affect transport infrastructure (*limited evidence, high agreement*). All infrastructure is vulnerable to freeze-thaw cycles; paved roads are particularly vulnerable to temperature extremes, unpaved roads and bridges to precipitation extremes. Transport infrastructure on ice or permafrost is especially vulnerable. [10.2, 10.4, 25.7, 26.7]

Climate change will affect tourism resorts, particularly ski resorts, beach resorts, and nature resorts (*robust evidence, high agreement*), and tourists may spend their holidays at higher altitudes and latitudes (*medium evidence, high agreement*). The economic implications of climate-change-induced changes in tourism demand and supply entail gains for countries closer to the poles and countries with higher elevations and losses for other countries. [10.6, 25.7]

Global mean temperature increase of 2.5°C above preindustrial levels may lead to global aggregate economic losses between 0.2 and 2.0% of income (*medium evidence, medium agreement*). Losses increase with greater warming, but little is known about aggregate economic impacts above 3°C. Impact estimates are incomplete and depend on a large number of assumptions, many of which are disputable, and aggregate impacts hide large differences between and within countries. The incremental economic impact of emitting a tonne of carbon dioxide lies between a few dollars and several hundreds of dollars per tonne of carbon (*robust evidence, medium agreement*). Estimates vary strongly with the assumed discount rate, with larger ranges for lower discount rates. [10.9]

Human health

Until mid-century, climate change will impact human health mainly by exacerbating health problems that already exist (*very high confidence*), and climate change throughout the 21st century will lead to increases in ill-health in many regions, as compared to a baseline without climate change (*high confidence*). Examples include greater likelihood of injury, disease, and death due to more intense heat waves and fires; increased likelihood of under-nutrition resulting from diminished food production in poor regions; risks from lost work capacity and reduced labor productivity in vulnerable populations; and increased risks from food- and water-borne diseases. Impacts on health will be reduced, but not eliminated, in populations that benefit from rapid social and economic development, particularly among the poorest and least healthy groups. Climate change will increase demands for health care services and facilities, including public health programs, disease prevention activities, health care personnel, infrastructure, and supplies for treatment (*medium evidence, high agreement*). Positive effects will include modest improvements in cold-related mortality and morbidity in some areas due to fewer cold extremes, shifts in food production, and reduced capacity of disease-carrying vectors (*medium confidence*). Globally, positive impacts will be outweighed by the magnitude and severity of negative impacts (*high confidence*). The most effective adaptation measures for health in the near-term are programs that implement basic public health measures such as provision of clean water and sanitation, secure essential health care including vaccination and child health services, increase capacity for disaster preparedness and response, and alleviate poverty (*very high confidence*). For RCP8.5 by 2100, the combination of high temperature and humidity in some areas for parts of the year will compromise normal human activities, including growing food or working outdoors (*high confidence*). See Figure TS.10. [8.2, 10.8, 11.3-8, 19.3, 22.3, 25.8, 26.6, Box CC-HS]

[INSERT FIGURE TS.10
Figure TS.10: Conceptual presentation of health risks from climate change and the potential for risk reduction through adaptation. Risks are identified in eight health-related categories based on assessment of the literature and

expert judgments by authors of Chapter 11.The width of the slices indicates in a qualitative way relative importance in terms of burden of ill-health globally at present. Risk levels are assessed for the present and for the near-term era of committed climate change (here, for 2030-2040). For some categories, e.g., vector-borne diseases, heat/cold stress, and agricultural production and undernutrition, there may be benefits to health in some areas, but the net impact is expected to be negative. Risks levels are also presented for the longer-term era of climate options (here, for 2080-2100) for global mean temperature increase of 4°C above preindustrial levels. For each timeframe, risk levels are estimated for the current state of adaptation and for a hypothetical highly adapted state, indicated by different colors. [Figure 11-6]]

Human security

Human security will be progressively threatened as the climate changes (*robust evidence, high agreement*). Human insecurity almost never has single causes, but instead emerges from the interaction of multiple factors. Climate change is an important factor in threats to human security through (i) undermining livelihoods, (ii) compromising culture and identity, (iii) increasing migration that people would rather have avoided, and (iv) challenging the ability of states to provide the conditions necessary for human security. See Figure TS.11. [12.1-4, 12.6]

Climate change will compromise the cultural values that are important for community and individual well-being (*medium evidence, high agreement*). The effect of climate change on culture will vary across societies and over time, depending on cultural resilience and the mechanisms for maintaining and transferring knowledge. Changing weather and climatic conditions threaten cultural practices embedded in livelihoods and expressed in narratives, world views, identity, community cohesion, and sense of place. Loss of land and displacement, for example on small islands and coastal communities, have well documented negative cultural and well-being impacts. [12.3, 12.4]

Climate change over the 21st century will have significant impacts on forms of migration that compromise human security (*medium evidence, high agreement*). Coastal inundation and loss of permafrost can lead to migration and resettlement. Mobility is a widely used strategy to maintain livelihoods in response to social and environmental changes. Populations that lack the resources for mobility and migration often experience higher exposure to weather-related extremes, in both rural and urban areas, particularly in low-income countries. Expanding opportunities for mobility can reduce vulnerability, but altered migration flows can also create risks as well as potential benefits for migrants and for sending and receiving regions and states. [9.3, 12.4, 19.4, 22.3, 22.6, 25.9]

Climate change indirectly increases risks from violent conflict in the form of civil war, inter-group violence, and violent protests by exacerbating well-established drivers of these conflicts such as poverty and economic shocks (*medium confidence*). Statistical studies show that climate variability is significantly related to these forms of conflict. Poorly designed adaptation and mitigation strategies can increase risks from violent conflict. [12.5, 13.2, 19.4]

Climate change over the 21st century will lead to new challenges to states and will increasingly shape national security policies (*medium evidence, medium agreement*). Small-island states and other states highly vulnerable to sea-level rise face major challenges to their territorial integrity. Some transboundary impacts of climate change, such as changes in sea ice, shared water resources, and migration of fish stocks, have the potential to increase rivalry among states. The presence of robust institutions can manage many of these rivalries to reduce conflict risks. [12.5-6, 23.9, 25.9]

[INSERT FIGURE TS.11 HERE
Figure TS.11: Schematic of climate change risks for human security and the interactions between livelihoods, conflict, culture, and migration. Interventions and policies are indicated by the difference between initial conditions (solid black circles) and the outcome of intervention (white circles). Some interventions (blue arrows) show net increase in human security while others (red arrows) lead to net decrease in human security. [Figure 12-3]]

Livelihoods and poverty

Throughout the 21st century, climate change impacts will slow down economic growth and poverty reduction, further erode food security, and trigger new poverty traps, the latter particularly in urban areas and emerging hotspots of hunger (*medium confidence*). Climate change will exacerbate poverty in low and lower-middle income countries, including high mountain states, countries at risk from sea-level rise, and countries with indigenous peoples, and create new poverty pockets in upper-middle- to high-income countries in which inequality is increasing. In urban and rural areas, wage-labor-dependent poor households that are net buyers of food will be particularly affected due to food price increases, including in regions with high food insecurity and high inequality (particularly Africa), although the agricultural self-employed could benefit. Insurance programs, social protection measures, and disaster risk reduction may enhance long-term livelihood resilience among poor and marginalized people, if policies address multidimensional poverty. [8.1, 8.4, 9.3, 10.9, 13.2-4, 22.3, 26.8]

_____ START BOX TS.7 HERE _____

Box TS.7. Ocean Acidification

Anthropogenic ocean acidification and global warming share the same primary cause, which is the increase of atmospheric CO_2 (Box TS.7 Figure 1A). [WGI AR5 2.2] Eutrophication, upwelling, and deposition of atmospheric nitrogen and sulfur contribute to ocean acidification locally. [5.3, 6.1, 30.3] The fundamental chemistry of ocean acidification is well understood (*robust evidence, high agreement*). [30.3; WGI AR5 3.8, 6.4] It has been more difficult to understand and project changes within the more complex coastal systems. [5.3, 30.3]

Ocean acidification occurs on a backdrop of other environmental changes, both globally (e.g., warming, decreasing oxygen levels) and locally (e.g., pollution, eutrophication), yet their combined impacts remain poorly understood. A pattern of positive and negative impacts of ocean acidification emerges for processes and organisms (*high confidence*; Box TS.7 Figure 1B), but key uncertainties remain from organismal to ecosystem levels. A wide range of sensitivities exists within and across organisms, with higher sensitivity in early life stages. [6.3] Lower pH decreases the rate of calcification of most, but not all, sea-floor calcifiers, reducing their competitiveness with non-calcifiers (*robust evidence, medium agreement*). [5.4, 6.3] Ocean acidification stimulates dissolution of calcium carbonate (*very high confidence*). Growth and primary production are stimulated in seagrasses and some phytoplankton (*high confidence*), and harmful algal blooms could become more frequent (*limited evidence, medium agreement*). Serious behavioral disturbances have been reported in fishes (*high confidence*). [6.3] Natural analogues at CO_2 vents indicate decreased species diversity, biomass, and trophic complexity. Shifts in organisms' performance and distribution will change both predator-prey and competitive interactions, which could impact food webs and higher trophic levels (*limited evidence, high agreement*). [6.3]

A few studies provide *limited evidence* for adaptation in phytoplankton and mollusks. However, mass extinctions in Earth history occurred during much slower rates of change in ocean acidification, combined with other drivers, suggesting that evolutionary rates may be too slow for sensitive and long-lived species to adapt to the projected rates of future change (*medium confidence*). [6.1]

The biological, ecological, and biogeochemical changes driven by ocean acidification will affect key ecosystem services. The oceans will become less efficient at absorbing CO_2 and hence moderating climate (*very high confidence*). [WGI AR5 Figure 6.26] The impacts of ocean acidification on coral reefs, together with those of thermal stress (driving mass coral bleaching and mortality) and sea-level rise, will diminish their role in shoreline protection as well as their direct and indirect benefits to fishing and tourism industries (*limited evidence, high agreement*). [Box CC-CR] The global cost of production loss of mollusks could be over 100 billion US$ by 2100 (*low confidence*). The largest uncertainty is how the impacts on lower trophic levels will propagate through the food webs and to top predators. Models suggest that ocean acidification will generally reduce fish biomass and catch (*low confidence*) and complex additive, antagonistic, and/or synergistic interactions will occur with disruptive ramifications for ecosystems as well as for important ecosystem goods and services.

[INSERT BOX TS.7 FIGURE 1 HERE
Box TS.7 Figure 1: (A) Overview of the chemical, biological, and socioeconomic impacts of ocean acidification and of policy options. (B) Effect of near-future acidification (seawater pH reduction of 0.5 unit reduction or less) on

major response variables estimated using weighted random effects meta-analyses, with the exception of survival, which is not weighted. The log-transformed response ratio (LnRR) is the ratio of the mean effect in the acidification treatment to the mean effect in a control group. It indicates which process is most uniformly affected by ocean acidification, but large variability exists between species. Significance is determined when the 95% bootstrapped confidence interval does not cross zero. The number of experiments used in the analyses is shown in parentheses. '*' denotes a statistically significant effect. [Figure OA-1, Box CC-OA]]

_____ END BOX TS.7 HERE _____

B-3. Regional Risks and Potential for Adaptation

Climate change will amplify climate-related risks to natural and human systems in most parts of the world. Key regional risks identified with *medium* to *high confidence* are presented in Table TS.5. Projected changes in climate and increasing atmospheric CO_2 will have positive effects for some sectors in some locations. For extended summary of regional risks and the more limited potential benefits, see introductory overviews for each region below and also Chapters 21-30.

[INSERT TABLE TS.5 HERE
Table TS.5: Key regional risks from climate change and the potential for reducing risks through mitigation and adaptation. Risks have been identified based on assessment of the relevant scientific, technical, and socioeconomic literature, as detailed in supporting chapter sections. Each key risk is characterized as very low to very high for three timeframes: the present, near-term (here, assessed over 2030-2040), and longer-term (here, assessed over 2080-2100). Assessed risk levels integrate probability and consequence over the full range of possible outcomes, acknowledging the importance of differences in values and objectives in interpretation of the assessed risk levels. For the near-term era of committed climate change, projected levels of global mean temperature increase do not diverge substantially across emission scenarios. For the longer-term era of climate options, risk levels are presented for global mean temperature increase of 2°C and 4°C above preindustrial levels, illustrating the potential role of mitigation in reducing risks. For the present, risk levels are estimated for current adaptation and a hypothetical highly adapted state, identifying where current adaptation deficits exist. For the future, risk levels are estimated for a continuation of current adaptation and for a highly adapted state, representing the potential for and limits to adaptation. Relevant climate variables are indicated by icons. Risk levels are not necessarily comparable, especially across regions, because the assessment considers potential impacts and adaptation in different physical, biological, and human systems across diverse regional contexts.]

***Africa.* Climate change will amplify existing stress on water availability and on agricultural systems particularly in semi-arid environments (*high confidence*).** Increasing temperatures and changes in precipitation are *very likely* to reduce cereal crop productivity with strong adverse effects on food security (*high confidence*). Progress has been achieved on managing risks to food production from current climate variability and near-term climate change, but these will not be sufficient to address long-term impacts of climate change. Adaptive agricultural processes such as collaborative, participatory research that includes scientists and farmers, strengthened communication systems for anticipating and responding to climate risks, and increased flexibility in livelihood options provide potential pathways for strengthening adaptive capacities. Climate change is a multiplier of existing health vulnerabilities including insufficient access to safe water and improved sanitation, food insecurity, and limited access to health care and education. Strategies that integrate consideration of climate change risks with land and water management and disaster risk reduction bolster resilient development. [22.3-4, 22.6]

***Europe.* Climate change will increase the likelihood of systemic failures across European countries caused by extreme climate events affecting multiple sectors (*medium confidence*).** Sea-level rise and increases in extreme rainfall are projected to further increase coastal and river flood risks and without adaptive measures will substantially increase flood damages (i.e., people affected and economic losses); adaptation can prevent most of the projected damages (*high confidence*). Heat-related deaths and injuries are *likely* to increase, particularly in southern Europe (*medium confidence*). Climate change is *likely* to increase cereal crop yields in northern Europe (*medium confidence*) but decrease yields in southern Europe (*high confidence*). Climate change will increase irrigation needs in Europe, and future irrigation will be constrained by reduced runoff, demand from other sectors, and economic costs, with integrated water management a strategy for addressing competing demands. Hydropower production is *likely* to decrease in all sub-regions except Scandinavia. Climate change is *very likely* to cause changes in habitats and species, with local extinctions (*high confidence*), continental-scale shifts in species distributions (*medium confidence*), and significantly reduced alpine-plant habitat (*high confidence*). Climate change is *likely* to entail the loss or displacement of coastal wetlands. The introduction and expansion of invasive species, especially those with high migration rates, from outside Europe is *likely* to increase with climate change (*medium confidence*). [23.2-9]

Asia. **Climate change will cause declines in agricultural productivity in many subregions of Asia, for crops such as rice (*medium confidence*).** In Central Asia, cereal production in northern and eastern Kazakhstan could benefit from the longer growing season, warmer winters, and slight increase in winter precipitation, while droughts in western Turkmenistan and Uzbekistan could negatively affect cotton production, increase water demand for irrigation, and exacerbate desertification. The effectiveness of potential and practiced agricultural adaptation strategies is not well understood. Future projections of precipitation at subregional scales and thus of freshwater availability in most parts of Asia are uncertain (*low confidence* in projections), but increased water demand from population growth, increased water consumption per capita, and lack of good management will increase water scarcity challenges for most of the region (*medium confidence*). Adaptive responses include integrated water management strategies, such as development of water saving technologies, increased water productivity, and water reuse. Extreme climate events will have an increasing impact on human health, security, livelihoods, and poverty, with the type and magnitude of impact varying across Asia (*high confidence*). In many parts of Asia, observed terrestrial impacts, such as permafrost degradation and shifts in plant species' distributions, growth rates, and timing of seasonal activities, will increase due to climate change projected during the 21st century. Coastal and marine systems in Asia, such as mangroves, seagrass beds, salt marshes, and coral reefs, are under increasing stress from climatic and non-climatic drivers. In the Asian Arctic, sea-level rise interacting with projected changes in permafrost and the length of the ice-free season will increase rates of coastal erosion (*medium evidence, high agreement*). [24.4, 30.5]

Australasia. **Without adaptation, further changes in climate, atmospheric CO_2, and ocean acidity are projected to have substantial impacts on water resources, coastal ecosystems, infrastructure, health, agriculture, and biodiversity (*high confidence*).** Freshwater resources are projected to decline in far south-west and far south-east mainland Australia (*high confidence*) and for some rivers in New Zealand (*medium confidence*). Rising sea levels and increasing heavy rainfall are projected to increase erosion and inundation, with consequent damages to many low-lying ecosystems, infrastructure, and housing (*high confidence*); increasing heat waves will increase risks to human health; rainfall changes and rising temperatures will shift agricultural production zones; and many native species will suffer from range contractions and some may face local or even global extinction. Uncertainty in projected rainfall changes remains large for many parts of Australia and New Zealand, which creates significant challenges for adaptation. Some sectors in some locations have the potential to benefit from projected changes in climate and increasing atmospheric CO_2, for example due to reduced energy demand for winter heating in New Zealand and southern parts of Australia, and due to forest growth in cooler regions except where soil nutrients or rainfall are limiting. Indigenous peoples in both Australia and New Zealand have higher than average exposure to climate change due to a heavy reliance on climate-sensitive primary industries and strong social connections to the natural environment, and face additional constraints to adaptation (*medium confidence*). [25.2-3, 25.5-8, Boxes 25-1, 25-2, 25-5, and 25-8]

North America. **Many climate-related hazards that carry risk, particularly related to severe heat, heavy precipitation, and declining snowpack, will increase in frequency and/or severity in North America in the next decades (*very high confidence*).** Climate change will amplify risks to water resources already affected by non-climatic stressors, with potential impacts associated with decreased snowpack, decreased water quality, urban flooding, and decreased water supplies for urban areas and irrigation (*high confidence*). More adaptation options are available to address water supply deficits than flooding and water quality concerns (*medium confidence*). Ecosystems are under increasing stress from rising temperatures, CO_2 concentrations, and sea levels, with particular vulnerability to climate extremes (*very high confidence*). In many cases, climate stresses exacerbate other anthropogenic influences on ecosystems, including land-use changes, non-native species, and pollution. Projected increases in temperature, reductions in precipitation in some regions, and increased frequency of extreme events would result in net productivity declines in major North American crops by the end of the 21st century without adaptation, although some regions, particularly in the north, may benefit. Adaptation, often with mitigation co-benefits, could offset projected negative yield impacts for many crops at 2°C global mean temperature increase above preindustrial, with reduced effectiveness of adaptation at 4°C (*high confidence*). Although larger urban centers would have higher adaptive capacities, high population density, inadequate infrastructures, lack of institutional capacity, and degraded natural environments increase future climate risks from heat waves, droughts, storms, and sea-level rise (*medium evidence*, *high agreement*). Future risks from climate extremes can be reduced, for example through targeted and sustainable air conditioning, more effective warning and response systems, enhanced pollution controls, urban planning strategies, and resilient health infrastructure (*high confidence*). [26.3-6, 26.8]

Central and South America. **Despite improvements, high and persistent levels of poverty in most countries result in high vulnerability to climate variability and change (*high confidence*).** Climate change impacts on agricultural productivity are expected to exhibit large spatial variability, for example with sustained or increased productivity through mid-century in southeast South America and decreases in productivity in the near-term (by 2030) in Central America, threatening food security of the poorest populations (*medium confidence*). Reduced precipitation and increased evapotranspiration in semi-arid regions will increase risks from water-supply shortages, affecting cities, hydropower generation, and agriculture (*high confidence*). Ongoing adaptation strategies include reduced mismatch between water supply and demand, and water-management and coordination reforms (*medium confidence*). Conversion of natural ecosystems, a driver of anthropogenic climate change, is the main cause of biodiversity and ecosystem loss (*high confidence*). Climate change is expected to increase rates of species extinction (*medium confidence*). In coastal and marine systems, sea-level rise and human stressors increase risks for fish stocks, corals, mangroves, recreation and tourism, and control of diseases (*high confidence*). Climate change will exacerbate future health risks given regional population growth rates and vulnerabilities due to pollution, food insecurity in poor regions, and existing health, water, sanitation, and waste collection systems (*medium confidence*). [27.2-3]

Polar Regions. **In the Arctic, climate change and often-interconnected non-climate-related drivers, including environmental changes, demography, culture, and economic development, interact to determine physical, biological, and socioeconomic risks, with rates of change that may be faster than social systems can adapt (*high confidence*).** Thawing permafrost and changing precipitation patterns have the potential to affect infrastructure and related services, with particular risks for residential buildings, for example in Arctic cities and small rural settlements. Climate change will especially impact Arctic communities that have narrowly based economies limiting adaptive choices. Increased Arctic navigability and expanded land- and freshwater-based transportation networks will increase economic opportunities. Impacts on the informal, subsistence-based economy will include changing sea-ice conditions that increase the difficulty of hunting marine mammals. Polar bears have been and will be affected by loss of annual ice over continental shelves, decreased ice duration, and decreased ice thickness. Already, accelerated rates of change in permafrost thaw, loss of coastal sea ice, sea-level rise, and increased intensity of weather extremes are forcing relocation of some indigenous communities in Alaska (*high confidence*). In the Arctic and Antarctic, some marine species will shift their ranges in response to changing ocean and sea ice conditions (*medium confidence*). Climate change will increase the vulnerability of terrestrial ecosystems to invasions by non-indigenous species, the majority expected to arrive through direct human assistance (*high confidence*). [6.3, 6.5, 28.2-4]

Small Islands. **Small islands have high vulnerability to climatic and non-climatic stressors (*high confidence*).** Diverse physical and human attributes and their sensitivity to climate-related drivers lead to variable climate change risk profiles and adaptation from one island region to another and among countries in the same region. Risks can originate from transboundary interactions, for example associated with existing and future invasive species and human health challenges. Sea-level rise poses one of the most widely recognized climate change threats to low-lying coastal areas on islands and atolls. Projected sea-level rise at the end of the 21st century, superimposed on extreme sea-level events, presents severe coastal-flooding and erosion risks for low-lying coastal areas and atoll islands. Wave over-wash will degrade groundwater resources. Coral reef ecosystem degradation associated with increasing sea surface temperature and ocean acidification will negatively impact island communities and livelihoods, given the dependence of island communities on coral reef ecosystems for coastal protection, subsistence fisheries, and tourism. [29.3-5, 29.9, 30.5, Figure 29-1, Table 29-3, Box CC-CR]

The Ocean. **Warming will increase risks to ocean ecosystems (*high confidence*).** Coral reefs within coastal boundary systems, semi-enclosed seas, and sub-tropical gyres are rapidly declining as a result of local non-climatic stressors (i.e., coastal pollution, overexploitation) and climate change. Projected increases in mass coral bleaching and mortality will alter or eliminate ecosystems, increasing risks to coastal livelihoods and food security (*medium* to *high confidence*). An analysis of the CMIP5 ensemble projects loss of coral reefs from most sites globally to be *very likely* by 2050 under mid to high rates of ocean warming. Reducing non-climatic stressors represents an opportunity to strengthen ecological resilience. The highly productive high-latitude spring bloom systems in the Northeastern Atlantic are responding to warming (*medium evidence, high agreement*), with the greatest changes being observed since the late 1970s in the phenology, distribution, and abundance of plankton assemblages, and the reorganization of fish assemblages, with a range of consequences for fisheries (*high confidence*). Projected warming increases the likelihood of greater thermal stratification in some regions, which can lead to reduced O_2 ventilation and encourage the formation of hypoxic zones, especially in the Baltic and Black Seas (*medium confidence*). Changing surface winds and waves, sea level, and storm intensity will increase the vulnerability of ocean-based industries such as shipping, energy, and mineral extraction. New opportunities as well as international issues over access to resources and vulnerability may accompany warming waters particularly at high latitudes. [5.3-4, 6.4, 28.2-3, 30.3, 30.5-6, Table 30-1, Figures 30-4 and 30-10, Boxes 6-1, CC-CR, and CC-MB]

Understanding of extreme events and their interactions with climate change is particularly important for managing risks in a regional context. Table TS.6 provides a summary of observed and projected trends in some types of temperature and precipitation extremes.

[INSERT TABLE TS.6
Table TS.6: Observed and projected future changes in some types of temperature and precipitation extremes over 26 sub-continental regions as defined in SREX. Confidence levels are indicated by symbol color. Likelihood terms are given only for *high* or *very high confidence* statements. Observed trends in temperature and precipitation extremes, including dryness and drought, are generally calculated from 1950, using 1961-1990 as the reference period, unless otherwise indicated. Future changes are derived from global and regional climate model projections for 2071-2100 compared with 1961-1990 or for 2080-2100 compared with 1980-2000. Table entries are summaries of information in SREX Tables 3.2 and 3.3 supplemented with or superseded by material from WGI AR5 2.6, 14.4, and Table 2.13 and WGII AR5 Table 25-1. The source(s) of information for each entry are indicated by superscripts: (a) SREX Table 3.2; (b) SREX Table 3.3; (c) WGI AR5 2.6 and Table 2.13; (d) WGI AR5 14.4; (e) WGII AR5 Table 25-1. [Tables 21-7 and SM21-2, Figure 21-4]]

C) MANAGING FUTURE RISKS AND BUILDING RESILIENCE

Managing the risks of climate change involves decisions with implications for future societies, economies, environment, and climate. Figure TS.12 provides an overview of entry points, approaches, and core considerations in addressing climate change.

Starting with principles for effective adaptation, this section evaluates the ways that interlinked human and natural systems can build resilience through adaptation, mitigation, and sustainable development. It describes understanding of climate-resilient pathways, of incremental versus transformational changes, and of limits to adaptation, and it considers co-benefits, synergies, and tradeoffs among mitigation, adaptation, and development.

[INSERT FIGURE TS.12 HERE
Figure TS.12: An overview of overlapping entry points and approaches, as well as core considerations, in responding to climate change, as assessed in the WGII AR5. Bracketed references indicate sections of this summary with corresponding assessment findings.]

C-1. Principles for Effective Adaptation

The report assesses a wide variety of approaches for managing risks and building resilience. Strategies and approaches to climate change adaptation include efforts to decrease vulnerability or exposure and/or increase resilience or adaptive capacity. Mitigation is assessed in the WGIII AR5. An overview of types of responses to climate change is presented in Table TS.7.

[INSERT TABLE TS.7 HERE
Table TS.7: Managing the risks of climate change: entry points, strategies, and adaptation options. These approaches should be considered overlapping rather than discrete, and they are often pursued simultaneously. Examples given can be relevant to more than one category.]

Adaptation is highly regionally and context specific, with no single approach for reducing risk appropriate across all settings (*medium confidence*). Effective risk reduction and adaptation strategies consider the dynamics of vulnerability and exposure and their linkages with development and climate change (*high confidence*). [2.1, 8.3-4, 13.1, 13.3-4, 15.2-3, 15.5, 16.2-3, 16.5, 17.2, 17.5, 19.6, 21.3, 22.4, 25.4, 26.8-9, 29.6, 29.8]

From individuals to governments, actors across scales and regions have complementary roles in enabling adaptation planning and implementation (*high confidence*), for example through increasing awareness of climate change risks, learning from experience with climate variability, and achieving synergies with disaster risk reduction. Local government and the private sector are increasingly recognized as critical to progress in adaptation, given their roles in scaling up adaptation of communities and households and in managing risk information and financing (*medium evidence, high agreement*). National governments can coordinate adaptation by local and subnational governments, creating legal frameworks, protecting vulnerable groups, and providing information, policy frameworks, and financial support (*robust evidence, high agreement*). Public action can influence the degree to which private parties undertake adaptation actions. [2.1-4, 3.6, 8.3-4, 9.3-4, 14.2, 15.2-3, 15.5, 16.2-5, 17.2-3, 22.4, 24.4, 25.4, 26.8-9, 30.7, Tables 21-1, 21-5, and 21-6, Boxes 16-1, 16-2, and 25-7]

In many cases, a first step towards adaptation to future climate change is reducing vulnerability and exposure to present climate through low-regrets measures and actions emphasizing co-benefits (*high confidence*). Available strategies and actions can increase resilience across a range of possible future climates while helping to improve human livelihoods, social and economic well-being, and environmental quality. Integration of adaptation into planning and decision-making can promote synergies with development. Adaptation strategies that also strengthen livelihoods, enhance development, and reduce poverty include improved social protection, improved water and land governance, enhanced water storage and services, greater involvement in planning, and elevated attention to urban and peri-urban areas heavily affected by migration of poor people. See Table TS.7. [3.6, 9.4, 11.2, 14.2, 15.2-3, 15.5, 17.2, 20.4, 20.6, 22.4, 24.4, 25.10, 27.3-5, Boxes 25-2, 25-6, 25-8, and 25-9]

Integration of adaptation into planning and decision-making can promote synergies with development and reduce the possibility of maladaptive actions (*robust evidence, high agreement*). Such mainstreaming embeds climate-sensitive thinking in existing and new institutions and organizations**.** Adaptation can generate larger benefits when connected with development activities and disaster risk reduction (*medium confidence*). [8.3, 9.3, 14.2, 14.6, 15.3-4, 17.2, 20.2-3, 22.4, 24.5, 29.6, Box CC-UR]

Multiple simultaneous constraints can interact to impede adaptation planning and implementation (*high confidence*). Common constraints on implementation arise from the following: uncertainty about projected impacts; limited financial and human resources; limited integration or coordination of different levels of governance; different perceptions of risks; inadequate responses from political institutions; competing values; absence of adaptation leaders and champions; and limited tools to monitor adaptation effectiveness. Underestimating the complexity of adaptation as a social process can create unrealistic expectations. [3.6, 4.4, 8.4, 9.4, 13.2-3, 14.2, 15.2-3, 15.5, 16.2-3, 16.5, 17.2, 22.3-5, 23.6-7, 24.5, 25.4, 25.10, 26.8-9, 30.6, Table 25-2, Boxes 16-1, 16-3, and CC-EA]

Poor planning, overemphasizing short-term outcomes, or discounting or failing to consider all consequences can result in maladaptation (*medium evidence, high agreement*). Narrow focus on quantifiable costs and benefits can bias decisions against the poor, against ecosystems, and against those in the future whose values can be excluded or are understated. Maladaptation can increase the vulnerability or exposure of the target group in the future, or the vulnerability of other locations or sectors. [14.6, 15.5, 17.2-3, 22.4, 25.9]

Existing and emerging economic instruments can foster adaptation by providing incentives for anticipating and reducing impacts (*medium confidence*). Instruments include risk sharing and transfer mechanisms, loans, public-private finance partnerships, payments for environmental services, improved resource pricing (e.g., water markets), charges and subsidies including taxes, norms and regulations, and behavioral approaches. Risk financing mechanisms across scales contribute to increasing resilience to climate extremes and climate variability, but can also provide disincentives, cause market failure, and decrease equity. Mechanisms include insurance, reinsurance, micro insurance, and national, regional, and global risk pools. The public sector often plays a key role as regulator, provider, or insurer of last resort. [10.7, 10.9, 13.3, 17.4-5, 22.4, Box 25-7]

Indigenous, local, and traditional forms of knowledge are a major resource for adapting to climate change (*robust evidence, high agreement*). Natural resource dependent communities, including indigenous peoples, have a long history of adapting to highly variable and changing social and ecological conditions. But the salience of indigenous, local, and traditional knowledge will be challenged by climate change impacts. Such forms of knowledge are often neglected in policy and research, and their mutual recognition and integration with scientific knowledge will increase the effectiveness of adaptation. [9.4, 12.3, 15.2, 22.4, 24.4, 24.6, 25.8, Table 15-1]

Global adaptation cost estimates are substantially greater than current adaptation funding and investment, particularly in developing countries, suggesting a funding gap and a growing adaptation deficit (*medium confidence*). The most recent global adaptation cost estimates suggest a range from 70 to 100 US$ billion per year in developing countries from 2010 to 2050 (*low confidence*). Important omissions and shortcomings in data and methods render these estimates highly preliminary (*high confidence*). [17.4]

C-2. Climate-resilient Pathways and Transformation

Climate-resilient pathways are development trajectories that combine adaptation and mitigation to realize the goal of sustainable development. They can be seen as iterative, continually evolving processes for managing change within complex systems.

Climate-resilient pathways include strategies, choices, and actions that reduce climate change and its impacts. They also include actions to ensure that effective risk management and adaptation can be implemented and sustained (*high confidence*). Delaying actions may reduce options for climate-resilient pathways in the future. See Figure TS.13. Prospects for climate-resilient development pathways are related fundamentally to what the world accomplishes with climate change mitigation. Climate-resilient development pathways will have only marginal effects on poverty reduction, unless structural inequalities are addressed and needs for equity among poor and non-poor people are met (*medium confidence*). [1.1, 2.5, 13.4, 20.2-4, 20.6, Figure 1-5]

[INSERT FIGURE TS.13 HERE

Figure TS.13: Multiple stressors and climate-resilient pathways. The literature assessed in this report shows that climate change is just one of the many stressors that influence resilience. Climate-related risks interact with other biophysical stressors (such as biodiversity loss, soil erosion, and water contamination) and with social stressors (such as inequalities, poverty, gender discrimination, and lack of institutions). Rapid advances in knowledge about climate change and its risks along with experience and other factors provide policy relevant information for decision-making that can lead to climate-resilient development pathways. The decisions that societies make within this opportunity space can increase resilience and lower risks. Such decisions and choices are core elements of an iterative risk management process. [Figure 1-5]]

Greater rates and magnitude of climate change increase the likelihood of exceeding adaptation limits that emerge from the interaction among climate change and biophysical and socioeconomic constraints (*high confidence*). See Box TS.8. Adaptation and greenhouse gas mitigation are complementary risk management strategies, but residual loss and damage will occur from climate change despite adaptive and mitigative action. Opportunities to take advantage of positive synergies between adaptation and mitigation may decrease with time, particularly if limits to adaptation are exceeded. In some parts of the world, current failures to address emerging impacts are already eroding the basis for sustainable development. [1.1, 11.8, 16.2-7, 17.2, 20.2-4, 20.5-6, 25.10, 26.5, 26.9, Boxes 16-1, 16-3, and 16-4]

Transformations in political, economic, and technological systems resulting from changes in paradigms and goals can facilitate adaptation and mitigation and promote sustainable development (*high confidence*). Transformational adaptation is an important consideration for decisions involving long life- or lead-times, and it can be a response to adaptation limits. It includes adaptation at greater scale or magnitude, introduction of new technologies or practices, formation of new structures or systems of governance, or shifts in the location of activities. Societal debates over risks from forced and reactive transformations as opposed to deliberate transitions to sustainability may place new and increased demands on governance structures to reconcile conflicting goals and visions for the future. [1.1, 2.1, 2.5, 8.4, 14.1, 14.3, 16.2-7, 17.3, 20.5, 22.4, 25.4, 25.10, Figure 1-5, Boxes 16-1 and 16-4]

Examples of co-benefits, synergies, and tradeoffs among adaptation, mitigation, and sustainable development

Significant co-benefits, synergies, and tradeoffs exist between mitigation and adaptation and between alternative adaptation responses; interactions occur both within and across regions (*very high confidence*). Illustrative examples include the following.

- Increasing efforts to mitigate and adapt to climate change imply an increasing complexity of interactions, particularly at the intersections among water, energy, land use, and biodiversity, but tools to understand and manage these interactions remain limited (*very high confidence*). See Box TS.9. Widespread transformation of terrestrial ecosystems in order to mitigate climate change, such as carbon sequestration through planting fast-growing tree species into ecosystems where they did not previously occur, or the conversion of previously uncultivated or non-degraded land to bioenergy plantations, will lead to negative impacts on ecosystems and biodiversity (*high confidence*). [3.7, 4.2-4, 22.6, 24.6, 25.7, 25.9, 27.3, Boxes 25-10 and CC-WE]
- Climate policies such as increasing energy supply from renewable resources, encouraging bioenergy crop cultivation, or facilitating payments under REDD+ will affect some rural areas both positively (e.g., increasing employment opportunities) and negatively (e.g., land use changes, increasing scarcity of natural capital) (*medium confidence*). These secondary impacts, and trade-offs between mitigation and adaptation in rural areas, have implications for governance, including benefits of promoting participation of rural stakeholders. Mitigation policies with social co-benefits expected in their design, such as CDM and REDD+, have had limited or no effect in terms of poverty alleviation and sustainable development (*medium confidence*). Mitigation efforts focused on land acquisition for biofuel production show preliminary negative impacts for the poor in many low and middle-income countries, and particularly for indigenous people and (women) smallholders. [9.3, 13.3, 22.6]
- Mangrove, sea grass, and salt marsh ecosystems offer important carbon storage and sequestration opportunities (*limited evidence*, *medium agreement*), in addition to ecosystem services such as protection against coastal erosion and storm damage and maintenance of habitats for fisheries species. For ocean-related mitigation and adaptation in the context of anthropogenic ocean warming and acidification, international frameworks offer opportunities to solve problems collectively, for example managing fisheries across national borders and responding to extreme events. [5.4, 25.6, 30.6-7]

- Geoengineering approaches involving manipulation of the ocean to ameliorate climate change (such as nutrient fertilization, binding of CO_2 by enhanced alkalinity, or direct CO_2 injection into the deep ocean) have very large environmental and associated socioeconomic consequences (*high confidence*). Alternative methods focusing on solar radiation management (SRM) leave ocean acidification unabated as they cannot mitigate rising atmospheric CO_2 emissions. [6.4]
- Some agricultural practices can reduce emissions and also increase resilience of crops to temperature and rainfall variability (*high confidence*). [23.8, Table 25-7]
- Many solutions for reducing energy and water consumption in urban areas with co-benefits for climate change adaptation (e.g., greening cities and recycling water) are already being implemented (*high confidence*). Transport systems promoting active transport and reduced motorized-vehicle use can improve air quality and increase physical activity (*medium confidence*). [11.9, 23.8, 24.4, 26.3, 26.8, Boxes 25-2 and 25-9]
- Improved energy efficiency and a shift to cleaner energy sources can reduce local emissions of health-damaging climate-altering air pollutants (*very high confidence*). [11.9, 23.8]
- In Africa, experience in implementing integrated adaptation–mitigation responses that leverage developmental benefits encompasses some participation of farmers and local communities in carbon offset systems and increased use of agroforestry and farmer-assisted tree regeneration (*high confidence*). [22.4, 22.6]
- In Asia, development of sustainable cities with fewer fossil-fuel-driven vehicles and with more trees and greenery would have a number of co-benefits, including improved public health (*high confidence*). [24.4-7]
- In Australasia, transboundary effects from climate change impacts and responses outside Australasia have the potential to outweigh some of the direct impacts within the region, particularly economic impacts on trade-intensive sectors such as agriculture (*medium confidence*) and tourism (*limited evidence, high agreement*), but they remain among the least-explored issues. [25.7, 25.9, Box 25-10]
- In North America, policies addressing local concerns (e.g., air pollution, housing for the poor, declines in agricultural production) can be adapted at low or no cost to fulfill adaptation, mitigation, and sustainability goals (*medium confidence*). [26.9]
- In Central and South America, biomass-based renewable energy can impact land use change and deforestation, and could be affected by climate change (*medium confidence*). The expansion of sugarcane, soy, and oil palm may have some effect on land use, leading to deforestation in parts of the Amazon and Central America, among other subregions, and to loss of employment in some countries. [27.3]
- For small islands, energy supply and use, tourism infrastructure and activities, and coastal wetlands offer opportunities for adaptation-mitigation synergies (*medium confidence*). [29.6-8]

Table TS.8 provides further specific examples of interactions among adaptation, mitigation, and sustainable development to complement the assessment findings above.

[INSERT TABLE TS.8 HERE
Table TS.8: Illustrative examples of intra-regional interactions among adaptation, mitigation, and sustainable development.]

_____ START BOX TS.8 HERE _____

Box TS.8. Adaptation Limits and Transformation

Adaptation can expand the capacity of natural and human systems to cope with a changing climate. Risk-based decision-making can be used to assess potential limits to adaptation. Such limits to adaptation may be signaled by the inability to prevent intolerable risks to an actor's objectives and/or to the needs of an ecosystem. Limits to adaptation are context-specific and closely linked to cultural norms and societal values. Judgments of what constitutes an intolerable risk may differ among actors, but understandings of limits to adaptation can be informed by historical experiences, or by anticipation of impacts, vulnerability, and adaptation associated with different scenarios of climate change. The greater the magnitude of climate change, the greater the likelihood that adaptation will encounter limits. [16.2-4, 20.5, 20.6, 22.4, 25.4, 25.10, Box 16-2]

Limits to adaptation may be influenced by the subjective values of societal actors, which can affect both the perceived need for adaptation and the perceived appropriateness of specific policies and measures. While limits imply that intolerable risks and the increased potential for losses and damages can no longer be avoided, the dynamics of social and ecological systems mean that there are both “soft” and “hard” limits to adaptation. For “soft” limits, there are opportunities in the future to alter limits and reduce risks, for example through the emergence of new technologies or changes in laws, institutions, or values. In contrast, “hard” limits are those where there are no reasonable prospects for avoiding intolerable risks. Recent studies on tipping points, key vulnerabilities, and planetary boundaries provide some insights on the behavior of complex systems. [16.2-7, 25.10]

In cases where the limits to adaptation have been surpassed, losses and damage may increase and the objectives of some actors may no longer be achievable. There may be a need for transformational adaptation to change fundamental attributes of a system in response to actual or expected impacts of climate change. It may involve adaptations at a greater scale or intensity than previously experienced, adaptations that are new to a region or system, or adaptations that transform places or lead to a shift in the location of activities. [16.2-4, 20.3, 20.5, 22.4, 25.10, Boxes 25-1 and 25-9]

The existence of limits to adaptation suggests transformational change may be a requirement for sustainable development in a changing climate; i.e., not only for adapting to the impacts of climate change, but for altering the systems and structures, economic and social relations, and beliefs and behaviors that contribute to climate change and social vulnerability. However, just as there are ethical implications associated with some adaptation options, there are also legitimate concerns about the equity and ethical dimensions of transformation. Societal debates over risks from forced and reactive transformations as opposed to deliberate transitions to sustainability may place new and increased demands on governance structures at multiple levels to reconcile conflicting goals and visions for the future. [1.1, 16.2-7, 20.5, 25.10]

_____ START BOX TS.9 HERE _____

Box TS.9. The Water-Energy-Food Nexus

Water, energy, and food/feed/fiber are linked through numerous interactive pathways affected by a changing climate (Box TS.9 Figure 1). [Box CC-WE] The depth and intensity of those linkages vary enormously among countries, regions, and production systems. Many energy sources require significant amounts of water and produce a large quantity of waste water that requires energy for treatment. [3.7, 7.3, 10.2-3, 22.3, 25.7, Box CC-WE] Food production, refrigeration, transport, and processing also require both energy and water. A major link between food and energy as related to climate change is the competition of bioenergy and food production for land and water, and the sensitivity of precipitation, temperature, and crop yields to climate change (*robust evidence, high agreement*). [7.3, Boxes 25-10 and CC-WE]

Most energy production methods require significant amounts of water, either directly (e.g., crop-based energy sources and hydropower) or indirectly (e.g., cooling for thermal energy sources or other operations) (*robust evidence, high agreement*). [10.2-3, 25.7, Box CC-WE] Water is required for mining, processing, and residue disposal of fossil fuels or their byproducts. [25.7] Water for energy currently ranges from a few percent in most developing countries to more than 50% of freshwater withdrawals in some developed countries, depending on the country. [Box CC-WE] Future water requirements will depend on electric demand growth, the portfolio of generation technologies, and water management options. Future water availability for energy production will change due to climate change (*robust evidence, high agreement*). [3.4-5]

Energy is also required to supply and treat water. Water may require significant amounts of energy for lifting (especially as aquifers continue to be depleted), transport, and distribution and for its treatment either to use it or to depollute it. Wastewater and even excess rainfall in cities requires energy to be treated or disposed. Some non-conventional water sources (wastewater or seawater) are often highly energy intensive. [Table 25-7, Box 25-2] Energy intensities per m^3 of water vary by about a factor of 10 among different sources, e.g., locally produced potable water from ground/surface water sources vs. desalinated seawater. [Boxes 25-2 and CC-WE] Groundwater is generally more energy intensive than surface water. [Box CC-WE]

Linkages among water, energy, food/feed/fiber, and climate are strongly related to land use and management, such as afforestation, which can affect water as well as other ecosystem services, climate, and water cycles (*robust* *evidence*, *high agreement*). [4.4, Box 25-10] Land degradation often reduces efficiency of water and energy use (e.g., resulting in higher fertilizer demand and surface runoff), and many of these interactions can compromise food security. [3.7, 4.4] On the other hand, afforestation activities to sequester carbon have important co-benefits of reducing soil erosion and providing additional (even if only temporary) habitat, but may reduce renewable water resources. [Box 25-10]

Consideration of the interlinkages of energy, food/feed/fiber, water, land use, and climate change has implications for security of supplies of energy, food, and water; adaptation and mitigation pathways; air pollution reduction; and health and economic impacts. This nexus is increasingly recognized as critical to effective climate-resilient-pathway decision-making (*medium evidence*, *high agreement*), although tools to support local- and regional-scale assessments and decision-support remain very limited.

_____ END BOX TS.9 HERE _____

Table TS.1.

REGION	Snow & Ice, Rivers & Lakes, Floods & Drought	Terrestrial Ecosystems	Coastal Erosion & Marine Ecosystems	Food Production & Livelihoods
Africa	Retreat of tropical highland glaciers in East Africa (H,C) Lake surface warming and water column stratification increases in the Great Lakes and Lake Kariba (H,C) Increased soil moisture drought in the Sahel since 1970, partially wetter conditions since 1990 (M,C) [22.2.2-3, 22.3.2, Tables 18-5, 18-6, and 22-3]	Tree density decreases in Sahel & semi-arid Morocco, beyond changes due to land use (M,C) Range shifts of several southern plants & animals, beyond changes due to land use (M,C) [22.3.2, Tables 18-7 and 22-3]		
Europe	Retreat of Alpine, Scandinavian, and Icelandic glaciers (H,C) Increase in rock slope failures in Western Alps (M,C) [18.3.1, 23.3.1, Table 18-5; WGI AR5 4.3.3]	Earlier greening, leaf emergence, & fruiting in temperate & boreal trees (H,C) Increased colonization of alien plant species in Europe, beyond a baseline of some invasion (M,C) Earlier arrival of migratory birds in Europe since 1970 (M,C) Increasing burnt forest areas during recent decades in Portugal and Greece, beyond some increase due to land use (H,C) [4.3.2-3, Tables 18-7 and 23-6]	Northward distributional shifts of zooplankton, fishes, seabirds, & benthic invertebrates in Northeast Atlantic (H,C) Northward and depth shift in distribution of many fish species across European seas (M,C) Plankton phenology changes in Northeast Atlantic (M,C) Spread of warm water species into the Mediterranean, beyond changes due to invasive species and human impacts (M,C) [6.3.1, 23.6.4-5, 30.5.1, 30.5.3, Tables 6-2 and 18-8, Boxes 6-1 and CC-MB]	Impacts on livelihoods of Sámi people in northern Europe, beyond effects of economic and sociopolitical changes (M,C) Stagnation of wheat yields in some countries in recent decades, despite improved technology (M,c) Positive yield impacts for some crops mainly in northern Europe, beyond increase due to improved technology (M,c) Spread of bluetongue virus in sheep, and of ticks across parts of Europe (M,c) [23.4.1, 23.4.2, Table 18-9, Figure 7-2]
Asia	Permafrost degradation in Siberia, Central Asia, & Tibetan Plateau (H,C) Shrinking mountain glaciers across Asia (M,C) Increased flow in many rivers due to shrinking glaciers in the Himalayas & Central Asia (H,C) Earlier timing of maximum spring flood in Russian rivers (M,C) Reduced soil moisture in North Central and Northeast China (1950-2006) (M,C) Surface water degradation in parts of Asia beyond changes due to land use (M,c) [24.4.1-2, 28.2.1, Tables 18-5 and 18-6, Boxes 3-1 and 3-2; WGI AR5 4.3.2-3, 10.5.3]	Changes in plant phenology & growth in many parts of Asia (earlier greening), particularly in the north & east (M,C) Distribution shifts of many plant & animal species upwards in elevation or polewards, particularly in the north of Asia (M,C) Advance of shrubs into the Siberian tundra (H,C) [4.3.2-3, 24.4.2, 28.2.3, Table 18-7, Figure 4-4]	Decline in coral reefs & large seaweeds in tropical Asian waters & coastal waters of western Japan, beyond decline due to human impacts (H,C) Northward range extension of coral reefs and predatory fish in Sea of Japan (M,C) [24.4.3, 30.5.1, Table 18-8]	Negative impacts on aggregate wheat yields in South Asia, against a baseline of increase due to improved technology (M,c) [7.2.1, Table 18-9, Figure 7-2]
Australasia	Significant decline in late-season snow depth at 3 of 4 alpine sites in Australia (1957-2002) (M,C) Substantial reduction in ice and glacier ice volume in New Zealand (M,C) Reduced inflow in river systems in southwestern Australia (since the mid-1970s) (H,C) [25.5.1, Tables 18-5, 18-6, and 25-1; WGI AR5 4.3.3]	Changes in genetics, growth, distribution, & phenology of many species, in particular birds, butterflies, & plants in Australia, beyond fluctuations due to variable local climates, land use, pollution, & invasive species (H,C) Expansion of monsoon rainforest at expense of savannah and grasslands in northern Australia (M,C) [Tables 18-7 and 25-3]	Southward shifts in the distribution of marine species near Australia, beyond changes due to short-term environmental fluctuations, fishing, and pollution (M,C) Increased coral bleaching in Great Barrier Reef and Western Australian Reefs, beyond effects from pollution & physical disturbance (H,C) Changed coral disease patterns at Great Barrier Reef, beyond effects from pollution (M,C) [6.3.1, 25.6.2, Tables 18-8 and 25-3]	Advanced timing of wine-grape maturation in recent decades, beyond advance due to improved management (M,C) [Tables 18-9 and 25-3]

REGION	Snow & Ice, Rivers & Lakes, Floods & Drought	Terrestrial Ecosystems	Coastal Erosion & Marine Ecosystems	Food Production & Livelihoods
North America	Shrinkage of glaciers across western and northern North America (H,C) Decreasing amount of water in spring snowpack in western North America (1960-2002) (H,C) Shift to earlier peak flow in snow dominated rivers in western North America (H,C) [Tables 18-5 and 18-6; WGI AR5 2.6.2, 4.3.3]	Phenology changes & species distribution shifts upward in elevation & northward across multiple taxa (M,C) Increased wildfire frequency in subarctic conifer forests and tundra (M,C) Increase in wildfire activity, fire frequency & duration, & burnt area in boreal forest of North America, beyond changes due to land use & fire management (M,c) [26.4.1, 28.2.3, Table 18-7, Box 26-2]	Northward distributional shifts of Northwest Atlantic fish species (H,C) Changes in musselbeds along the west coast of US (H,C) Changed migration and survival of salmon in northeast Pacific (H,C) Increased coastal erosion in Alaska and Canada (M,C) [18.3.1, 18.3.3, 30.5.1, Tables 6-2 and 18-8]	Impacts on livelihoods of indigenous groups in the Canadian Arctic, beyond effects of economic and sociopolitical changes (M,C) [18.4.6, Tables 18-4 and 18-9, 28.2.4]
Central & South America	Shrinkage of Andean glaciers (H,C) Changes in extreme flows in Amazon River (M,C) Changing discharge patterns in rivers in the Western Andes (M,c) Increased streamflow in sub-basins of the La Plata River, beyond increase due to land use change (H,C) [27.3.1, Tables 18-5, 18-6, and 27-3; WGI AR5 4.3.3]		Increased coral bleaching in western Caribbean, beyond effects from pollution & physical disturbance (H,C) [27.3.3, Table 18-8]	More vulnerable livelihood trajectories for indigenous Aymara farmers in Bolivia due to water shortage, beyond effects of increasing social and economic stress (M,C) Increase in agricultural yields and expansion of agricultural areas in southeastern South America, beyond increase due to improved technology (M,C) [13.1.4, 27.3.4, Table 18-9]
Polar Regions	Decreasing Arctic sea ice cover in summer (H,C) Reduction in ice volume in Arctic glaciers (H,C) Decreasing snow cover extent across the Arctic (M,C) Widespread permafrost degradation, especially in the southern Arctic (H,C) Ice mass loss along coastal Antarctica (M,C) Increased winter minimum river flow in most sectors of the Arctic (M,C) Increased lake water temperatures 1985–2009 and prolonged ice-free seasons (M,C) Disappearance of thermokarst lakes due to permafrost degradation in the low Arctic. New lakes created in areas of formerly frozen peat (H,C) [28.2.1, 28.2.3, Tables 18-5 and 18-6; WGI AR5 4.2.2-3, 4.3.3, 4.4, 4.6, 10.5.2-3]	Increased shrub cover in tundra in North America & Eurasia (H,C). Advance of Arctic tree-line in latitude & altitude (M,C). Changed breeding area & population size of subarctic birds, due to snowbed reduction &/or tundra shrub encroachment (M,C) Loss of snow-bed ecosystems & tussock tundra (H,C). Impacts on tundra animals from increased ice layers in snow pack, following rain-on-snow events (M,C) Increased plant species ranges in the West Antarctic Peninsula & nearby islands over the past 50 years (H,C) [28.2.3, Table 18-7]	Increased coastal erosion across Arctic (M,C) Negative effects on non-migratory Arctic species (H,C) Decreased reproductive success in Arctic seabirds (M,C) Decline in Southern Ocean seals & seabirds (M,C) Reduced thickness of foraminiferal shells in southern oceans (M,C) Reduced krill density in Scotia Sea (M,C) [6.3.2, 18.3.1, 18.3.3, 24.4.3, 28.2.2, 28.2.4, 28.3.4, Table 18-8]	Impact on livelihoods of Arctic indigenous peoples, beyond effects of economic and sociopolitical changes (M,C) Increased shipping traffic across the Bering Strait (M,C) [18.4.6, 28.2.4, 28.2.6, Tables 18-4 and 18-9, Figure 28-4]
Small Islands		Tropical bird population changes in Mauritius (M,C) Decline of an endemic plant in Hawai'i (M,C) [29.3.2, Table 18-7]	Increased coral bleaching near many tropical small islands, beyond effects of degradation due to fishing and pollution (H,C) [29.3.1, Table 18-8]	

Table TS.2.

Early warning systems for heat
EXPOSURE AND VULNERABILITY : Factors affecting exposure and vulnerability include age, pre-existing health status, level of outdoor activity, socioeconomic factors including poverty and social isolation, access to and use of cooling, physiological and behavioral adaptation of the population, urban heat island effects, and urban infrastructure. [8.2.3-4, 11.3.3-4, 11.4.1, 11.7, 13.2.1, 19.3.2, 23.5.1, 25.3, 25.8.1, SREX Table SPM.1]
CLIMATE INFORMATION AT THE GLOBAL SCALE: **Observed:** *Very likely* decrease in the number of cold days and nights and increase in the number of warm days and nights, on the global scale between 1951 and 2010. [WGI AR5 2.6.1] *Medium confidence* that the length and frequency of warm spells, including heat waves, has increased globally since 1950. [WGI AR5 2.6.1] **Projected:** *Virtually certain* that, in most places, there will be more hot and fewer cold temperature extremes as global mean temperatures increase, for events defined as extremes on both daily and seasonal timescales. [WGI AR5 12.4.3]
CLIMATE INFORMATION AT THE REGIONAL SCALE: **Observed:** *Likely* that heat wave frequency has increased since 1950 in large parts of Europe, Asia, and Australia. [WGI AR5 2.6.1] *Medium confidence* in overall increase in heat waves and warm spells in North America since 1960. Insufficient evidence for assessment or spatially varying trends in heat waves or warm spells for South America and most of Africa. [SREX Table 3-2; WGI AR5 2.6.1] **Projected:** *Likely* that, by the end of the 21st century under RCP8.5 in most land regions, a current 20-year high temperature event will at least double its frequency and in many regions occur every two years or annually, while a current 20-year low temperature event will become exceedingly rare. [WGI AR5 12.4.3] *Very likely* more frequent and/or longer heat waves or warm spells over most land areas. [WGI AR5 12.4.3]
DESCRIPTION: Heat-health early warning systems are instruments to prevent negative health impacts during heat waves. Weather forecasts are used to predict situations associated with increased mortality or morbidity. Components of effective heatwave and health warning systems include identifying weather situations that adversely affect human health, monitoring weather forecasts, communicating heatwave and prevention responses, targeting notifications to vulnerable populations, and evaluating and revising the system to increase effectiveness in a changing climate. Warning systems for heat waves have been planned and implemented broadly, for example in Europe, the United States, Asia, and Australia. [11.7.3, 24.4.6, 25.8.1, 26.6, Box 25-6]
BROADER CONTEXT: •Heat health warning systems can be combined with other elements of a health protection plan, for example building capacity to support communities most at risk, supporting and funding health services, and distributing public health information. •In Africa, Asia, and elsewhere, early warning systems have been used to provide warning of and reduce a variety of risks, related to famine and food insecurity; flooding and other weather-related hazards; exposure to air pollution from fire; and vector-borne and food-borne disease outbreaks. [7.5.1, 11.7,15.4.2, 22.4.5, 24.4.6, 25.8.1, 26.6.3, Box 25-6]
Mangrove restoration to reduce flood risks and protect shorelines from storm surge
EXPOSURE AND VULNERABILITY : Loss of mangroves increases exposure of coastlines to storm surge, coastal erosion, saline intrusion, and tropical cyclones. Exposed infrastructure, livelihoods, and people are vulnerable to associated damage. Areas with development in the coastal zone, such as on small islands, can be particularly vulnerable. [5.4.3, 5.5.6, 29.7.2, Box CC-EA]
CLIMATE INFORMATION AT THE GLOBAL SCALE: **Observed:** *Likely* increase in the magnitude of extreme high sea level events since 1970, mostly explained by rising mean sea level. [WGI AR5 3.7.5] *Low confidence* in long-term (centennial) changes in tropical cyclone activity, after accounting for past changes in observing capabilities. [WGI AR5 2.6.3] **Projected:** *Very likely* significant increase in the occurrence of future sea level extremes by 2050 and 2100. [WGI AR5 13.7.2] In the 21st century, *likely* that the global frequency of tropical cyclones will either decrease or remain essentially unchanged. *Likely* increase in both global mean tropical cyclone maximum wind speed and rainfall rates. [WGI AR5 14.6]
CLIMATE INFORMATION AT THE REGIONAL SCALE: **Observed:** Change in sea level relative to the land (relative sea level) can be significantly different from the global mean sea level change because of changes in the distribution of water in the ocean and vertical movement of the land. [WGI AR5 3.7.3] **Projected:** *Low confidence* in region-specific projections of storminess and associated storm surges. [WGI AR5 13.7.2] Projections of regional changes in sea level reach values of up to 30% above the global mean value in the Southern Ocean and around North America, and between 10% to 20% above the global mean value in equatorial regions. [WGI AR5 13.6.5] *More likely than not* substantial increase in the frequency of the most intense tropical cyclones in the western North Pacific and North Atlantic. [WGI AR5 14.6]
DESCRIPTION: Mangrove restoration and rehabilitation has occurred in a number of locations (e.g., Vietnam, Djibouti, and Brazil) to reduce coastal flooding risks and protect shorelines from storm surge. Restored mangroves have been shown to attenuate wave height and thus reduce wave damage and erosion. They protect aquaculture industry from storm damage and reduce saltwater intrusion. [2.4.3, 5.5.4, 8.3.3, 22.4.5, 27.3.3]

BROADER CONTEXT:
•Considered a low-regrets option benefiting sustainable development, livelihood improvement, and human well-being through improvements for food security and reduced risks from flooding, saline intrusion, wave damage, and erosion. Restoration and rehabilitation of mangroves, as well as of wetlands or deltas, is ecosystem-based adaptation that enhances ecosystem services.
•Synergies with mitigation given that mangrove forests represent large stores of carbon.
•Well-integrated ecosystem-based adaptation can be more cost effective and sustainable than non-integrated physical engineering approaches.
[5.5, 8.4.2, 14.3.1, 24.6, 29.3.1, 29.7.2, 30.6.1-2, Table 5-4, Box CC-EA]

Community-based adaptation and traditional practices in small island contexts

EXPOSURE AND VULNERABILITY:
With small land area, often low elevation coasts, and concentration of human communities and infrastructure in coastal zones, small islands are particularly vulnerable to rising sea levels and impacts such as inundation, saltwater intrusion, and shoreline change. [29.3.1, 29.3.3, 29.6.1-2, 29.7.2]

CLIMATE INFORMATION AT THE GLOBAL SCALE:
Observed: *Likely* increase in the magnitude of extreme high sea level events since 1970, mostly explained by rising mean sea level. [WGI AR5 3.7.5]
Low confidence in long-term (centennial) changes in tropical cyclone activity, after accounting for past changes in observing capabilities. [WGI AR5 2.6.3]
Since 1950 the number of heavy precipitation events over land has *likely* increased in more regions than it has decreased. [WGI AR5 2.6.2]
Projected: *Very likely* significant increase in the occurrence of future sea level extremes by 2050 and 2100. [WGI AR5 13.7.2]
In the 21st century, *likely* that the global frequency of tropical cyclones will either decrease or remain essentially unchanged. *Likely* increase in both global mean tropical cyclone maximum wind speed and rainfall rates. [WGI AR5 14.6]
Globally, for short-duration precipitation events, *likely* shift to more intense individual storms and fewer weak storms. [WGI AR5 12.4.5]

CLIMATE INFORMATION AT THE REGIONAL SCALE:
Observed: Change in sea level relative to the land (relative sea level) can be significantly different from the global mean sea level change because of changes in the distribution of water in the ocean and vertical movement of the land. [WGI AR5 3.7.3]
Projected: *Low confidence* in region-specific projections of storminess and associated storm surges. [WGI AR5 13.7.2]
Projections of regional changes in sea level reach values of up to 30% above the global mean value in the Southern Ocean and around North America, and between 10% to 20% above the global mean value in equatorial regions. [WGI AR5 13.6.5]
More likely than not substantial increase in the frequency of the most intense tropical cyclones in the western North Pacific and North Atlantic. [WGI AR5 14.6]

DESCRIPTION:
Traditional technologies and skills can be relevant for climate adaptation in small island contexts. In the Solomon Islands, relevant traditional practices include elevating concrete floors to keep them dry during heavy precipitation events and building low aerodynamic houses with palm leaves as roofing to avoid hazards from flying debris during cyclones, supported by perceptions that traditional construction methods are more resilient to extreme weather. In Fiji after cyclone Ami in 2003, mutual support and risk sharing formed a central pillar for community-based adaptation, with unaffected households fishing to support those with damaged homes. Participatory consultations across stakeholders and sectors within communities and capacity building taking into account traditional practices can be vital to the success of adaptation initiatives in island communities, such as in Fiji or Samoa. [29.6.2]

BROADER CONTEXT:
• Perceptions of self-efficacy and adaptive capacity in addressing climate stress can be important in determining resilience and identifying useful solutions.
•The relevance of community-based adaptation principles to island communities, as a facilitating factor in adaptation planning and implementation, has been highlighted, for example with focus on empowerment and learning-by-doing, while addressing local priorities and building on local knowledge and capacity. Community-based adaptation can include measures that cut across sectors and technological, social, and institutional processes, recognizing that technology by itself is only one component of successful adaptation.
[5.5.4, 29.6.2]

Adaptive approaches to flood defense in Europe

EXPOSURE AND VULNERABILITY :
Increased exposure of persons and property in flood risk areas has contributed to increased damages from flood events over recent decades. [5.4.3-4, 5.5.5, 23.3.1, Box 5-1]

CLIMATE INFORMATION AT THE GLOBAL SCALE:
Observed: *Likely* increase in the magnitude of extreme high sea level events since 1970, mostly explained by rising mean sea level. [WGI AR5 3.7.5]
Since 1950 the number of heavy precipitation events over land has *likely* increased in more regions than it has decreased. [WGI AR5 2.6.2]
Projected: *Very likely* that the time-mean rate of global mean sea level rise during the 21st century will exceed the rate observed during 1971-2010 for all RCP scenarios. [WGI AR5 13.5.1]
Globally, for short-duration precipitation events, *likely* shift to more intense individual storms and fewer weak storms. [WGI AR5 12.4.5]

CLIMATE INFORMATION AT THE REGIONAL SCALE:
Observed: *Likely* increase in the frequency or intensity of heavy precipitation in Europe, with some seasonal and/or regional variations. [WGI AR5 2.6.2] Increase in heavy precipitation in winter since the 1950s in some areas of northern Europe (*medium confidence*). Increase in heavy

precipitation since the 1950s in some parts of west-central Europe and European Russia, especially in winter (*medium confidence*). [SREX Table 3-2]
Increasing mean sea level with regional variations, except in the Baltic sea where the relative sea level is decreasing due to vertical crustal motion. [5.3.2, 23.2.2]
Projected: Over most of the mid-latitude land-masses, extreme precipitation events will *very likely* be more intense and more frequent in a warmer world. [WGI AR5 12.4.5]
Overall precipitation increase in northern Europe and decrease in southern Europe (*medium confidence*). [23.2.2]
Increased extreme precipitation in northern Europe during all seasons, particularly winter, and in central Europe except in summer (*high confidence*). [23.2.2; SREX Table 3.3]

DESCRIPTION:
Several governments have made ambitious efforts to address flood risk and sea level rise over the coming century. In the Netherlands, government recommendations include "soft" measures preserving land from development to accommodate increased river inundation, maintaining coastal protection through beach nourishment, and ensuring necessary political-administrative, legal, and financial resources. Through a multi-stage process, the British government has also developed extensive adaptation plans to adjust and improve flood defenses in order to protect London from future storm surges and river flooding. Pathways have been analyzed for different adaptation options and decisions, depending on eventual sea level rise, with ongoing monitoring of the drivers of risk informing decisions. [5.5.4, 23.7.1, Box 5-1]

BROADER CONTEXT:
•The Dutch plan is considered a paradigm shift, addressing coastal protection by "working with nature" and providing "room for river."
•The British plan incorporates iterative, adaptive decisions depending on the eventual sea level rise with numerous and diverse measures possible over the next 50-100 years to reduce risk to acceptable levels.
• In cities in Europe and elsewhere, the importance of strong political leadership or government champions in driving successful adaptation action has been noted.
[5.5.3-4, 8.4.3, 23.7.1-2, 23.7.4, Boxes 5-1 and 26-3]

Index-based insurance for agriculture in Africa

EXPOSURE AND VULNERABILITY:
Susceptibility to food insecurity and depletion of farmers' productive assets following crop failure. Low prevalence of insurance due to absent or poorly developed insurance markets or to amount of premium payments. The most marginalized and resource-poor especially may have limited ability to afford insurance premiums. [10.7.6, 13.3.2, Box 22-1]

CLIMATE INFORMATION AT THE GLOBAL SCALE:
Observed: *Very likely* decrease in the number of cold days and nights and increase in the number of warm days and nights, on the global scale between 1951 and 2010. [WGI AR5 2.6.1]
Medium confidence that the length and frequency of warm spells, including heat waves, has increased globally since 1950. [WGI AR5 2.6.1]
Since 1950 the number of heavy precipitation events over land has *likely* increased in more regions than it has decreased. [WGI AR5 2.6.2]
Low confidence in a global-scale observed trend in drought or dryness (lack of rainfall). [WGI AR5 2.6.2]
Projected: *Virtually certain* that, in most places, there will be more hot and fewer cold temperature extremes as global mean temperatures increase, for events defined as extremes on both daily and seasonal timescales. [WGI AR5 12.4.3]
Regional to global-scale projected decreases in soil moisture and increased risk of agricultural drought are *likely* in presently dry regions, and are projected with *medium confidence* by the end of this century under the RCP8.5 scenario. [WGI AR5 12.4.5]
Globally, for short-duration precipitation events, *likely* shift to more intense individual storms and fewer weak storms. [WGI AR5 12.4.5]

CLIMATE INFORMATION AT THE REGIONAL SCALE:
Observed: *Medium confidence* in increase in frequency of warm days and decrease in frequency of cold days and nights in southern Africa. [SREX Table 3-2]
Medium confidence in increase in frequency of warm nights in northern and southern Africa. [SREX Table 3-2]
Projected: *Likely* surface drying in southern Africa by the end of this century under RCP8.5 (*high confidence*). [WGI AR5 12.4.5]
Likely increase in warm days and nights and decrease in cold days and nights in all regions of Africa (*high confidence*). Increase in warm days largest in summer and fall (*medium confidence*). [Table SREX 3-3]
Likely more frequent and/or longer heat waves and warm spells in Africa (*high confidence*). [Table SREX 3-3]

DESCRIPTION:
A recently introduced mechanism that has been piloted in a number of rural locations, including in Malawi, Sudan, and Ethiopia, as well as in India. When physical conditions reach a particular predetermined threshold where significant losses are expected to occur--weather conditions such as excessively high or low cumulative rainfall or temperature peaks--the insurance pays out. [9.4.2, 13.3.2, 15.4.4, Box 22-1]

BROADER CONTEXT:
•Index-based weather insurance is considered well-suited to the agricultural sector in developing countries.
•The mechanism allows risk to be shared across communities, with costs spread over time, while overcoming obstacles to traditional agricultural and disaster insurance markets. It can be integrated with other strategies such as micro-finance and social protection programs.
•Risk-based premiums can help encourage adaptive responses and foster risk awareness and risk reduction by providing financial incentives to policyholders to reduce their risk profile.
•Challenges can be associated with limited availability of accurate weather data and difficulties in establishing which weather conditions cause losses. Basis risk (i.e., farmers suffer losses but no payout is triggered based on weather data) can promote distrust. There can also be difficulty in scaling up pilot schemes.

•Insurance for work programs can enable cash-poor farmers to work for insurance premiums by engaging in community-identified disaster risk reduction projects.
[10.7.4-6, 13.3.2, 15.4.4, Table 10-7, Box 22-1, Box 25-7]

Relocation of agricultural industries in Australia

EXPOSURE AND VULNERABILITY :
Crops sensitive to changing patterns of temperature, rainfall, and water availability. [7.3, 7.5.2]

CLIMATE INFORMATION AT THE GLOBAL SCALE:
Observed: *Very likely* decrease in the number of cold days and nights and increase in the number of warm days and nights, on the global scale between 1951 and 2010. [WGI AR5 2.6.1]
Medium confidence that the length and frequency of warm spells, including heat waves, has increased globally since 1950. [WGI AR5 2.6.1]
Medium confidence in precipitation change over global land areas since 1950. [WGI AR5 2.5.1]
Since 1950 the number of heavy precipitation events over land has *likely* increased in more regions than it has decreased. [WGI AR5 2.6.2]
Low confidence in a global-scale observed trend in drought or dryness (lack of rainfall). [WGI AR5 2.6.2]
Projected: *Virtually certain* that, in most places, there will be more hot and fewer cold temperature extremes as global mean temperatures increase, for events defined as extremes on both daily and seasonal timescales. [WGI AR5 12.4.3]
Virtually certain increase in global precipitation as global mean surface temperature increases. [WGI AR5 12.4.1]
Regional to global-scale projected decreases in soil moisture and increased risk of agricultural drought are *likely* in presently dry regions, and are projected with *medium confidence* by the end of this century under the RCP8.5 scenario. [WGI AR5 12.4.5]
Globally, for short-duration precipitation events, *likely* shift to more intense individual storms and fewer weak storms. [WGI AR5 12.4.5]

CLIMATE INFORMATION AT THE REGIONAL SCALE:
Observed: Cool extremes rarer and hot extremes more frequent and intense over Australia and New Zealand, since 1950 (*high confidence*). [Table 25-1]
Likely increase in heat wave frequency since 1950 in large parts of Australia. [WGI AR5 2.6.1]
Late autumn/winter decreases in precipitation in Southwestern Australia since the 1970s and Southeastern Australia since the mid-1990s, and annual increases in precipitation in Northwestern Australia since the 1950s (*very high confidence*). [Table 25-1]
Mixed or insignificant trends in annual daily precipitation extremes, but a tendency to significant increase in annual intensity of heavy precipitation in recent decades for sub-daily events in Australia (*high confidence*). [Table 25-1]
Projected: Hot days and nights more frequent and cold days and nights less frequent during the 21st century in Australia and New Zealand (*high confidence*). [Table 25-1]
Annual decline in precipitation over southwestern Australia (*high confidence*) and elsewhere in southern Australia (*medium confidence*). Reductions strongest in the winter half-year (*high confidence*). [Table 25-1]
Increase in most regions in the intensity of rare daily rainfall extremes and in sub-daily extremes (*medium confidence*) in Australia and New Zealand. [Table 25-1]
Drought occurrence to increase in Southern Australia (*medium confidence*). [Table 25-1]
Snow depth and snow area to decline in Australia (*very high confidence*). [Table 25-1]
Freshwater resources projected to decline in far southeastern and far southwest Australia (*high confidence*). [25.5.2]

DESCRIPTION:
Industries and individual farmers are relocating parts of their operations, for example for rice, wine, or peanuts in Australia, or are changing land use in situ in response to recent climate change or expectations of future change. For example, there has been some switching from grazing to cropping in South Australia. Adaptive movement of crops has also occurred elsewhere. [7.5.1, 25.7.2, Table 9-7, Box 25-5]

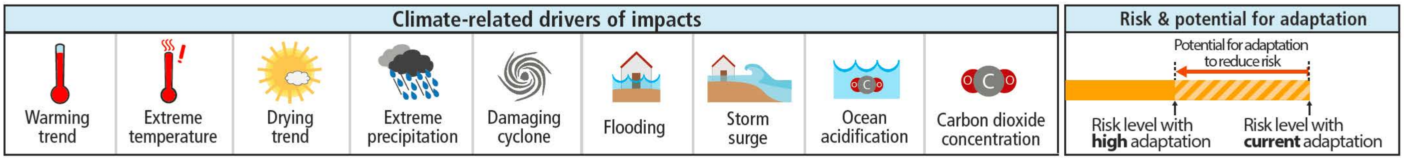
BROADER CONTEXT:
•Considered transformational adaptation in response to impacts of climate change.
•Positive or negative implications for the wider communities in origin and destination regions.
[25.7.2, Box 25-5]

Table TS.3.

#	Hazard	Key vulnerabilities		Key risks	Emergent risks
i	Sea level rise and coastal flooding including storm surges. [5.4.3, 8.1.4, 8.2.3-4, 13.1.4, 13.2.2, 24.4-5, 26.7-8, 29.3, 30.3.1, Figure 26-2, Boxes 25-1 and 25-7; WGI AR5 3.7, 13.5, Table 13-5]	High exposure of people, economic activity, and infrastructure in low-lying coastal zones and Small Island Developing States (SIDS). Urban population unprotected due to substandard housing and inadequate insurance. Marginalized rural population with multidimensional poverty and limited alternative livelihoods. Inadequate local governmental attention to disaster risk reduction.	exposure social vulnerability institutional vulnerability	Death, injury, and disruption to livelihoods, food supplies, and drinking water. Loss of common-pool resources, sense of place, and identity, especially among indigenous populations in rural coastal zones.	Interaction of rapid urbanization, sea level rise, increasing economic activity, disappearance of natural resources, and limits of insurance; burden of risk management shifted from the state to those at risk leading to greater inequality.
ii	Warming, drought, and precipitation variability. [7.4-5, 11.3, 11.6.1, 13.2, 19.3.2, 19.4.1, 22.3.4, 24.4.4, 26.8, 27.3.4; WGI AR5 11.3.2]	Poorer populations in urban and rural settings are susceptible to resulting food insecurity; includes particularly farmers who are net food buyers and people in low-income, agriculturally dependent economies that are net food importers. Limited ability to cope among the elderly and female-headed households.	social vulnerability institutional vulnerability	Risk of harm and loss of life due to reversal of progress in reducing malnutrition.	Interactions of climate changes, population growth, reduced productivity, biofuel crop cultivation, and food prices with persistent inequality, and ongoing food insecurity for the poor increases malnutrition, giving rise to larger burden of disease. Exhaustion of social networks reduces coping capacity.
iii	Extreme precipitation and inland flooding. [3.2.7, 3.4.8, 8.2.3-4, 13.2.1, 25.10, 26.3, 26.7-8, 27.3.5, Box 25-8; WGI AR5 11.3.2]	Large numbers of people exposed in urban areas to flood events, particularly in low-income informal settlements. Overwhelmed, aging, poorly maintained, and inadequate urban drainage infrastructure and limited ability to cope and adapt due to marginalization, high poverty, and culturally imposed gender roles. Inadequate governmental attention to disaster risk reduction.	exposure social vulnerability institutional vulnerability	Death, injury, and disruption of human security, especially among children, elderly, and disabled.	Interaction of increasing frequency of intense precipitation, urbanization, and limits of insurance; burden of risk management shifted from the state to those at risk leading to greater inequality, eroded assets due to infrastructure damage, abandonment of urban districts, and the creation of high risk/high poverty spatial traps.
iv	Drought. [3.2.7, 3.4.8, 3.5.1, 8.2.3-4, 9.3.3, 9.3.5, 13.2.1, 19.3.2, 24.4; WGI AR5 12.4.1, 12.4.5]	Urban populations with inadequate water services. Existing water shortages (and irregular supplies), and constraints on increasing supplies. Lack of capacity and resilience in water management regimes including rural-urban linkages.	social vulnerability institutional vulnerability	Insufficient water supply for people and industry yielding severe harm and economic impacts.	Interaction of urbanization, infrastructure insufficiency, groundwater depletion.
		Poorly endowed farmers in drylands or pastoralists with insufficient access to drinking and irrigation water. Limited ability to compensate for losses in water-dependent farming and pastoral systems, and conflict over natural resources.	exposure	Loss of agricultural productivity and/or income of rural people. Destruction of livelihoods particularly for those depending on water-intensive agriculture. Risk of food insecurity.	Interactions across human vulnerabilities: deteriorating livelihoods, poverty traps, heightened food insecurity, decreased land productivity, rural outmigration, and increase in new urban poor in low- and middle-income countries. Potential tipping point in rain-

		Lack of capacity and resilience in water management regimes, inappropriate land policy, and misperception and undermining of pastoral livelihoods.	social vulnerability institutional vulnerability		fed farming system and/or pastoralism.
v	Novel hazards yielding systemic risks. [8.1.4, 8.2.4, 10.2-3, 12.6, 23.9, 25.10, 26.7-8; WGI AR5 11.3.2]	Populations and infrastructure exposed and lacking historical experience with these hazards. Overly hazard-specific management planning and infrastructure design, and/or low forecasting capability.	exposure institutional vulnerability	Failure of systems coupled to electric power system, e.g., drainage systems reliant on electric pumps or emergency services reliant on telecommunications. Collapse of health and emergency services in extreme events.	Interactions due to dependence on coupled systems lead to magnification of impacts of extreme events. Reduced social cohesion due to loss of faith in management institutions undermines preparation and capacity for response.
vi	Rising ocean temperature, stratification, ocean acidification, and loss of Arctic sea ice. [5.4.2, 6.3.1-2, 7.4.2, 9.3.5, 22.3.2, 25.6, 27.3.3, 28.2-3, 29.3.1, 30.5-6, Boxes CC-OA and CC-CR; WGI AR5 11.3.3]	High susceptibility of warm-water coral reefs and respective ecosystem services for coastal communities; high susceptibility of polar systems, e.g., to invasive species. Susceptibility of coastal and SIDS fishing communities depending on these ecosystem services; and of Arctic settlements and culture.	environmental vulnerability economic vulnerability environmental vulnerability	Loss of coral cover, Arctic species, and associated ecosystems with reduction of biodiversity and potential losses of important ecosystem services. Risk of loss of endemic species, mixing of ecosystem types, and increased dominance of invasive organisms.	Interactions of stressors such as acidification and warming on calcareous organisms enhancing risk.
vii	Rising land temperatures, and changes in precipitation patterns and in frequency and intensity of extreme heat. [4.3.4, 19.3.2, 22.4.5, 27.3, Table 23-2, Box CC-WE; WGI AR5 11.3.2]	Susceptibility of human systems, agro-ecosystems and natural ecosystems to (i) loss of regulation of pests and diseases, fire, landslide, erosion, flooding, avalanche, water quality, and local climate (ii) loss of provision of food, livestock, fiber, bioenergy (iii) loss of recreation, tourism, aesthetic and heritage values, and biodiversity.	economic vulnerability environmental vulnerability	Reduction of biodiversity and potential losses of important ecosystem services. Risk of loss of endemic species, mixing of ecosystem types, and increased dominance of invasive organisms.	Interaction of social-ecological systems with loss of ecosystem services upon which they depend.
viii	Increasing frequency and intensity of extreme heat, including urban heat island effect. [8.2.3, 11.3, 11.4.1, 13.2, 23.5.1, 24.4.6, 25.8.1, 26.6, 26.8, Box CC-HS; WGI AR5 11.3.2]	Increasing urban population of the elderly, the very young, expectant mothers, and people with chronic health problems in settlements subject to higher temperatures. Inability of local organizations that provide health, emergency, and social services to adapt to new risk levels for vulnerable groups.	social vulnerability institutional vulnerability	Increased mortality and morbidity during periods of extreme heat.	Interaction of demographic shifts with changes in regional temperature extremes, local heat island, and air pollution. Overloading of health and emergency services. Mortality, morbidity, and productivity loss among manual workers in hot climates.

Table TS.4.



Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
Global Risks					
Reduction in terrestrial carbon sink: Carbon stored in terrestrial ecosystems is vulnerable to loss back into the atmosphere, resulting from increased fire frequency due to climate change and the sensitivity of ecosystem respiration to rising temperatures (*medium confidence*)	• Adaptation options include managing land use (including deforestation), fire and other disturbances, and non-climatic stressors.		4.2-3	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low / Medium / Very high
Boreal tipping point: Arctic ecosystems are vulnerable to abrupt change related to the thawing of permafrost, spread of shrubs in tundra, and increase in pests and fires in boreal forests (*medium confidence*)	• There are few adaptation options in the Arctic.		4.3, Box 4-4	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low / Medium / Very high
Amazon tipping point: Moist Amazon forests could change abruptly to less-carbon-dense, drought- and fire-adapted ecosystems (*medium confidence*)	• Policy and market measures can reduce deforestation and fire.		4.3, Box 4-3	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low / Medium / Very high
Increased risk of species extinction: A large fraction of the species assessed is vulnerable to extinction due to climate change, often in interaction with other threats. Species with an intrinsically low dispersal rate, especially when occupying flat landscapes where the projected climate velocity is high, and species in isolated habitats such as mountaintops, islands, or small protected areas are especially at risk. Cascading effects through organism interactions, especially those vulnerable to phenological changes, amplify risk (*high confidence*)	• Adaptation options include reduction of habitat modification and fragmentation, pollution, over-exploitation, and invasive species; protected area expansion; assisted dispersal; and *ex situ* conservation.		4.3-4	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low / Medium / Very high
Reduced growth and survival of commercially valuable shellfish and other calcifiers (e.g., reef building corals, calcareous red algae) due to ocean acidification (*high confidence*)	• Evidence for differential resistance and evolutionary adaptation of some species exists but is *likely* to be limited at higher CO_2 concentrations and temperatures. • Adaptation options include exploiting more resilient species or protecting habitats with low natural CO_2 levels, as well as reducing other stresses, mainly pollution, and limiting pressures from tourism and fishing.		5.3, 6.1, 6.3-4, 30.3, Box CC-OA	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low / Medium / Very high
Marine biodiversity loss with high rate of climate change (*medium confidence*)	• Adaptation options are limited to reducing other stresses, mainly pollution, and limiting pressures from coastal human activities such as tourism and fishing.		6.3-4, Table 30-4, Box CC-MB	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low / Medium / Very high
Negative impacts on average crop yields and increases in yield variability due to climate change (*high confidence*)	• With or without adaptation, negative impacts on average yields become *likely* from the 2030s with median yield impacts of 0 to -2% per decade projected for the rest of the century, and after 2050 the risk of more severe impacts increases.		7.2-5, Box 7-1	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low / Medium / Very high

Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
Global Risks					
Urban risks associated with water supply systems (*high confidence*)	• Adaptation options include changes to network infrastructure as well as demand-side management to ensure sufficient water supplies and quality, increased capacities to manage reduced freshwater availability, and flood risk reduction.		8.2-3	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Urban risks associated with energy systems (*high confidence*)	• Most urban centers are energy intensive, with energy-related climate policies focused only on mitigation measures. A few cities have adaptation initiatives underway for critical energy systems. There is potential for non-adapted, centralized energy systems to magnify impacts, leading to national and transboundary consequences from localized extreme events.		8.2, 8.4	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Urban risks associated with housing (*high confidence*)	• Poor quality, inappropriately located housing is often most vulnerable to extreme events. Adaptation options include enforcement of building regulations and upgrading. Some city studies show the potential to adapt housing and promote mitigation, adaptation, and development goals simultaneously. Rapidly growing cities, or those rebuilding after a disaster, especially have opportunities to increase resilience, but this is rarely realized. Without adaptation, risks of economic losses from extreme events are substantial in cities with high-value infrastructure and housing assets, with broader economic effects possible.		8.3	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Displacement associated with extreme events (*high confidence*)	• Adaptation to extreme events is well understood, but poorly implemented even under present climate conditions. Displacement and involuntary migration are often temporary. With increasing climate risks, displacement is more likely to involve permanent migration.		12.4	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Voilent conflict arising from deterioration in resource-dependent livelihoods such as agriculture and pastoralism (*high confidence*)	Adaptation options: • Buffering rural incomes against climate shocks, for example through livelihood diversification, income transfers, and social safety net provision • Early warning mechanisms to promote effective risk reduction • Well-established strategies for managing violent conflict that are effective but require significant resources, investment, and political will		12.5	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Declining work productivity, morbidity (e.g., dehydration, heat stroke, and heat exhaustion), and mortality from exposure to heat waves. Particularly at risk are agricultural and construction workers as well as children, homeless people, the elderly, and women who have to walk long hours to collect water (*high confidence*)	• Adaptation options are limited for people who are dependent on agriculture and cannot afford agricultural machinery. • Adaptation options are limited in the construction sector where many poor people work under insecure arrangements. • Adaptation limits may be exceeded in certain areas in a +4°C world.		13.2, Box 13-1	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Reduced access to water for rural and urban poor people due to water scarcity and increasing competition for water (*high confidence*)	• Adaptation through reducing water use is not an option for the many people already lacking adequate access to safe water. Access to water is subject to various forms of discrimination, for instance due to gender and location. Poor and marginalized water users are unable to compete with water extraction by industries, large-scale agriculture, and other powerful users.		13.2, Box 13-1	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	
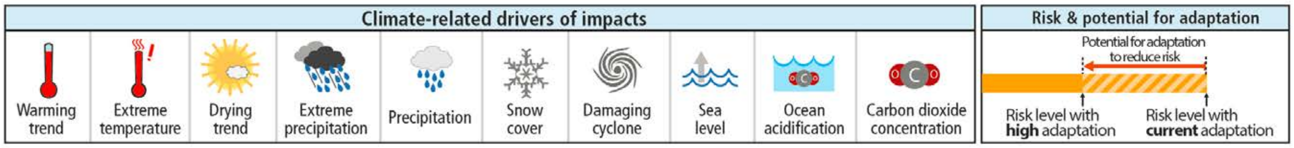
Table TS.5.



Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
Africa					
Compounded stress on water resources facing significant strain from overexploitation and degradation at present and increased demand in the future (*high confidence*)	• Reducing non-climate stressors on water resources • Strengthening institutional capacities for demand management, groundwater assessment, integrated water-wastewater planning, and integrated land and water governance		22.3-4	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high
Reduced crop productivity with strong adverse effects on regional, national, and household food security, also given increased pest and disease damage and flood impacts on food system infrastructure (*high confidence*)	• Technological adaptation responses (e.g., stress-tolerant crop varieties, irrigation) • Enhancing smallholder access to credit and other critical production resources and diversifying livelihoods • Strengthening institutions at local to regional levels to support agriculture and gender-oriented policy support		22.3-4	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high
Changes in the incidence and geographic range of vector- and water-borne diseases due to changes in the mean and variability of temperature and precipitation, particularly along the edges of their distribution (*medium confidence*)	• Achieving development goals, particularly improved access to safe water and improved sanitation, and enhancement of public health functions such as surveillance • Vulnerability mapping and early warning systems • Coordination across sectors		22.3	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high

Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
Europe					
Increased economic losses and people affected by flooding in river basins and coasts, driven by increasing urbanization and by increasing sea levels and peak river discharges (*high confidence*)	Adaptation can prevent most of the projected damages (*high confidence*). • Significant experience in hard flood-protection technologies • High costs for increasing flood protection • Potential barriers to implementation: demand for land in Europe and environmental and landscape concerns		23.2-3, 23.7	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high
Increased water restrictions. Significant reduction in water availability from river abstraction and from groundwater resources, combined with increased water demand (e.g., for irrigation, energy and industry, domestic use) and with reduced water drainage and runoff as a result of increased evaporative demand (*high confidence*)	• Proven adaptation potential from adoption of more water-efficient technologies and of water-saving strategies (e.g., for irrigation, crop species, land cover, industries, domestic use) • Further adaptation possible through solar desalinization with mitigation co-benefits		23.4, 23.7	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high
Increased economic losses and people affected by extreme heat events: impacts on health and well-being, labor productivity, crop production, and air quality (*medium confidence*)	• Implementation of warning systems • Adaptation of dwellings and workplaces and of transport and energy infratructure • Reductions in emissions to improve air quality • Improved wildfire management		23.3, 23.5-7	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high

Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
Asia					
Increased flooding leading to widespread damage to infrastructure and settlements in Asia (*medium confidence*)	• Exposure reduction via effective land-use planning, selective relocation, and structural measures • Reduction in the vulnerability of lifeline infrastructure and services (e.g., water, energy, waste management, food, biomass, mobility, local ecosystems, telecommunications) • Assistance to vulnerable sectors and households		24.4	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high

Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
Asia (continued)					
Increased risk of heat-related mortality (*high confidence*)	• Heat health warning systems • Urban planning to reduce heat islands • Improvement of the built environment		24.4	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low / Medium / Very high
Increased risk of drought-related water and food shortage causing malnutrition (*high confidence*)	• Disaster preparedness including early-warning systems and local response strategies		24.4	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low / Medium / Very high

Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
Australasia					
Significant change in community composition and structure of coral reefs and montane ecosystems and risk of loss of some native species in Australia (*high confidence*)	• Ability to adapt naturally is limited especially for species that occupy narrow climatic ranges and fragmented habitats. • Main human adaptation options are to reduce other pressures (e.g., pollution, runoff, fishing, tourism, introduced predators and pests) and improve early warning systems. Assisted colonization and other direct interventions such as shading of reefs have been proposed but remain untested at scale.		25.6, 25.10	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low / Medium / Very high
Increased frequency and intensity of flood damage to infrastructure and settlements in Australia and New Zealand (*high confidence*)	• Significant adaptation deficit in some regions to current flood risk. • Effective adaptation includes land-use controls and relocation as well as protection and accommodation of increased risk to ensure flexibility.		Table 25-1, Boxes 25-8 and 25-9	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low / Medium / Very high
Increasing risks to coastal infrastructure and low-lying ecosystems in Australia and New Zealand, with widespread damage towards the upper end of projected sea-level-rise ranges (*high confidence*)	• Adaptation deficit in some locations to current coastal erosion and flood risk. Successive building and protection cycles constrain flexible responses. • Effective adaptation includes land-use controls and ultimately relocation as well as protection and accommodation.		25.6, 25.10, Box 25-1	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low / Medium / Very high

Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
North America					
Loss of ecosystem integrity, property loss, human morbidity, and mortality due to wildfires (*high confidence*)	• Some ecosystems are more fire-adapted than others. Forest managers and municipal planners are increasingly incorporating fire protection measures (e.g., prescribed burning, introduction of resilient vegetation). Institutional capacity to support ecosystem adaptation is limited. • Adaptation of human settlements is constrained by rapid private property development in high-risk areas and by limited household-level adaptive capacity.		26.4, 26.8, Box 26-2	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low / Medium / Very high
Heat-related human mortality (*high confidence*)	• Residential air conditioning (A/C) can effectively reduce risk. However, availability and usage of A/C is often limited among the most vulnerable individuals and is subject to complete loss during power failures. Vulnerable populations include athletes and outdoor workers for whom A/C is not available. • Community- and household-scale adaptations have the potential to reduce exposure to heat extremes via family support, heat warnings, cooling centers, greening, and high albedo surfaces.		26.6, 26.8	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low / Medium / Very high
Property and infrastructure damage; supply chain, ecosystem, and social system disruption; public health impacts; and water quality impairment from river and coastal urban floods (*high confidence*)	• Implementing management of urban drainage is expensive and disruptive to urban areas. • Low-regret strategies with co-benefits include less impervious surfaces leading to more groundwater recharge, green infrastructure, and rooftop gardens. • Sea-level rise increases water elevations in coastal outfalls, which impedes drainage. In many cases, older rainfall design standards are being used that need to be updated to reflect current climate conditions.		26.2-4, 26.8	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low / Medium / Very high

Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
Central and South America					
Water availability in semi-arid and glacier-melt-dependent regions and flooding in urban areas due to extreme precipitation (*high confidence*)	• Water-supply deficit replacement and improved land use • Urban flood management (including infrastructure), early warning systems, better weather and runoff forecasts, and infectious disease control		27.3	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high
Decreased food production and food quality (*medium confidence*)	• Development of new crop varieties more adapted to changes in CO_2, temperature, and drought • Offsetting of human and animal health impacts of reduced food quality • Offsetting of economic impacts of land use change		27.3	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high

Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
Small Islands					
Loss of livelihoods, coastal settlements, and infrastructure in small islands (*high confidence*)	• Significant potential exists for adaptation in islands, but additional external resources and technologies will enhance response. • Efficacy of traditional community coping strategies is expected to be substantially reduced in the future.		Figure 29-4	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high
The interaction of rising global mean sea level in the 21st century with high-water-level events will threaten low-lying coastal areas in small islands (*high confidence*)	• High ratio of coastal area to land mass will make adaptation a significant financial and resource challenge for islands. • Adaptation options include maintenance and restoration of coastal landforms and ecosystems, improved management of soils and freshwater resources, and appropriate building codes and settlement patterns.		29.4, Table 29-1; WGI AR5 13.5, Table 13.5	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high

Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
The Ocean					
Distributional shift in fish and invertebrate species, and decrease in fishery catch potential at low latitudes, e.g., in equatorial upwelling and coastal boundary systems and sub-tropical gyres (*high confidence*)	• Evolutionary adaptation potential of fish and invertebrate species to warming is limited as indicated by their ongoing latitudinal shifts. • Human adaptation options: Large-scale translocation of industrial fishing activities following the regional decreases (low latitude) vs. possibly transient increases (high latitude) in catch potential; Flexible management that can react to variability and change; Improvement of fish resilience to thermal stress by reducing other stressors such as pollution and eutrophication; Expansion of aquaculture.		6.3, Box CC-MB	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high
Reduced biodiversity, fisheries abundance, and coastal protection by coral reefs due to heat-induced mass coral bleaching and mortality increases, e.g., in coastal boundary systems and sub-tropical gyres (*high confidence*)	• Evidence of rapid evolution by corals is very limited. Some corals may migrate to higher latitudes, but entire reef systems are not expected to be able to track the high rates of temperature shifts. • Human adaptation options are limited to reducing other stresses, mainly by enhancing water quality, and limiting pressures from tourism and fishing. These options will delay human impacts of climate change by a few decades, but their efficacy will be severely reduced as thermal stress increases.		5.4, 6.4, 30.3, 30.5, Box CC-CR	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high
Coastal inundation and habitat loss due to sea-level rise and intensified precipitation events, e.g., in coastal boundary systems and sub-tropical gyres (*medium* to *high confidence*)	• Human adaptation options are limited to reducing other stresses, mainly by reducing pollution and limiting pressures from tourism, fishing, and aquaculture. • Loss of ecosystems such as sea grass, mangroves, and coral reefs can be reduced by reducing deforestation and increasing reforestation of river catchments and coastal areas to retain sediments and nutrients.		5.5, 30.5-6, Box CC-CR	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high

Key

Symbols

- Increasing trend or signal
- Decreasing trend or signal
- Both increasing and decreasing trends or signals
- Inconsistent trend or signal or insufficient evidence
- No or only slight change

Level of confidence in findings

- Low confidence
- Medium confidence
- High confidence

Region/ region code	Trends in daytime temperature extremes (frequency of hot and cool days)		Trends in heavy precipitation (rain, snow)		Trends in dryness and drought	
	Observed	Projected	Observed	Projected	Observed	Projected
West North America WNA, 3	*Very likely* large increases in hot days (large decreases in cool days)[a]	*Very likely* increase in hot days (decrease in cool days)[b]	Spatially varying trends. General increase, decrease in some areas[a]	Increase in 20-year return value of annual maximum daily precipitation and other metrics over northern part of the region (Canada)[b] Less confidence in Southern part of the region, due to inconsistent signal in these other metrics[b]	No or overall slight decrease in dryness[a]	Inconsistent signal[b]
Central North America CNA, 4	Spatially varying trends: small increases in hot days in the north, decreases in the south[a]	*Very likely* increase in hot days (decrease in cool days)[b]	*Very likely* increase since 1950[a]	Increase in 20-year return value of annual maximum daily precipitation[b] Inconsistent signal in other heavy precipitation days metrics[b]	*Likely* decrease[a, c]	Increase in consecutive dry days and soil moisture in southern part of Central North America[b] Inconsistent signal in the rest of the region[b]
East North America ENA, 5	Spatially varying trends. Overall increases in hot days (decreases in cool days), opposite or insignificant signal in a few areas[a]	*Very likely* increase in hot days (decrease in cool days)[b]	*Very likely* increase since 1950[a]	Increase in 20-year return value of annual maximum daily precipitation. Additional metrics support an increase in heavy precipitation over northern part of the region[b] No signal or inconsistent signal in these other metrics in the southern part of the region[b]	Slight decrease in dryness since 1950[a]	Inconsistent signal in consecutive dry days, some consistent decrease in soil moisture[b]
Alaska/ Northwest Canada ALA, 1	*Very likely* large increases in warm days (decreases in cold days)[a]	*Very likely* increase in hot days (decrease in cool days)[b]	Slight tendency for increase[a] No significant trend in southern Alaska[a]	*Likely* increase in heavy precipitation[b]	Inconsistent trends[a] Increases in dryness in part of the region[a]	Inconsistent signal[b]
East Canada, Greenland, Iceland CGI, 2	*Likely* increases in hot days (decreases in cool days) in some areas, decrease in hot days (increase in cool days) in others[a]	*Very likely* increase in warm days (decrease in cold days)[b]	Increase in a few areas[a]	*Likely* increase in heavy precipitation[b]	Insufficient evidence[a]	Inconsistent signal[b]
Northern Europe NEU, 11	Increase in hot days (decrease in cool days), but generally not significant at the local scale[a]	*Very likely* increase in hot days (decrease in cool days) [but smaller trends than in central and southern Europe][b]	Increase in winter in some areas, but often insignificant or inconsistent trends at subregional scale, particularly in summer[a]	*Likely* increase in 20-year return value of annual maximum daily precipitation. *Very likely* increases in heavy preciptation intensity and frequency in winter in the north[b]	Spatially varying trends. Overall only slight or no increase in dryness, slight decrease in dryness in part of the region[a]	No major changes in dryness[b]

Region/ region code	Trends in daytime temperature extremes (frequency of hot and cool days)		Trends in heavy precipitation (rain, snow)		Trends in dryness and drought	
	Observed	Projected	Observed	Projected	Observed	Projected
Central Europe CEU, 12	*Likely* overall increase in hot days (decrease in cool days) since 1950 in most regions. *Very likely* increase in hot days (likely decrease in cool days) in west Central Europe[a] Lower confidence in trends in east Central Europe (due to lack of literature, partial lack of access to observations, overall weaker signals, and change point in trends)[a]	*Very likely* increase in hot days (decrease in cool days)[b]	Increase in part of the region, in particular central Western Europe and European Russia, especially in winter[a] Insignificant or inconsistent trends elsewhere, in particular in summer[a]	*Likely* increase in 20-year return value of annual maximum daily precipitation. Additional metrics support an increase in heavy precipitation in large part of the region over winter[b] Less confidence in summer, due to inconsistent evidence[b]	Spatially varying trends. Increase in dryness in part of the region but some regional variation in dryness trends and dependence of trends on studies considered (index, time period)[a]	Increase in dryness in central Europe and increase in short-term droughts[b]
Southern Europe and Mediterra-nean MED, 13	*Likely* increase in hot days (decrease in cool days) in most of the region. Some regional and temporal variations in the significance of the trends. Likely strongest and most significant trends in Iberian peninsula and southern France[a] Smaller or less significant trends in southeastern Europe and Italy due to change point in trends, strongest increase in hot days since 1976[a]	*Very likely* increase in hot days (decrease in cool days)[b]	Inconsistent trends across the region and across studies[a]	Inconsistent changes and/or regional variations[b]	Overall increase in dryness, *likely* increase in the Mediterranean[a,c]	Increase in dryness. Consistent increase in area of drought[b,d]
West Africa WAF, 15	Significant increase in temperature of hottest day and coolest day in some parts[a] Insufficient evidence in other parts[a]	*Likely* increase in hot days (decrease in cool days)[b]	Rainfall intensity increased[a]	Slight or no change in heavy precipitation indicators in most areas[b] Low model agreement in northern areas[b]	*Likely* increase but 1970s Sahel drought dominates the trend; greater inter- annual variation in recent years[a,c]	Inconsistent signal[b]
East Africa EAF, 16	Lack of evidence due to lack of literature and spatially non-uniform trends[a] Increases in hot days in Southern tip (decrease in cool days)[a]	*Likely* increase in hot days (decrease in cool days)[b]	Insufficient evidence[a]	*Likely* increase in heavy precipitation[b]	Spatially varying trends in dryness[a]	Decreasing dryness in large areas[b]
Southern Africa SAF, 17	*Likely* increase in hot days (decrease in cool days)[a,c]	*Likely* increase in hot days (decrease in cool days)[b]	Increases in more regions than decreases but spatially varying trends[a]	Lack of agreement in signal for region as a whole[b] Some evidence of increase in heavy precipitation in southeast regions[b]	General increase in dryness[a]	Increase in dryness, except eastern part[b,d] Consistent increase in area of drought[b]
Sahara SAH, 14	Lack of literature[a]	*Likely* increase in hot days (decrease in cool days)[b]	Insufficient evidence[a]	Low agreement[b]	Limited data, spatial variation of the trends[a]	Inconsistent signal of change[b]
Central America and Mexico CAM, 6	Increases in the number of hot days, decreases in the number of cool days[a]	*Likely* increase in hot days (decrease in cool days)[b]	Spatially varying trends. Increase in many areas, decrease in a few others[a]	Inconsistent trends[b]	Varying and inconsistent trends[a]	Increase in dryness in Central America and Mexico, with less confidence in trend in extreme South of region[b]

Region/ region code	Trends in daytime temperature extremes (frequency of hot and cool days)		Trends in heavy precipitation (rain, snow)		Trends in dryness and drought	
	Observed	Projected	Observed	Projected	Observed	Projected
Amazon AMZ, 7	Insufficient evidence to identify trends[a]	Hot days *likely* to increase (cool days *likely* to decrease)[b]	Increases in many areas, decreases in a few[a]	Tendency for increases in heavy precipitation events in some metrics[b]	Decrease in dryness for much of the region. Some opposite trends and inconsistencies[a]	Inconsistent signals[b]
Northeastern Brazil NEB, 8	Increases in the number of hot days[a]	Hot days *likely* to increase (cool days *likely* to decrease)[b]	Increases in many areas, decreases in a few[a]	Slight or no change[b]	Varying and inconsistent trends[a]	Increase in dryness[b]
Southeast-ern South America SSA, 10	Spatially varying trends (increases in some areas decreases in others)[a]	Hot days *likely* to increase (cool days *likely* decrease)[b]	Increases in northern areas[a] Insufficient evidence in southern areas[a]	Increases in northern areas[b] Insufficient evidence in southern areas[b]	Varying and inconsistent trends[a]	Inconsistent signals[b]
West Coast South America WSA, 9	Spatially varying trends (increases in some areas decreases in others)[a]	Hot days *likely* to increase (cool days *likely* decrease)[b]	Increases in many areas, decrease in a few areas[a]	Increases in tropics[b] Low confidence in extratropics[b]	Varying and inconsistent trends[a]	Decrease in consecutive dry days in the tropics, and increase in the extratropics[b] Increase in consecutive dry days and soil moisture in southwest South America[b]
North Asia NAS, 18	*Likely* increase in hot days (decrease cool days)[a]	*Likely* increase in hot days (decrease in cool days)[b]	Increase in some regions, but spatial variation[a]	*Likely* increase in heavy precipitation for most regions[b]	Spatially varying trends[a]	Inconsistent signal of change[b]
Central Asia CAS, 20	*Likely* increase in hot days (decrease cool days)[a]	*Likely* increase in hot days (decrease in cool days)[b]	Spatially varying trends[a]	Inconsistent signal in models[b]	Spatially varying trends[a]	Inconsistent signal of change[b]
East Asia EAS, 22	*Likely* increase in hot days (decrease cool days)[a]	*Likely* increase in hot days (decrease in cool days)[b]	Spatially varying trends[a]	Increase in heavy precipitation across the region[b]	Tendency for increased dryness[a]	Inconsistent signal of change[b]
Southeast Asia SEA, 24	Increase in hot days (decrease cool days) for northern areas[a] Insufficient evidence for Malay Archipelago[a]	*Likely* increase in hot days (decrease in cool days)[b]	Spatially varying trends, partial lack of evidence[a]	Increases in most metrics over most (especially non-continental) regions. One metric shows inconsistent signals of change[b]	Spatially varying trends[a]	Inconsistent signal of change[b]
South Asia SAS, 23	Increase in hot days (decrease cool days)[a]	*Likely* increase in hot days (decrease in cool days)[b]	Mixed signal in India[a]	More frequent and intense heavy precipitation days over parts of S. Asia. Either no change or some consistent increases in other metrics[b]	Inconsistent signal for different studies and indices[a]	Inconsistent signal of change[b]
West Asia WAS, 19	*Very likely* increase in hot days (decrease in cool days *more likely than not*)[a]	*Likely* increase in hot days (decrease in cool days)[b]	Decrease in heavy precipitation events[a]	Inconsistent signal of change[b]	Lack of studies, mixed results[a]	Inconsistent signal of change[b]
Tibetan Plateau TIB, 21	*Likely* increase in hot days (decrease cool days)[a]	*Likely* increase in hot days (decrease in cool days)[b]	Insufficient evidence[a]	Increase in heavy precipitation[b]	Insufficient evidence. Tendency to decreased dryness[a]	Inconsistent signal of change[b]
North Australia NAU, 25	*Likely* increase in hot days (decrease in cool days). Weaker trends in northwest[a]	*Very likely* increase in hot days (decrease in cool days)[b]	Spatially varying trends, which mostly reflect changes in mean rainfall[a]	Increase in most regions in the intensity of extreme (i.e. current 20 year return period) heavy rainfall events[a]	No significant change in drought occurrence over Australia (defined using rainfall anomalies)[a]	Inconsistent signal[b]

Region/ region code	Trends in daytime temperature extremes (frequency of hot and cool days)		Trends in heavy precipitation (rain, snow)		Trends in dryness and drought	
	Observed	Projected	Observed	Projected	Observed	Projected
South Australia/ New Zealand SAU, 26	*Very likely* increase in hot days (decrease in cool days)[a]	*Very likely* increase in hot days (decrease in cool days)[b]	Spatially varying trends in S Australia, which mostly reflect changes in mean rainfall[e] Spatially varying trends in NZ, which mostly reflect changes in mean rainfall[e]	Increase in most regions in the intensity of extreme (i.e. current 20 year return period) heavy rainfall events[e]	No significant change in drought occurrence over Australia (defined using rainfall anomalies)[e] No trend in drought occurrence over New Zealand (defined using a soil water balance model) since 1972[e]	Increase in drought frequency in southern Australia, and in many regions of New Zealand[e]

Table TS.7.

Overlapping Entry Points	Category	Examples	Chapter Reference(s)
Vulnerability reduction through development & planning *Including many low-regrets measures*	Human development	Improved access to education, nutrition, health facilities, energy, safe settlement structures, & social support structures; Reduced gender inequality & marginalization in other forms.	8.3, 9.3, 13.1-3, 14.2-3, 22.4
	Poverty alleviation	Insurance schemes; Social safety nets & social protection; Disaster risk reduction; Improved access to & control of local resources, land tenure, & storage facilities.	8.3, 9.3, 13.1-3, Box 8-4
	Livelihood security	Income, asset, & livelihood diversification; Improved infrastructure; Access to technology & decision-making fora; Enhanced agency; Changed cropping, livestock, & aquaculture practices; Reliance on social networks.	7.5, 13.1-3, 22.3-4, 23.4, 26.5, 27.3, 29.6, Table 24-7
	Disaster risk management	Early warning systems; Hazard & vulnerability mapping; Improved drainage; Flood & cyclone shelters; Building codes; Storm & wastewater management; Transport & road infrastructure improvements.	8.2-4, 11.7, 14.3, 15.3-4, 22.4, 24.4, 25.4, 26.6, 28.4
	Ecosystem management	Maintaining wetlands & urban green spaces; Coastal afforestation; Dam management; Reduction of other stressors on ecosystems & of habitat fragmentation; Maintenance of genetic diversity; Assisted translocation; Manipulation of disturbance regimes; Community-based natural resource management.	4.3-4, 8.3, 22.4, Table 3-3, Boxes 4-2, 4-3, 8-2, 15-1, 25-8, 25-9, & CC-EA
	Spatial or land-use planning	Provisioning of adequate housing, infrastructure, & services; Managing development in flood prone & other high risk areas; Urban upgrading programs; Land zoning laws; Easements; Protected areas.	4.4, 8.1, 8.3-4, 22.4, 23.7-8, 27.3, Box 25-8
Adaptation *Including incremental & transformational adjustments*	Structural/ physical	***Engineered & built-environment options:*** Sea walls & coastal protection structures; Flood levees; Water storage; Improved drainage; Flood & cyclone shelters; Building codes; Storm & wastewater management; Transport & road infrastructure improvements; Floating houses; Power plant & electricity grid adjustments.	3.5-6, 5.5, 8.2-3, 10.2, 11.7, 23.3, 24.4, 25.7, 26.3, 26.8, Boxes 15-1, 25-1, 25-2, & 25-8
		Technological options: New crop & animal varieties; Traditional technologies & methods; Efficient irrigation; Water-saving technologies; Conservation agriculture; Food storage & preservation facilities; Hazard mapping & monitoring; Early warning systems; Building insulation; Mechanical & passive cooling.	7.5, 8.3, 9.4, 10.3, 15.3-4, 22.4, 24.4, 26.3, 26.5, 27.3, 28.2, 28.4, 29.6-7, Table 25-2, Boxes 20-5 & 25-2
		Ecosystem-based options: Ecological restoration; Afforestation & reforestation; Mangrove conservation & replanting; Green infrastructure (e.g., shade trees, green roofs); Controlling overfishing; Fisheries co-management; Assisted migration or managed translocation; Ecological corridors; Ex situ conservation & seed banks; Community-based natural resource management.	4.4, 5.5, 8.3, 9.4, 11.7, 15.3-4, 22.4, 23.6-7, 24.4, 25.6, 26.4, 27.3, 28.2, 29.7, 30.6, Boxes 15-1, 22-2, 25-9, 26-2, & CC-EA
		Services: Social safety nets & social protection; Food banks & distribution of food surplus; Municipal services including water & sanitation; Vaccination programs; Essential public health services; Enhanced emergency medical services.	3.5-6, 8.3, 9.3-4, 11.7, 11.9, 22.4, 29.6, Box 13-2
	Institutional	***Economic options:*** Financial incentives including taxes & subsidies; Insurance; Catastrophe bonds; Payments for ecosystem services; Water tariffs; Microfinance; Disaster contingency funds; Cash transfers.	8.3-4, 9.4, 10.7, 11.7, 13.3, 15.4, 17.5, 22.4, 26.7, 27.6, 29.6, Box 25-7
		Laws & regulations: Land zoning laws; Building standards; Easements; Water regulations & agreements; Laws to support disaster risk reduction; Laws to encourage insurance purchasing; Defined property rights & land tenure security; Protected areas; Fishing quotas; Patent pools & technology transfer.	4.4, 8.3, 9.3, 10.5, 10.7, 15.2, 15.4, 17.5, 22.4, 23.4, 23.7-8, 24.4, 25.4, 26.3, 27.3, Table 25-2, Box CC-CR
		Government policies & programs: National & regional adaptation plans including mainstreaming; Sub-national & local adaptation plans; Urban upgrading programs; Municipal water management programs; Disaster planning & preparedness; Integrated water resource management; Integrated coastal zone management; Ecosystem-based management; Community-based adaptation.	2.2-4, 3.6, 4.4, 5.5, 6.4, 7.5, 8.3, 11.7, 15.2-4, 22.4, 23.7, 25.4, 25.8, 26.8-9, 27.3-4, 29.6, 30.6, Boxes 25-1, 25-2, & 25-9
	Social	***Educational options:*** Awareness raising & integrating into education; Gender equity in education; Extension services; Sharing local & traditional knowledge; Participatory action research & social learning; Knowledge-sharing & learning platforms.	8.3-4, 9.4, 11.7, 12.3, 15.2-4, 22.4, 25.4, 28.4, 29.6, Table 25-2
		Informational options: Hazard & vulnerability mapping; Early warning & response systems; Systematic monitoring & remote sensing; Climate services; Use of indigenous climate observations; Participatory scenario development.	2.4, 5.5, 8.3-4, 9.4, 11.7, 15.2-4, 22.4, 23.5, 24.4, 25.8, 26.6, 26.8, 27.3, 28.2, 28.5, Table 25-2, Box 26-3
		Behavioral options: Household preparation & evacuation planning; Migration; Soil & water conservation; Storm drain clearance; Livelihood diversification; Changed cropping, livestock, & aquaculture practices; Reliance on social networks.	5.5, 7.5, 9.4, 11.7, 12.4, 22.3-4, 23.4, 23.7, 25.7, 26.5, 27.3, 29.6, Table SM24-7, Box 25-5
Transformation	Spheres of change	***Practical:*** Social & technical innovations, behavioral shifts, or institutional & managerial changes that produce substantial shifts in outcomes.	8.3, 20.5, Box 25-5
		Political: Changes in the political, social, cultural, & ecological systems or structures that currently contribute to risk & vulnerability or impede practical transformations.	14.2-3, 20.5, 25.4, Table 14-1
		Personal: Changes in individual & collective assumptions, beliefs, values, & worldviews that influence climate change responses.	14.2-3, 20.5, 25.4, Table 14-1
Mitigation		See WGIII AR5.	

Table TS.8.

Green infrastructure and green roofs
Objectives: Storm water management, adaptation to increasing temperatures, reduced energy use, urban regeneration
Relevant Sectors: Infrastructure, energy use, water management
Overview: Benefits of green infrastructure and roofs can include reduction of storm water runoff and the urban heat island effect, improved energy performance of buildings, reduced noise and air pollution, health improvements, better amenity value, increased property values, improved biodiversity, and inward investment. Trade-offs can result between higher urban density to improve energy efficiency and open space for green infrastructure. [8.3.3, 11.7.4, 23.7.4, 24.6, Tables 11-3 and 25-5]
EXAMPLES WITH INTERACTIONS: **London:** The Green Grid for East London seeks to create interlinked and multi-purpose open spaces to support regeneration of the area. It aims to connect people and places, to absorb and store water, to cool the vicinity, and to provide a diverse mosaic of habitats for wildlife. [8.3.3] **New York**: In preparation for more intense storms, New York is using green infrastructure to capture rainwater before it can flood the combined sewer system, implementing green roofs, and elevating boilers and other equipment above ground. [8.3.3, 26.3.3, 26.8.4] **Singapore**: Singapore has used several anticipatory plans and projects to enhance green infrastructure, including its Streetscape Greenery Master Plan, constructed wetlands or drains, and community gardens. Under its Skyrise Greenery project, Singapore has provided subsidies and handbooks for rooftop and wall greening initiatives. [8.3.3] **Durban**: Ecosystem-based adaptation is part of Durban's climate change adaptation strategy. The approach seeks a more detailed understanding of the ecology of indigenous ecosystems and ways in which biodiversity and ecosystem services can reduce vulnerability of ecosystems and people. Examples include the Community Reforestation Programme, in which communities produce indigenous seedlings used in the planting and managing of restored forest areas. Development of ecosystem-based adaptation in Durban has demonstrated needs for local knowledge and data and the benefits of enhancing existing protected areas, land-use practices, and local initiatives contributing to jobs, business, and skill development. [8.3.3, Box 8-2]
Water management
Primary Objective: Water resource management given multiple stressors in a changing climate
Relevant Sectors: Water use, energy production and use, biodiversity, carbon sequestration, biofuel production, food production
Overview: Water management in the context of climate change can encompass ecosystem-based approaches (e.g., watershed management or restoration, flood regulation services, and reduction of erosion or siltation), supply-side approaches (e.g., dams, reservoirs, groundwater pumping and recharge, and water capture), and demand-side approaches (e.g., increased use efficiency through water recycling, infrastructure upgrades, water-sensitive design, or more efficient allocation). Water may require significant amounts of energy for lifting, transport, distribution, and treatment. [3.7.2, 26.3, Tables 9-8 and 25-5, Boxes CC-EA and CC-WE]
EXAMPLES WITH INTERACTIONS: **New York**: New York has a well-established program to protect and enhance its water supply through watershed protection. The Watershed Protection Program includes city ownership of land that remains undeveloped and coordination with landowners and communities to balance water-quality protection, local economic development, and improved wastewater treatment. The city government indicates it is the most cost-effective choice for New York given the costs and environmental impacts of a filtration plant. [8.3.3, Box 26-3] **Cape Town:** Facing challenges in ensuring future supplies, Cape Town responded by commissioning water management studies, which identified the need to incorporate climate change, as well as population and economic growth, in planning. During the 2005 drought, local authorities increased water tariffs to promote efficient water usage. Additional measures may include water restrictions, reuse of grey water, consumer education, or technological solutions such as low-flow systems or dual flush toilets. [8.3.3] **Capital cities in Australia:** Many Australian capital cities are reducing reliance on catchment runoff and groundwater—water resources most sensitive to climate change and drought—and are diversifying supplies through desalination plants, water reuse including sewage and storm water recycling, and integrated water cycle management that considers climate change impacts. Demand is being reduced through water conservation and water-sensitive urban design and, during severe shortfalls, through implementation of restrictions. The water augmentation program in Melbourne includes a desalination plant. Trade-offs beyond energy intensiveness have been noted, such as damage to sites significant to aboriginal communities and higher water costs that will disproportionately affect poorer households. [14.6.2, Table 25-7, Box 25-2]
Payment for environmental services and green fiscal policies
Primary Objective: Management incorporating the costs of environmental externalities and the benefits of ecosystem services
Relevant Sectors: Biodiversity, ecosystem services
Overview: Payment for environmental services (PES) is a market-based approach that aims to protect natural areas, and associated livelihoods and environmental services, by developing financial incentives for preservation. Mitigation-focused PES schemes are common, and there is emerging evidence of adaptation-focused PES schemes. Successful PES approaches can be difficult to design for services that are hard to define or quantify. [17.5.2, 27.6.2]
EXAMPLES WITH INTERACTIONS: **Central and South America**: A variety of PES schemes have been implemented in Central and South America. For example, national-level

programs have operated in Costa Rica and Guatemala since 1997 and in Ecuador since 2008. Examples to date have shown that PES can finance conservation, ecosystem restoration and reforestation, better land-use practices, mitigation, and more recently adaptation. Uniform payments for beneficiaries can be inefficient if, for example, recipients that promote greater environmental gains receive only the prevailing payment. [17.5.2, 27.3.2, 27.6.2, Table 27-8]

Brazil: Municipal funding in Brazil tied to ecosystem-management quality is a form of revenue transfer important to funding local adaptation actions. State governments collect a value-added tax redistributed among municipalities, and some states allocate revenues in part based on municipality area set aside for protection. This mechanism has helped improve environmental management and increased creation of protected areas. It benefits relations between protected areas and surrounding inhabitants, as the areas can be perceived as opportunities for revenue generation rather than as obstacles to development. The approach builds on existing institutions and administrative procedures and thus has low transaction costs. [8.4.3, Box 8-4]

Renewable Energy

Primary Objective: Renewable energy production and reduction of emissions

Relevant Sectors: Biodiversity, agriculture, food security

Overview: Renewable energy production can require significant land areas and water resources, creating the potential for both positive and negative interactions between mitigation policies and land management. [4.4.4, 13.3.1, 19.3.2, 19.4.1, Box CC-WE]

EXAMPLES WITH INTERACTIONS:

Central and South America: Renewable resources, especially hydroelectric power and biofuels, account for substantial fractions of energy production in countries such as Brazil. Where bioenergy crops compete for land with food crops, substantial trade-offs can exist. Land-use change to produce bioenergy can affect food crops, biodiversity, and ecosystem services. Lignocellulosic feedstocks, such as sugarcane second-generation technologies, do not compete with food. [19.3.2, 27.3.6, 27.6.1, Table 27-6]

Australia & New Zealand: Mandatory renewable energy targets and incentives to increase carbon storage support increased biofuel production and increased biological carbon sequestration, with impacts on biodiversity depending on implementation. Benefits can include reduced erosion, additional habitat, and enhanced connectivity, with risks or lost opportunities associated with large-scale monocultures especially if replacing more diverse landscapes. Large-scale land-cover changes can affect catchment yields and regional climate in complex ways. New crops such as oil mallees or other eucalypts may provide multiple benefits, especially in marginal areas, displacing fossil fuels or sequestering carbon, generating income for landholders (essential oils, charcoal, bio-char, biofuels), and providing ecosystem services. [Table 25-7, Box 25-10]

Disaster risk reduction and adaptation to climate extremes

Primary Objective: Increasing resilience to extreme weather events in a changing climate

Relevant Sectors: Infrastructure, energy use, spatial planning

Overview: Synergies and tradeoffs among sustainable development, adaptation, and mitigation occur in preparing for and responding to climate extremes and disasters. [13.2-4, 20.3-4]

EXAMPLES WITH INTERACTIONS:

Philippines: The Homeless People's Federation of the Philippines developed responses following disasters, including: community-rooted data gathering (e.g., assessing destruction and victims' immediate needs); trust and contact building; savings support; community-organization registration; and identification of needed interventions (e.g., building-materials loans). Community surveys mapped inhabitants especially at risk in informal settlements, raising risk-awareness among the inhabitants and increasing community engagement in planning risk reduction and early warning systems. [8.3.2, 8.4.2]

London: Within London, built form and other dwelling characteristics can have a stronger influence on indoor temperatures during heat waves than the urban heat island effect, and utilizing shade, thermal mass, ventilation control, and other passive-design features are effective adaptation options. Passive housing designs enhance natural ventilation and improve insulation, while also reducing household emissions. For example, in London the Beddington Zero Energy Development was designed to reduce or eliminate energy demand for heating, cooling, and ventilation for much of the year. [8.3.3, 11.7.4]

United States: In the United States, post-disaster funds for loss reduction are added to funds provided for disaster recovery. They can be used, for instance, to buy out properties that have experienced repetitive flood losses and relocate residents to safer locations, to elevate structures, to assist communities with purchasing property and altering land-use patterns in flood-prone areas, and to undertake other activities designed to lessen the impacts of future disasters. Executive Summary

The evolution of the IPCC assessments of impacts, adaptation, and vulnerability indicates an increasing emphasis on human beings, their role in managing resources and natural systems, and the societal impacts of climate change. The expanded focus on societal impacts and responses is evident in the composition of the IPCC author teams, the literature assessed, and the content of the IPCC assessment reports. Characteristics in the evolution of the Working Group II assessment reports are an increasing attention to: (i) adaptation limits and transformation in social and natural systems; (ii) synergies between multiple variables and factors that affect sustainable development, (iii) risk management, and (iv) institutional, social, cultural, and value-related issues. [1.1, 1.2]

The literature available for assessing climate change impacts, adaptation, and vulnerability more than doubled between 2005 and 2010, allowing for a more robust assessment that supports policy making *(high confidence).* The diversity of the topics and regions covered by the literature has similarly expanded, as has the geographic distribution of authors contributing to the knowledge base for climate change assessments. Authorship of literature from developing countries has increased, although still representing a small fraction of the total. This unequal distribution of literature presents a challenge to the production of a comprehensive and balanced global assessment. [1.1.1, Figure 1-1]

Rapidly advancing climate science provides policy relevant information that creates opportunities for decision making that can lead to climate-resilient development pathways (*robust evidence, medium agreement*). Climate change is just one of many stressors that influence resilience. The decisions that societies make within this opportunity space, also informed by observation, experience, and other factors, affect outcomes in human and natural systems. [1.1.1, 1.1.4, Figure 1-5]

Adaptation has emerged as a central area of climate change research, in country level planning, and in the implementation of climate change strategies *(high confidence)*. The body of literature, including government and private sector reports, shows an increased focus on adaptation opportunities and the interrelations between adaptation, mitigation, and alternative sustainable pathways. The literature shows an emergence of studies on transformative processes that take advantage of synergies between adaptation planning, development strategies, social protection, and disaster risk reduction and management. [1.1.4]

As a core feature and innovation of IPCC assessment, major findings are presented with defined, calibrated language that communicates the strength of scientific understanding, including uncertainties and areas of disagreement. Each finding is supported by a traceable account of the evaluation of evidence and agreement. 1.1.2.2, Box 1-1]

Impacts assessed in this report are based on climate model projections using both the IPCC Special Report on Emission Scenarios (SRES) and the new Representative Concentration Pathway (RCP) scenarios. The RCPs span the range of SRES scenarios for long-lived greenhouse gases, but they have a narrower range in terms of emissions of ozone and aerosol precursors and related pollutants. The SRES scenarios were used in the TAR and AR4. With AR5, the RCP scenarios present both emissions and greenhouse gas concentration pathways, and corresponding Shared Socio-economic Pathways (SSPs) have been developed. The four RCPs describe different levels of mitigation leading to 21st century radiative forcing levels of about 2.6, 4.5, 6.0 and 8.5 W m^{-2}), whereas the SRES scenarios are policy independent. [1.1.3, 1.3.3, 19.6.3.1, Box 21-1, 21.5.4, 24.3.3, see also WGI Chapters 1, 8, 11, 12]

1.1. The Setting

This chapter describes the information basis for the Fifth Assessment Report (AR5) of IPCC Working Group II (WGII) and the rationale for its structure. As the starting point of AR5 WGII, the chapter begins with an analysis of how the literature for the assessment has developed through time and proceeds with an overview of how the framing and content of the WGII reports have changed since the first IPCC report was published in 1990. The future climate scenarios used in AR5 are a marked change from those used in the Third (TAR, 2001) and Fourth (AR4, 2007) Assessment Reports; and this shift is described here, along with the new AR5 guidance for communicating scientific uncertainty. The chapter provides a summary of the most relevant key findings from the IPCC *Special Report on Renewable Energy Sources and Climate Change Mitigation* (IPCC, 2011a), the IPCC *Special Report on Managing the Risks of Extreme Events and Disasters to Advance Climate Change Adaptation* (IPCC, 2012), and the AR5 Working Group I (*The Physical Science Basis*) and AR5 Working Group III (*Mitigation of Climate Change*). Collectively these recent reports, new scenarios, and other advancements in climate change science set the stage for an assessment of impacts, adaptation, and vulnerability that could potentially overcome many of the limitations identified in the IPCC WGII AR4, particularly with respect to the human dimensions of climate change.

The critical review and synthesis of the scientific literature published since October 2006 (effective cutoff date for AR4) has required an expanded multidisciplinary approach that, in general, has focused more heavily on societal impacts and responses. This includes an assessment of impacts associated with coupled socio-ecological systems and the rapid emergence of research on adaptation and vulnerability.

AR5 WGII differs from the prior assessments primarily in the expanded outline and diversity of content that stems directly from the growth of the scientific basis for the assessment. AR5 WGII is published in two volumes (Part A. Global and Sectoral Aspects; Part B. Regional Aspects) permitting the presentation of more detailed regional analyses and an expanded coverage of the human dimensions such as adaptation. AR5 WGI was completed approximately six months in advance AR5 WGII, allowing the WGII authors more time to evaluate and include where possible the WGI findings, but AR5 WGIII was developed almost in parallel with the WGII report.

The point of departure in the title alludes to the availability of new information concerning the interactions between climate change and other biophysical and societal stressors. Societal stressors include poverty and inequality, low levels of human development, and psychological, institutional, and cultural factors. Even in the presence of these multiple stressors, policy relevant information from scientific research, direct experience, and observation provides an opportunity space to choose and design climate-resilient development pathways (see 1.1.4; 13.1.1; 14.2; 14.3; Figure 1-5).

1.1.1. Development of the Science Basis for the Assessment

The volume of literature available for assessing Climate Change Impacts, Adaptation and Vulnerability (CCIAV) has grown significantly over the past two decades (Figure 1-1). A bibliometric analysis of reports produced with two bibliographic search tools (Scopus[1] and ISI Web of Science[2]) indicates that fewer than 1,000 articles in journals, books, and conference proceedings were published in English on the topic of “climate change” between 1970 and 1990. By the end of 2012 the total number of such articles was reported as 102,573 (Scopus) and 62,155 (Web of Science). The current doubling rate of “climate change” publications remains short, less than 5 years: Scopus database lists 32,943 articles published between 1970 and 2005, and 76,130 published between 1970 and 2010. A doubling of the total number of publications on the topic of climate change impacts between 2005 and 2010 and on the topic of climate change adaptation between 2008 and 2010 has occurred (Figure 1-1c).

[FOOTNOTE 1: Scopus is a bibliographic database owned by Elsevier that contains abstracts and citations for peer-reviewed literature in the scientific, medical, and social sciences (including arts and humanities). Scopus has over 50 million bibliographic records (about 29 million from 1995 forward and about 21 million from 1823-1996), as of September 2013).]

[FOOTNOTE 2: Web of Science, owned by Thompson Reuters, is a bibliographic database of journals and conference proceedings for the sciences, social sciences, arts, and humanities. Web of Science includes records from over 12,000 journals and 148,000 conference proceedings dating from 1985 to present, as of September 2013.]

Since 1990 the geographic distribution of authors contributing to the climate change literature has expanded from Europe and North America to include a large fraction from Asia and Australasia. Literature from scientists affiliated with institutions in Africa and Central and South America, however, comprised approximately 5% of the total during 2001-2010 (Figure 1-1b). The proportion of literature focusing on individual countries within IPCC regions has also broadened over the past 3 decades, particularly for Asia (Figure 1-1a).[3] This brief chronicle does not differentiate across the various “sub-categories” of the climate literature nor claim to be comprehensive in terms of literature produced in languages other than English.

[INSERT FIGURE 1-1 HERE
Figure 1-1: Number of climate-change publications listed in the Scopus bibliographic database and results of literature searches conducted in four other languages. (a) Number of publications in English (as of July, 2011) summed by country affiliation of all authors of climate change publications and binned into IPCC regions. Each publication can be counted multiple times (i.e., the number of different countries in the author affiliation list). (b Number of climate change publications in English with individual countries mentioned in title, abstract, or key words (as of July, 2011) binned into IPCC regions for the decades 1981-1990, 1991-2000, and 2001-2010. Each publication can be counted multiple times if more than one country is listed.) (c) Annual global number of publications in English on climate change and related topics: impacts, adaptation, and costs for the years 1970-2010, as of September 2013. (d) Number of publications in five languages that include the words “climate change” and “climate change” plus “adaptation”, “impact”, and “cost” (translated) in the title, abstract or key words during the three decades ending in 2010. The following individuals conducted these literature searches during January, 2012-March, 2013: Valentin Przyluski (French), Huang Huanping (Chinese), Peter Zavialov and Vasily Kokore (Russian), and Saúl Armendáriz Sánchez (Spanish).]

[FOOTNOTE 3: Russia, Greenland, and Iceland are included with Europe; Mexico is included with North America.]

Recent growth in the total volume of literature about climate change and in particular that devoted to impacts and adaptation has influenced the depth and scope of assessment reports produced by WGII, and it has enabled substantial advances in the assessment of the full range of impacts, adaptation, and vulnerability (Figure 1-1a). The unequal distribution of literature (Figure 1-1a,b, d) presents a challenge to the development of a comprehensive and balanced assessment of the global impacts of climate change. The geographical and topical distribution of literature is influenced by factors such as the availability of funding for scientific research, level of capacity building, regional experience with climate-related disasters, and the availability of long-term observational records.

Literature published on the topic of “climate change” during 1970-1990 focused primarily on changes in the physical climate system and how these changes affected other aspects of the Earth’s physical environment. The proportion of climate-change literature in engineering journals has not changed appreciably over the past four decades, but there was a significant increase in the proportion of literature published in biological and agricultural science journals. The proportion of the literature on the topic of “climate change” published in social science journals increased from 6% (1970s-1980s) to 9% (1990s-2000s). The themes covered by literature on vulnerability to climate change have also expanded to issues of ethics, equity, and sustainable development. From the Scopus database, publications on the topic of climate change “impacts” crossed the threshold of 100 per year in 1991. Publications on climate change “adaptation” and societal “cost” reached this level in 2003.

While authors continue to publish primarily in English, climate-change literature in other languages has also expanded. Literature searches in Chinese, French, Russian, and Spanish revealed roughly a 4-fold or greater increase in literature published on the topic of “climate change” in each language during the past two decades (Figure 1-1d). Scientists from many countries tend to publish their work in English, as indicated by comparing the regional analysis and country affiliation of authors in Figure 1-1b with the results of the literature searches in the five languages. This process of “scientific internationalism”, by which English becomes the primary language of scientific communication, has been described as a growing trend among Russian (Kirchik, Gingras, and Ladviere, 2012), Spanish (Alcaide, Zurián, and Benavent, 2012), and French (Gingras and Mosbah-Natanson, 2010) researchers.

1.1.2. Evolution of the WGII Assessment Reports and Treatment of Uncertainty

1.1.2.1. Framing and Outlines of WGII Assessment Reports

The framing and contents of the IPCC WGII reports have evolved since the First Assessment Report (FAR; IPCC, 1990) as summarized in Figure 1-2. Four characteristics of this evolution are an increasing attention to: (i) adaptation limits and transformation in societal and natural systems; (ii) synergies between multiple variables and factors that affect sustainable development, (iii) risk management, and (iv) institutional, social, cultural, and value-related issues. WGII now focuses on understanding the interactions between the natural climate system, ecosystems, human beings, and societies, this being on top of the long-standing emphasis on the biogeophysical impacts of climate change on sectors and regions.

[INSERT FIGURE 1-2 HERE
Figure 1-2: Tables of Contents for the Working Group II contributions to the IPCC Assessments since 1990. The FAR (IPCC, 1990) of IPCC Working Group II (WGII) focused on the impacts of climate change. For the SAR (IPCC, 1996) the WGII contribution included mitigation and adaptation with the impacts assessment. With the TAR (IPCC, 2001) and AR4 (IPCC, 2007) climate change mitigation reverted to WGIII, and WG II remained focused on impacts, adaptation, and vulnerability with an expanded effort on the regional scale.]

The WGII FAR (296 pages) was organized into six major sectors: agriculture and forestry, terrestrial ecosystems, water resources, human settlements, and oceans and coastal zones. The report focused on the anticipated climate changes for a doubling of CO_2. The FAR Summary for Policymakers (SPM) highlighted the coupling of anthropogenic non-climate stresses with climate variability and greenhouse-gas-driven climate change. Given the state of the science in 1990, the FAR has understandably low confidence on some high-vulnerability topics (e.g., global agricultural potential may either increase or decrease), but is more quantitative on large-scale climate impacts (e.g., climatic zones shift poleward by hundreds of km). Health impacts were vague, emphasizing ozone depletion and UV-B damage. The IPCC WGII 1992 Supplementary Report followed with four assigned topics (regional climate change; energy; agriculture and forestry; sea-level rise) and was primarily a strategy report, e.g., urging that studies of change in tropical cyclones are of highest priority (IPCC, 1992).

For the IPCC Second Assessment Report (SAR; IPCC, 1996) WGII reviewed climate change impacts, vulnerability, and adaptation plus mitigation options for greenhouse gases (GHG). There were two introductory primers and eighteen chapters on impacts and adaptation (e.g., forests, rangelands, deserts, human settlements, agriculture, fisheries, financial services, human health) and seven chapters on sectoral mitigation (e.g., energy, industry, forests) but with cost analysis left to WGIII. The SAR made use of the new IPCC 1992 scenarios (IS92). Projections of 2100 sea level rise (15-95 cm) and temperature increase (1.0-3.5°C) were similar to the FAR's doubled-CO_2 scenario. The SAR notes "Impacts are difficult to quantify, and existing studies are limited in scope; Detection [of climate-induced changes] will be difficult," but some specifics are given (e.g., the number of people at risk of flooding from storm surges from sea level rise; the increase in malaria incidence). Vegetation models are used to map out projected changes in major biomes (see SAR WGII SPM Figure 2) – the first prediction figure in a WGII SPM.

The Third Assessment Report of WGII (TAR; IPCC, 2001) retained impacts, adaptation, and vulnerability, leaving the topic of mitigation to WGIII. It included five sectoral chapters (water resources, ecosystems, coastal and marine, human settlements and energy, and financial services), eight regional chapters, plus chapters on (i) adaptation, sustainable development, and equity, and (ii) vulnerability and reasons for concern. The TAR made the first strong conclusion on attributing impacts: "recent regional climate changes, particularly temperature increases, have already affected many physical and biological systems." Recent increases in floods and droughts, while affecting some human systems, could not be tied to GHG-driven climate change. The TAR introduced the "burning embers" diagram (SPM Figure 2, discussed in Chapters 18 and 19 of this report) as a way to represent "reasons for concern." The adaptive capacity, vulnerability, and key concerns for each region were laid out in detail (SPM, Table 2).

The Fourth Assessment Report of WGII (AR4; IPCC, 2007) retained the basic structure of the TAR with chapters on sectors and regions. The first chapter of AR4, drawing from the expanded literature, provided an “Assessment of Observed Changes in Natural and Human Systems”. AR4 incorporated several cross-chapter themes with case studies (such as impacts on deltas) as a unifying construct. Two graphics in the AR4 SPM (SPM Figure 1-2 and Table 1-1) give many examples of projected impacts of climate change, but the state of the science – both of WGI climate projections and WGII impacts – remained too uncertain at the time to give more quantitative estimates of the impacts or necessary adaptation.

This WGII fifth assessment continues and expands the sectoral and regional parts. The AR5 considers a wide and complex range of multiple stresses that influence the sustainability of human and ecological systems. The focus on climate change and related stressors, and the resulting vulnerability and risk, continues throughout this report, including the expanded “reasons for concern” (Chapters 2 and 19, see also Section 1.2.3).

1.1.2.2. Treatment of Uncertainties in IPCC Assessment Reports: a Brief History and Terms Used in AR5

An integral feature of IPCC reports is communication of the strength of and uncertainties in scientific understanding underlying assessment findings. Treatment of uncertainties and corresponding use of calibrated uncertainty language in IPCC reports have evolved across IPCC assessment cycles (Swart et al., 2009; Mastrandrea and Mach, 2011). In WGII, the use of calibrated language began in the SAR (1996), in which most chapters used qualitative levels of confidence in Executive Summary findings. With the TAR (2001), formal guidance across the Working Groups has was developed (Moss and Schneider, 2000) recognizing that “guidelines such as these will never truly be completed,” and an iterative process of learning and improvement of guidance has ensued, informed by experience in each assessment cycle (IPCC, 2005; Mastrandrea et al., 2010). Each subsequent guidance paper has presented related but distinct approaches for evaluating and communicating the degree of certainty in findings of the assessment process.

The AR5 Guidance Note (summarized in Box 1-1) continues to emphasize an overriding theme of clearly linking each key finding and corresponding assignment of calibrated uncertainty language to associated chapter text, as part of the traceable account of the author team’s evaluation of evidence and agreement supporting that finding.

_____ START BOX 1-1 HERE _____

Box 1-1. Communication of Uncertainty in the Working Group II Fifth Assessment

Based on the Guidance Note for Lead Authors of the IPCC Fifth Assessment Report on Consistent Treatment of Uncertainties (Mastrandrea et al., 2010), the AR5 WGII relies on two metrics for communicating the degree of certainty in key findings:

- Confidence in the validity of a finding, based on the type, amount, quality, and consistency of evidence (e.g., mechanistic understanding, theory, data, models, expert judgment) and the degree of agreement. Confidence is expressed qualitatively.
- Quantified measures of uncertainty in a finding expressed probabilistically (based on statistical analysis of observations, model results, or expert judgment).

Each finding has its foundation in an author team's evaluation of associated evidence and agreement. The type and amount of evidence available varies for different topics, and that evidence can vary in quality. The consistency of different lines of evidence can also vary. Beyond consistency of evidence, the degree of agreement indicates the consensus within the scientific community on a topic and the degree to which established, competing, or speculative scientific explanations exist.

The Guidance Note provides summary terms to describe the available evidence: *limited*, *medium*, or *robust*; and the degree of agreement: *low*, *medium*, or *high*. These terms are presented with some key findings. In many cases, author teams additionally evaluate their confidence about the validity of a finding, providing a synthesis of the evaluation of evidence and agreement. Levels of confidence include five qualifiers: *very low*, *low*, *medium*, *high*, and *very high*. Figure 1-3 illustrates the relationship between the summary terms for evidence and agreement and the confidence metric. There is flexibility in this relationship; increasing confidence is associated with increasing evidence and agreement, but different levels of confidence can be assigned for a given evidence and agreement statement. The degree of certainty in findings based on qualitative evidence is expressed using levels of confidence and summary terms.

[INSERT FIGURE 1-3 HERE
Figure 1-3: Evidence and agreement statements and their relationship to confidence. The coloring increasing towards the top-right corner indicates increasing confidence. Generally, evidence is most robust when there are multiple, consistent independent lines of high-quality evidence.]

In some cases, available evidence incorporates quantitative analyses, based on which uncertainties can be expressed probabilistically. In such cases, a finding can include calibrated likelihood language or a more precise presentation of probability. The likelihood terms and their corresponding probability ranges are presented below. Use of likelihood is not an alternative to use of confidence: an author team will have a level of confidence about the validity of a probabilistic finding. Unless otherwise indicated, findings assigned a likelihood term are associated with *high* or *very high* confidence. When authors evaluate the likelihood of some well-defined outcome having occurred or occurring in the future, the terms and associated meanings are:

Term*	**Likelihood of the outcome**
Virtually certain	99–100% probability
Very likely	90–100% probability
Likely	66–100% probability
About as likely as not	33–66% probability
Unlikely	0–33% probability
Very unlikely	0–10% probability
Exceptionally unlikely	0–1% probability

* Additional terms used more occasionally are *extremely likely:* 95–100% probability, *more likely than not:* >50–100% probability, and *extremely unlikely:* 0–5% probability.

_____ END BOX 1-1 HERE _____

1.1.3. Scenarios Used as Inputs to Working Group II Assessments

A scenario is a story line or image that describes a potential future, developed to inform decision-making under uncertainty (Parson et al. 2007). Scenarios have been part of IPCC future climate projections since the FAR (1990), where WGIII generated four scenarios (Bau = business-as-usual, B, C, and D) used by WGI to project climate change. The IPCC Supplementary Report (IPCC, 1992), a joint effort of WGI and WGIII, defined six new scenarios (IS92a-f) used in the SAR (1996). For the TAR (2001), the IPCC Special Report on Emissions Scenarios (SRES: Nakicenkovic et al., 2000) created many scenarios from four Integrated Assessment Models (IAMs), out of which a representative range of marker scenarios were selected (A1B, A1T, A1FI, A2, B1, B2). In the SRES, scenarios had had socio-economic storylines but climate-mitigation options were not included. The SRES scenarios carried over into the AR4 (2007) and formed the basis for the large number of ensemble climate simulations (CMIP3), which are still in use for climate-change studies relevant to AR5 WGII.[4]

[FOOTNOTE 4: The Coupled Model Intercomparison Project is an activity of the World Climate Research Programme's Working Group on Coupled Modelling. Climate model output from simulations of the past, present and future climate archived mainly in 2005-2006 constituted phase 3 of the Coupled Model Intercomparison Project (CMIP3). Similar climate simulations by an expanded set of models with a close off date of March 2013 are being used in AR5 and constitute phase 5 of the project (CMIP5). CMIP3 used the SRES scenarios, and CMIP5 used the RCP scenarios.]

With AR5, the development of scenarios fundamentally changed from the IPCC-led SRES process. An ad hoc group of experts, anticipating AR5, built a new structure for scenarios called Representative Concentration Pathways (RCPs) (Moss et al., 2010; van Vuuren et al., 2011) using updated IAMs and intended to provide a flexible, interactive, and iterative approach to climate change scenarios. The four RCPs are keyed to a range of trajectories of GHG concentrations and climate forcing. They are labeled by their approximate radiative forcing (RF, W m^{-2}) that is reached during or near the end of the 21st century (RCP2.6, RCP4.5, RCP6.0, RCP8.5). The quantitative link between the socio-economic pathway, human activities and GHG emissions, and subsequently RF is weaker or non-existent with current RCP than with SRES scenarios. For example, the RCPs rely on a single parametric model (Meinshausen et al., 2011; TAR, 2001) to map from emissions to RF; whereas IPCC WGI traditionally assesses this critical linkage using the current state of scientific knowledge (see AR5 WGI Chapters 6, 11, 12, Annex II). In addition, socioeconomic scenarios, emissions, and subsequent radiative forcing pathways were not linked one-to-one in the initial RCPs, however, efforts to derive socio-economic pathways consistent with each RCP are discussed in Chapter 20.

1.1.3.1. Comparison of RCP and SRES Scenarios

While WGI AR5 is based primarily on results from the RCP CMIP5, the AR5 WGII also uses results from the SRES CMIP3, and thus we identify similar or parallel scenarios from each set. The radiative forcing from the SRES and RCP scenarios are compared in Figure 1-4a. For the latter half of the 21st century, SRES A1FI lies above all RCP and other SRES; SRES A2 has a similar trajectory to RCP8.5 with both reaching about 8 W m^{-2} by 2100; and SRES B1 approximately matches RCP4.5 with both leveling off at about 4 W m^{-2}. RCP6.0 starts similarly to both RCP4.5 and SRES B1, but after 2060 it increases to about 5 W m^{-2}. RCP2.6, a strong mitigation scenario with net CO_2 removal by 2100, falls well outside the SRES range B1 to A2, peaking at about 2.6 W m^{-2} in 2040 and dropping thereafter (AR5 WGI, Figure 1-15, Tables AII.6.1-10).

Total RF does not adequately describe the differences in climate change between SRES and RCP scenarios. All RCPs adopted stringent air pollution mitigation policies and thus have much lower tropospheric ozone and aerosol abundances than the SRES scenarios, which ignored the role of air quality regulations (AR5 WGI Tables AII.2.16-22). In terms of ozone and particulate matter precursor emissions, there is almost no overlap between SRES and RCP scenarios (AR5 WGI Tables AII.2.16-22). In terms of surface ozone at the continental scale, after 2060 the RCPs are similar to low-end SRES B1 (AR5 WGI Tables AII.7.1-2).

Global mean surface temperature change for these scenarios is shown in Figure 1-4b, based on AR5 WGI (Chapters 11 & 12, Tables AII.7.5-6) and AR4 WGI (Figure 10.26). For the purposes here, that of understanding differences in impact studies using different scenarios, only model CMIP5 ensemble means are shown for the RCPs. If the standard deviation of the models were plotted, all RCPs would touch or overlap through the century (WGI AII.7.5), but even this range underestimates the uncertainties in temperature change for those scenarios (see WGI Chapter 12). The AR5 RCP data is taken directly from the CMIP5 runs, whereas the AR4 data is based on a simple model, parameterized to match the different CMIP3 models (see figure caption). In terms of temperature change, RCP8.5 is close to SRES A2, but below SRES A1FI. RCP4.5 follows SRES B2 up to 2060, but then drops to track SRES B1. RCP6.0 has lower temperature change to start, following SRES B1, but then increases towards SRES B2 by 2100. In general, scenarios SRES A1B, A1T and B2 lie in the large gap between RCP8.5 and RCP4.5/6.0. The RCP2.6 temperature change stabilizes at about 1°C above the reference period (1986-2005). The other RCPS and all SRES scenarios span the range 1.8 – 4.1 °C for the 2090s. The CMIP5 reference period is about 0.6 °C above earliest observing period 1850-1900 (WGI Chapter 2).

[INSERT FIGURE 1-4 HERE
Figure 1-4: (a) Projected RF (W m^{-2}) and (b) global mean surface temperature change (°C) over the 21st century from the SRES and RCP scenarios. RF for the RCPs are taken from their published CO_2-equivalent (Meinshausen et al., 2011), and RF for SRES are from the TAR Appendix II (Table II.3.11). For RF derived from the CMIP5 models see WGI (Chapter 12.3, Tables AII.6.9-10). The ensemble total effective RF at 2100 for CMIP5 concentration-driven projections are 2.2, 3.8, 4.8 and 7.6 W m^{-2} for RCP2.6, RCP4.5, RCP6.0 and RCP8.5, respectively. The SRES RF are shifted upward by 0.12 W m^{-2} to match the RCPs at year 2000 since (i) the climate change over the 21st century is driven primarily by the changes in RF and (ii) the offset is due primarily to improvements in model physics including the aerosol RF. For more details and comparison with pre-SRES scenarios, see WGI Chapter 1 (Figure 1-15). Temperature changes are decadal averages (e.g., 2020s = 2016-2025) based on the model ensemble mean CMIP5 data for the RCPs (colored lines). The same analysis is applied to CMIP3 SRES A1B (yellow circles). See AR5 WGI Chapters 11, 12, Table AII.7.5. The colored squares show the temperature change for all six SRES scenarios based on a simple climate model tuned to the CMIP3 models (AR4 WG1 Figure 10.26). The difference between the yellow circles and yellow squares reflects differences between the simple model and analysis of the CMIP3 model ensemble in parallel with the CMIP5 data. For an assessment of uncertainties and *likely* ranges of temperature change see WGI Figures 11.24-25, 12.4-5, 12.40.]

1.1.3.2. Shared Socio-Economic Pathways

Shared Socioeconomic Pathways (SSPs) are being generated (Arnell et al., 2011; Kriegler et al., 2012) to form more complete scenarios that link each RCP's climate path to a range of human development pathways. The SSPs include three elements: a) storylines, which are descriptions of the state of the world, b) Integrated Assessment Models (IAMs) quantitative variables (such as population, GDP, technology availability), and c) other variables, not included in the IAMs, such as ecosystem productivity and sensitivity or governance index. With these elements a goal of the SSP effort is to characterize a global socio-economic future for the 21st century as a reference for climate change analysis (O'Neill et al., 2012). Combined SSP-RCP scenarios are needed to support synthesis across all IPCC Working Groups and, particularly for WGII, to facilitate the use of new climate modeling results with impacts, adaptation, and vulnerability (IAV) research. Five basic SSPs have been proposed, representing a wide range of possible development pathways, primarily at global or large regional scales. For each RCP it is expected that one or more SSP could lead to that climate path. Several chapters of this report refer to the SSPs in their discussion of analyses of future impacts and vulnerability. Chapter 20 (20.6.1) describes SSPs in more detail, and Chapter 21 (21.2.2) notes how the time lags in producing SSPs has limited the use of CMIP5-RCP scenarios in AR5.

1.1.4. Evolution of Understanding the Interaction between Climate Change Impacts, Adaptation, and Vulnerability with Human and Sustainable Development

The continuing increase in greenhouse gas emissions has highlighted the commitment to climate change and its varied impacts and has contributed to an increasing emphasis on vulnerability, adaptation, and sustainability. The possible range of socio-economic trajectories in countries with low, medium, high, and very high human development is among the largest sources of uncertainty in scenario building and climate projections. A deeper understanding of development patterns, adaptation limits, and maladaptation, as well as options for more climate resilient pathways, has helped identify a larger range of potential climate change impacts and the risks they pose to society.

The first three WGII reports focused primarily on characterizing the biophysical impacts of climate change, with a progressively more elaborated understanding of economic and social impacts. Literature of the last decade indicates a more integrated understanding of the physical and social impacts of climate change. The extent and structure of AR5 WGII shows such advancements. The AR4 Synthesis Report asserted that "climate change impacts depend on the characteristics of natural and human systems, their development pathways and their specific locations" (IPCC

2007c, p. 64). AR4 WGII Chapter 20 offered a catalogue of multiple stresses jointly impacting people and communities and also highlighted questions of justice and equity in shaping development pathways in the context of climate change.

1.1.4.1. Vulnerability and Multiple Stressors

Climate-related risks interact with other biophysical and social stressors. Vulnerability is defined in the TAR WGII Glossary in terms of susceptibility and as a "function of the character, magnitude, and rate of climate variation to which a system is exposed, its sensitivity, and its adaptive capacity". Since then, the understanding of vulnerability has acquired increased complexity as a multi-dimensional concept, with more attention to the relation with structural conditions of poverty and inequality. AR5 WGII defines vulnerability simply as the propensity or predisposition to be adversely affected, and many chapters identify such vulnerabilities through societal risks, particularly in low-income economies. Recent studies suggest that climate impacts could slow down or reverse past development achievements, hinder global efforts on poverty reduction, and lead to human and environmental insecurity, displacement and conflict, maladaptation, and negative synergies (Barnett and O'Neill, 2010; Boyd and Juhola, 2009; Jerneck and Olsson, 2008; Ogallo, 2010; see also 3.5.1; 8.2.4; 12.2.1; 12.4.1; 12.5.1; 13.2.1; and 14.7).

The concept of resilience emerged from ecological sciences and has been increasingly used by social sciences. In climate change literature it describes the ability of a system to respond to disturbances, self-organize, learn, and adapt (Brown, 2013; Turner, 2010; AR5 WGII Glossary). Vulnerability, adaptation, and resilience are determined by multiple stressors, a combination of biophysical and social factors that jointly determine the propensity and predisposition to be adversely affected. For example, adaptive capacity in many urban centers in less developed countries is constrained by poverty, unemployment, quality of housing, or lack of access to potable water, sanitation, health care, and education interacting with land degradation, water stress, or biodiversity loss (8.2.4; 11.6.2; 22.4.4). Adaptation options and limits for high-end warming scenarios are often contextualized in relation to socio-economic vulnerabilities and other stressors (Brown, 2012; Gupta et al., 2010; New et al., 2010; Stafford Smith et al., 2011; World Bank, 2012; see also 16.4.2.4).

1.1.4.2. Adaptation, Mitigation, and Development

Impacts of climate change will vary across regions and populations, through space and time, dependent on myriad factors including non-climate stressors and the extent of mitigation and adaptation. Changes in both climate and development are key drivers of the core components of risk (exposure, vulnerability, and physical hazards). The relations with development are complex and contested. There is disagreement about fundamental issues, such as the compatibility of development goals and climate change mitigation, the prioritization of responses (reducing consumption versus investment in sustainable technologies), and the stage of development at which countries should take action (see Box1-2 for terms used to characterize stages of development) (Brooks, Grist, and Brown, 2009; Grist, 2008; Schipper, 2007). The literature points to how inequalities, trade imbalances, intellectual property rights, gender injustice, or agricultural systems, *inter alia*, cannot be addressed with development focusing solely on increasing economic growth (Alston, 2011; Büscher et al., 2012; McMichael, 2009; OECD, 2013; Pogge, 2008; UNDP, 2007, 2011).

_____ START BOX 1-2 HERE _____

Box 1-2. Country Development Terminology

There are diverse approaches for categorizing countries on the basis of their level of development and for defining terms such as industrialized, developed, or developing. Table 1-1 presents selected categorizations used in this report. In the United Nations system, there is no established convention for the designation of developed and developing countries or areas (UN DESA, 2012). The United Nations Statistics Division specifies developed and developing regions based on "common practice." In addition, specific countries are designated as least developed countries, landlocked developing countries, small island developing states, and transition economies. Many countries appear in more than one of these categories. The World Bank uses income as the main criterion for classifying countries (World Bank, 2013). The UNDP aggregates indicators for life expectancy, educational attainment and income into a single composite human development index (HDI) (UNDP, 2013).

[INSERT TABLE 1-1 HERE
Table 1-1: Selected country development categorizations used in this report.]

_____ END BOX 1-2 HERE _____

The recent literature shows increasing attention to questions of ethics, justice, and responsibilities relating to climate change (Arnold, 2011; Caney, 2012; Gardiner, 2011; Marino and Ribot, 2012; O'Brien et al., 2010; Pelling, 2010; Timmons and Parks, 2007). As basic resources such as energy, land, food, or water become threatened, inequalities and unfairness may deepen leading to maladaptation and new forms of vulnerability. Responses to climate change may have consequences and outcomes that favor certain populations or regions. For example, there are increasing cases of land-grabbing and large acquisitions of land or water rights for industrial agriculture, mitigation projects, or biofuels that have negative consequences on local and marginalized communities (Borras, McMichael, and Scoones, 2011, see also 14.7). Ethical perspectives are also important in relation to adaptation constraints and limits (see 16.7) and mitigation (see 1.3.4 and AR5 WGIII).

Climate change impacts have become a central issue in the work of developmental organizations such as the United Nations specialized agencies, bilateral donor institutions, and non-governmental organizations (NGOs) who link adaptation concerns with ongoing development efforts. The increase in adaptation literature and experience, however, has led to the development of adaptation policies in many parts of the world, as reflected in four chapters here devoted to adaptation (14-17) and all of the regional chapters of this report. At the policy level, individual country National Adaptation Programmes of Action and National Communication reports to the United Nations Framework Convention on Climate Change (UNFCCC) had in the past focused primarily on physical climate change drivers and impacts. An analysis of National Communications documents submitted through 2004 by many of the Annex 1 countries, for example, showed that climate change impacts and adaptation receive very limited attention relative to the discussion of greenhouse gas emissions and mitigation policies (Gagnon-Lebrun and Agrawala, 2006). However, concern and actual progress towards adaptation is evident in Latin America (Gutierrez and Espinosa, 2010) and in recent National Communications of some non-Annex 1 countries, such as India (2012) and Iran (2010), which devoted a substantive part of their recent reports to the topic of adaptation.

Some researchers and institutions have sought to identify a continuum between development, adaptation strategies, and financing, including increasing attention to co-benefits with mitigation (Heltberg, Siegel and Jorgensen, 2009; Mearns and Norton, 2010; Richardson et al., 2011; OECD, 2013; USAID, 2008; World Bank, 2010). "Greener" development and market-based mechanisms are being explored as instruments to achieve synergies between mitigation and adaptation efforts, development financing and planning, and links to energy needs are some of the instruments explored. Large concerns remain, however, about the preconditions needed for market mechanisms to work as intended, the problems of carbon leakage, and the potential negative effects of some mitigation strategies (Liverman, 2010; see also; 13.1.3 and WGIII Chapter 15).

1.1.4.3. Transformation and Climate Resilient Pathways

Transformation – a change in the fundamental attributes of a system including altered goals or values – has emerged as a key concept in describing the dimensions, types, and rates of societal response to climate change. In the context of adaptation, we can distinguish between incremental and transformative adaptation, the latter referring to changes in the fundamental attributes of a system in response to climate change and its effects (WGII Glossary, Park et al., 2012). The SREX recognized transformation in technological, financial, regulatory, legislative, and administrative systems (IPCC, 2012; see 1.3.1; 20.5). Recent literature points to changes in values, norms, belief systems, culture, and conceptions of progress and wellbeing as either facilitating or preventing transformation (Kates et al., 2012; O'Brien, 2013; Pelling, 2011; Stafford Smith et al., 2011). Transformation of this nature requires a particular understanding of risks, adaptive management, learning, innovation, and leadership, and may lead to climate resilient development pathways (see 1.2.3 and Chapter 20). Transformational change is not called for in all circumstances (Pelling, 2010) and in some cases may lead to negative consequences for some locations or social groups, contributing to social inequities (O'Brien, 2013). Climate-resilient pathways include actions, strategies and choices that reduce climate change impacts while assuring that risk management and adaptation can be implemented and sustained.

1.1.4.4. The Opportunity Space for Decision Making

Recognizing the need for policy relevant science, much scientific activity tends to be coordinated through international programmes that focus on, for example, biodiversity, desertification, food security, impacts on social practices and institutions, and monitoring sea level rise. The trend in research is to create synergies across the sciences by including social and human sciences perspectives and transdisciplinarity. The production of information with non-scientific sources such as indigenous knowledge or stakeholder views is also enriching climate change research. This trend has led to the merging of relevant global programmes of the international councils for science and for social science (ICSU and ISSC) under the umbrella "Future Earth" (see also ISSC, 2013). This expanded scientific focus combined with increased practice and experience with adaptation creates a new opportunity space for evaluating policy options and their risks in the search for climate resilient development pathways (Figure 1-5) (2.1; 2.4.3; 20.2 and 20.3.3). Human and social-ecological systems can build resilience through adaptation, mitigation, and sustainable development.

Over the next few decades, global temperatures are projected to increase along broadly similar pathways, whether or not mitigation of greenhouse gases occurs (1.3.3). During this near-term era of committed climate change, risks will evolve as socioeconomic trends interact with the changing climate and societal responses, including adaptation, will influence near-term outcomes. In the second half of the 21st century and beyond, global temperature increases diverge across emissions scenarios. During this longer-term era of climate options, near-term and ongoing mitigation efforts as well as development trajectories will determine the risks associated with climate change.

[INSERT FIGURE 1-5 HERE
Figure 1-5: Multiple stressors and climate resilient pathways. The literature assessed in this report shows that climate change is just one of the many stressors that influence resilience. Climate-related risks interact with other biophysical stressors (such as biodiversity loss, soil erosion, and water contamination) and with social stressors (such as inequalities, poverty, gender discrimination, and lack of institutions). Rapid advances in knowledge about climate change and its impacts along with experience and other factors provide policy relevant information for decision making that can lead to climate-resilient development pathways. The decisions that societies make within this opportunity space can increase resilience and lower risks. Such decisions and choices are core elements of an iterative risk management process.]

1.2. Major Conclusions of the WGII Fourth Assessment Report (AR4)

This section presents highlights of AR4 that are particularly relevant to AR5 as a point of departure. These highlights are drawn from the AR4 Synthesis Report, the WGII Summary for Policymakers, and the WGII chapter Executive Summaries.

1.2.1. Observed Impacts

Evidence presented in Chapter 1 of the WGII Fourth Assessment Report (AR4) indicated that physical and biological systems on all continents and in most oceans were being affected by recent climate changes, particularly regional temperature increases (Rosenzweig et al., 2007, page 81). In terrestrial ecosystems, warming trends were consistent with observed change in the timing of spring events and poleward and upward shifts in plant and animal ranges. The authors found that the geographical locations of observed changes during the period 1970-2004 are consistent with spatial patterns of atmospheric warming. The types of hydrologic changes reported included: effects on snow, ice and frozen ground; the number and size of glacial lakes; increased runoff and earlier spring peak discharge in many glacier- and snow-fed rivers; thermal structure and water quality of rivers and lakes; and more intense drought and heavy rains in some regions. The authors concluded from a synthesis of studies "that the spatial agreement between regions of significant warming and the locations of significant observed changes is *very unlikely* to be due solely to natural variability of temperatures or natural variability of the systems" (IPCC, 2007d, page 9).

Observed regional impacts to human systems were less obviously attributed to anthropogenic climate change. The authors of AR4 concluded that "**There is *medium confidence* that other effects of regional climate change on natural and human environments are emerging, although many are difficult to discern due to adaptation and non-climatic drivers"** (IPCC, 2007c, page 3)**.** They presented evidence on the effects of temperature increases on agricultural and forest management at Northern Hemisphere higher latitudes (e.g. earlier spring planting of crops, alterations in disturbance regimes of forests due to fires and pests); on some aspects of human health (e.g. heat-related mortality in Europe, changes in infectious disease vectors in some areas, and allergenic pollen in Northern Hemisphere high and mid-latitudes); and some human activities in the Arctic (e.g. hunting and travel over snow and ice) and in lower-elevation alpine areas (such as mountain sports).

The authors of AR4 concluded that "Recent climate changes and climate variations are beginning to have effects on many other natural and human systems. However, based on published literature, the impacts have not yet become established trends" (IPCC, 2007d, page 9). Three examples were cited: in mountain regions melting glaciers enhanced risk of glacier lake outburst floods on settlements; in the Sahelian region of Africa warmer and drier conditions had detrimental effects on some crops; and in coastal areas sea-level rise and human development contributed to losses of coastal wetlands and mangroves and to increases in damage from coastal flooding.

1.2.2. Key Vulnerabilities, Risks, and Reasons for Concern

In an effort to provide some insights into the seriousness of the impacts of climate change TAR WGII (Chapter 19) identified five ''Reasons for Concern'' (RFC) focusing on: (1) unique and threatened systems, (2) extreme climate events, (3) distribution of impacts, (4) aggregate impacts, and (5) large scale discontinuities (see Figure SPM-2 in IPCC, 2001c). Considering new evidence of observed changes on every continent, coupled with a more thorough understanding of the concept of vulnerability, the AR4 concluded that the five 'reasons for concern' identified in the TAR remained a viable framework to consider key vulnerabilities (IPCC 2007c, page 19).

The AR4 Synthesis Report Summary for Policymakers concluded with the following key message: **Responding to climate change involves an iterative risk management process that includes both adaptation and mitigation and takes into account climate change damages, co-benefits, sustainability, equity and attitudes to risk** (2007c, page 22). The concept of risk (the confluence of likelihood and consequence) is the focus of this AR5 Report. All chapters, especially 2, 18 and 19, now focus on climate change, related stressors, resulting vulnerabilities, and associated risks. Correlating the risk-based framing of the RFC in AR5 WGII with the conclusions reported the AR4 SPM is straightforward (italics indicate new terms that have been added to the RFC definitions from the IPCC, 2007c, page 19):

- Risks to Unique and Threatened Systems: "There is new and stronger evidence of observed impacts of climate change on unique and vulnerable systems (such as polar and high mountain communities and ecosystems), with increasing levels of adverse impacts as temperatures increase."
- *Risks Associated with* Extreme Weather Events: **"**Responses to some recent extreme events reveal higher levels of vulnerability than the TAR. There is now higher confidence in the projected increases in droughts, heat waves and floods, as well as their adverse impacts."
- *Risks Associated with the* Distribution of Impacts: "There are sharp differences across regions and those in the weakest economic position are often the most vulnerable to climate change. There is increasing evidence of greater vulnerability of specific groups such as the poor and elderly not only in developing but also in developed countries. Moreover, there is increased evidence that low-latitude and less developed areas generally face greater risk, for example, in dry areas and megadeltas."

- *Risks of Associated with* Aggregate Impacts: "Compared to the TAR, initial net market-based benefits from climate change are projected to peak at a lower magnitude of warming, while damages would be higher for larger magnitudes of warming."
- Risks Associated with Large Scale Discontinuities: "There is high confidence that global warming over many centuries would lead to a sea level rise contribution from thermal expansion alone that is projected to be much larger than observed over the 20th century, with loss of coastal area and associated impacts. There is better understanding than in the TAR that the risk of additional contributions to sea level rise from both the Greenland and possibly Antarctic ice sheets may be larger than projected by ice sheet models and could occur on century time scales."

Chapters 18 and 19 of AR5 WGII recognize new evidence about the RFC in the context of risk. Chapter 18 expands our understanding of how observed and attributed impacts, vulnerabilities, and associated risks support the identification of the dependence of the RFC on temperature "up to the present". Chapter 19 extends this analysis to future temperatures. Both chapters demonstrate how accounting for both components of risk in assessing the RFC permits a clearer understanding of "key vulnerabilities".

1.2.3. Interaction of Adaptation and Mitigation in a Policy Portfolio

A conclusion of AR4 is that coping with risks of climate change will involve a portfolio of initiatives that will evolve iteratively over time as new information about the workings of the climate system and new insights into how various responses are actually working and penetrating the global socio-economic structure. The AR4 WGII concluded that (i) neither adaptation nor mitigation alone can avoid all climate change impacts; though together they can significantly reduce the risks of climate change, (ii) adaptation is necessary in the short and longer term to address impacts, even for the lowest stabilization scenarios assessed, but there are barriers, limits and costs, but these are not fully understood, (iii) unmitigated climate change would, in the long term, be *likely* to exceed the capacity of natural, managed and human systems to adapt, and (iv) many impacts can be reduced, delayed or avoided by mitigation, while delayed emission reductions significantly constrain the opportunities to achieve lower stabilization levels and increase the risk of more severe climate change impacts." (IPCC 2007c, page 19).

WGII AR5 devotes considerable attention to the interface of adaptation and mitigation and the mechanisms for iterating decisions as described in a collection of chapters (16, 17, 19, and 20) designed explicitly for this purpose. These chapters build substantially upon key messages from the AR4 chapter entitled "Inter-relationships between adaptation and mitigation" (IPCC 2007b, page 747), including:

- Even the most stringent mitigation efforts cannot avoid further impacts of climate change in the next few decades, which makes adaptation unavoidable.
- Without mitigation, a magnitude of climate change is likely to be reached that makes adaptation impossible for some natural systems; while for most human systems it would involve very high social and economic costs.
- **"Creating synergies between adaptation and mitigation can increase the cost-effectiveness of actions and make them more attractive to stakeholders, including potential funding agencies (medium confidence)."** Such synergies, however, provide no guarantee that resources are used in the most efficient manner and opportunities for synergies are greater in some sectors (e.g., agriculture and forestry) than others (e.g., energy, health, and coastal systems).
- **"It is not yet possible to answer the question as to whether or not investment in adaptation would buy time for mitigation (high confidence)."** Barriers to understanding the trade-offs of the immediate benefits of localized adaptation and the longer-term global benefits of mitigation, coupled with the limitation of models to simulate the intricacies of the interactions of the two, present a challenge to designing and implementing and "optimal mix" of response strategies.
- **"People's capacities to adapt and mitigate are driven by similar sets of factors (high confidence).** These factors represent a generalised response capacity that can be mobilised for both adaptation and mitigation." The authors noted that even societies with high adaptive capacity can be vulnerable to climate change, variability, and extremes.

1.3. Major Conclusions of More Recent IPCC Reports

Since the publication of the Fourth Assessment Report (AR4) in 2007 the IPCC has produced two Special Reports: the SRREN produced by Working Group III and published in 2011 and the SREX produced jointly by WGI and WGII and published in 2012. In addition, the AR5 has staggered the assessment work for its three working groups. AR5 WGI was published before AR4 WGII in 2013, and AR5 WGIII will be published after, in 2014. In this section we summarize the major conclusions of the SREX, the SRREN, AR5 WGI, and preliminary findings from AR5 WGIII. We focus on the key findings, framings, and conceptual innovations these reports bring to AR5 WGII.

One common theme that cuts across the Working Groups is the connection of three basic elements of climate change: (i) detection of climate change or its impacts; (ii) attribution of that observed climate change to the increases in greenhouse gases (i.e., human cause, WGI) or attribution of local impacts to the observed climate change in that region; and (iii) projection of these impacts and climate change into the 21st century. Table 1-2 gives a summary of phenomena for which such detection, attribution, or projection has been made across the Working Groups. A schematic presentation of this detection-attribution-projection sequence from preceding reports is given in Figure 1-6. For AR5 WGII attributions, see Chapter 18; and for projections, see the other chapters.

[INSERT TABLE 1-2 HERE
Table 1-2: Confidence in the observation, attribution, and projection of changes in climate system phenomena.]

[INSERT FIGURE 1-6 HERE
Figure 1-6: Confidence in the attributed (squares) and projected 21st century (yellow circles) changes in climate system phenomena plotted as a function of confidence in their detection to date. Phenomena and sources (AR4, SREX, AR5 WGI) are given in Table 1-2. Strength of confidence is sorted into the six bins as noted on the axes (very low confidence or not assessed; low or medium confidence; high confidence (no quantification) or likely; very likely; extremely likely; virtually certain). Attribution is to either human influence (blue squares, as used by WGI) or observed local/regional climate change (red squares, as used by WGII). Projections assume global warming exceeding 2°C. For AR5 WGII results see, *inter alia*, Chapters 18 and 19.]

1.3.1. Special Report on Renewable Energy Sources and Climate Change Mitigation (SRREN)

The SRREN (IPCC, 2011a) assesses literature on the challenges of integrating renewable energy sources into existing energy sources to meet the goals of climate change mitigation and sustainable development. More specifically, it examines six renewable energy sources (bioenergy, direct solar energy, geothermal energy, hydropower, ocean, and wind energy) in terms of available technologies, technological potential, and associated costs. The SRREN found that the deployment of renewable energy technologies has increased rapidly in recent years, often associated with cost reductions that are expected to continue with advancing technology. Despite the small contribution of renewable energy to current energy supplies, SRREN shows the global potential of renewable energy to be substantially higher than the global energy demand. It is therefore not the technological potential of renewable energy that constrains its development, but rather economic factors, system integration, infrastructure constraints, public acceptance, and sustainability concerns (IPCC, 2011a). Several SRREN findings have clear linkages with this assessment of climate change impacts, adaptation and vulnerability, as summarized in Table 1-3.

[INSERT TABLE 1-3 HERE
Table 1-3: Examples of linkages between the SRREN and the AR5 WGII with chapter references in parentheses.]

1.3.2. Special Report on Managing the Risks of Extreme Events and Disasters to Advance Climate Change Adaptation (SREX)

The SREX (IPCC, 2012) is the first IPCC Special Report produced jointly by Working Groups I and II and is the first IPCC report focused specifically on risk management. The report integrates perspectives from historically distinct research communities studying climate science, climate impacts, extreme events and impacts, climate adaptation, and disaster risk management. It assesses relationships between climate change and the characteristics of extreme weather and climate events. The SREX provides information on existing societal exposure and vulnerability to climate-related extreme events and disasters; observed trends in weather- and climate-related disasters, disaster losses, and in disaster risk management; projected changes in weather and climate extremes during the 21st century; approaches for managing the increasing risks of climate extremes and disasters; and implications for sustainable development. SREX Chapter 9 is devoted to fourteen case studies that illustrate the impacts of extreme climate-related events and options for risk management and adaptation, such as early-warning systems, new forms of insurance coverage, and expansion of social safety nets.

1.3.2.1. Themes and Findings of SREX

The most relevant results of the SREX assessment are presented below. They are synthesized along the major themes – changing weather and climate-related extreme events, trends in disaster losses, and managing the risks of extreme events and disasters. Other examples of findings presented in the SREX concerning the type, magnitude, and frequency of extreme weather and climate events are presented in Table 1-2 of this chapter.

- Based on observations since 1950 there is evidence of changes in some climate-related extremes. It is *very likely* that there had been an overall decrease in the number of cold days and nights, and increase in the number of warm days and nights, at the global scale. [SREX SPM, 3.3.1, Table 3-2] It is *likely* that there has been an increase in extreme coastal high water events related to increases in mean sea level. [SREX SPM, 3.5.3] It is *likely* that anthropogenic influences have led to warming of extreme daily minimum and maximum temperatures at the global scale. [SREX SPM, 3.2.2, 3.3.1, 3.3.2, 3.4.4, 3.5.3, Table 3-1]
- The models project substantial warming in temperature extremes by the end of the 21st century. It is *virtually certain* that increases in the frequency and magnitude of warm daily temperature extremes and decreases in cold extremes will occur in the 21st century at the global scale. It is *very likely* that the length, frequency, and/or intensity of warm spells or heat waves will increase over most land areas. [SREX SPM, 3.3.2,3.3.4, Table 3-3, Figure 3-5]
- It is *likely* that the frequency of heavy precipitation will increase in the 21st century over many areas of the globe. [SREX SPM, 3.3.2, 3.4.4 Table 3-3, Figure 3-7]
- Economic losses from weather- and climate-related disasters have increased, but with large spatial and interannual variability *(high confidence*, based o*n high agreement, medium evidence*). [SREX SPM, 4.5.1, 4.5.3, 4.5.4] Trends in losses have been heavily influenced by increasing exposure of people and economic assets *(high confidence*). [SREX SPM, 4.5.3]
- Economic, including insured, disaster losses associated with weather, climate related events, and geophysical events are higher in developed countries. Fatality rates and economic losses expressed as a proportion of gross domestic product (GDP) are higher in developing countries (*high confidence*). Deaths from natural disasters occur much more in developing countries. From 1970 to 2008 for example, more than 95% of deaths from natural disasters were in developing countries. [SREX SPM, 4.5.2, 4.5.4]
- Development practice, policy and outcomes contribute to shaping disaster risks (*high confidence*): skewed development that may lead to environmental degradation, unplanned urbanization, failure of governance or reduction of livelihood options result in increased exposure and vulnerability to disasters. [SREX SPM 1.1.2, 1.1.3 and 2.2.2, 2.5]
- Post-disaster recovery and reconstruction provide an opportunity for reducing the risks posed by future weather- and climate-related disasters (robust evidence, high agreement). [SREX SPM, 5.2.3, 8.4.1, 8.5.2]
- Socio-economic, demographic, health related differences, access to livelihoods, good governance and entitlements are some of the factors that lead to inequalities between people and countries. Inequalities influence local coping and adaptive capacity and pose challenges for risk management systems from local to national levels (*high agreement, robust evidence*). [SREX SPM 5.5.1, 6.2, 6.3.2, 6.6]
- The incorporation of climate change adaptation and disaster risk management into the local, national and international developments practices and policies, could bring benefits (*medium evidence, high agreement*). [SREX SPM, 5.4, 5.5, 5.6, 6.3.1, 6.3.2, 6.4.2, 6.6, 7.4]

- Combining local knowledge with scientific and technical expertise helps communities reduce their risk and adapt to climate change (*robust evidence, high agreement*). Risk management works best when tailored to local circumstances. [SREX SPM, 5.4.4]
- Many measures for managing current and future risks have additional benefits, such as improving peoples' livelihoods, conserving biodiversity, and improving human well-being (*medium evidence, high agreement*). [SREX SPM, 6.3.1, Table 6-1]
- Many measures, when implemented effectively, make sense under a range of future climates. These "low regrets" measures include: systems that warn people of impending disasters; changes in land use planning; sustainable land management; ecosystem management; improvements in health surveillance, water supplies, and drainage systems; development and enforcement of building codes; and better education and awareness. [SREX SPM, 5.3,1, 5.3.43, 6.3.1, 6.5.1, 6.5.2, 7.4.3 and Case Studies 9.2.11, 9.2.14]
- An iterative process involving monitoring, research, evaluation, learning and innovation can promote adaptive management and reduce disaster risk in the context of climate extremes (*robust evidence, high agreement*). [SREX SPM, 8.63, 8.7]
- Actions ranging from incremental improvements in governance and technology to more transformational changes are essential for reducing risk from climate extremes (*robust evidence, high agreement*). [SREX SPM, 8.6, 8.6.3, 8.7]

1.3.2.2. Advances in Conceptualizing Climate Change Vulnerability, Adaptation, and Risk Management in the Context of Human Development

The conceptual framing of the SREX reflects the diversity of expert communities involved in that assessment. It links exposure and vulnerability with socio-economic development pathways as determinants of impacts and disaster risk for both human society and natural ecosystems. It is important to note that the SREX acknowledges the fundamental role that values and aspirations play in people's perception of risk, of change and causality, and of imagining present and future situations. This value-based approach is put to work as a tool for managing the risks of extreme events and disasters enabling the recognition that socio-economic systems are in constant flux, and that there are many conflicting and contradictory values in play. The conceptual framing of the problem space offered by the SREX (Figure SPM 1-1) serves as a point of departure for many chapters in the AR5. Equally important is the conceptualization of a feasible solution space offered in the SREX. The solution space is further refined in the AR5 through emphasis on the co-benefits of adaptation and mitigation and the further development of transformational change to enable climate resilient development.

1.3.3. Relevant Findings from IPCC Working Group I Fifth Assessment Report

This section is a WGII synthesis of the AR5 WGI report that focuses on topics relevant to WGII science.[5] The relevant WGI chapters and sections where relevant are denoted in brackets [ ]. Where statements have *high confidence* or *likely* or better quantification, these qualifiers are dropped for readability. Likewise, many phrases are exact quotations but are not presented in quotes. An overall assessment of climate change over the last several decades from WGI is: Warming of the climate system is unequivocal, and since the 1950s, many of the observed changes are unprecedented over decades to millennia. Human influence on the climate system is clear; it has been detected in warming of the atmosphere and the ocean, in changes in the global water cycle, in reductions in snow and ice, in global mean sea level rise, and in changes in some climate extremes [SPM].

[FOOTNOTE 5: This narrative is taken primarily from the executive summaries of the WGI Final Draft chapters and is updated to reflect the WGI SPM approved on 27 September 2013 in Stockholm. For the most part, WGI findings summarized here have *high confidence* or a *likely* or better quantification are used here, and hence the confidence and likelihood statements have been dropped for readability. All quantitative ranges are *likely* (66% confidence) or *very likely* (90% confidence) or the modeled range (where noted). In a few instances, assessments with *low confidence* are included and so noted. This WGII narrative is intended to be accurate, but for the purpose here the exact WGI language has been edited and concatenated where possible (e.g., 1950 is substituted for "the middle of the 20th century"). Although quotation marks are not used, there remain long phrases that are direct quotes from the

WGI chapters. All numerical values are verbatim. For the level of uncertainty and the precise wording of the WGI assessment refer directly to the WGI approved SPM and the accepted chapters.]

Greenhouse gases and climate forcing. Human activities are the dominant cause of the observed increase in well mixed greenhouse gases (GHGs) since 1750 and of the consequent increase in climate forcing. The GHGs and their forcing continued to increase since AR4 [2, 6, 8]. Ozone and stratospheric water vapor also contribute to this forcing [8]. Aerosols partially offset this forcing and dominate the uncertainty in determining total anthropogenic forcing of climate change [8]. Total anthropogenic climate forcing is positive and has increased more rapidly since 1970 than during prior decades [8]. Present-day (2011) abundances of CO_2, CH_4, and N_2O exceed the range over the past 800,000 years found in ice cores [5, 6]. Annual emission of CO_2 from fossil fuels and cement production was 9.5 GtC in 2011, 54% above the 1990 level [SPM]. More than 20% of added CO_2 will remain in the atmosphere for longer than 1000 years [6]. Anthropogenic land use change has increased the land surface albedo (a negative forcing) and has also affected climate through the hydrologic cycle, but these effects are more uncertain and difficult to quantify [8.3.5]. Spatial gradients in forcing (i.e., aerosols, ozone, land use change) affect regional temperature responses [8]. Cumulative CO_2 emissions from 1750 to 2011 are 365 GtC (fossil fuel and cement) plus 180 GtC (deforestation and other land-use change) [SPM]. This 545 GtC represents about half of the 1000 GtC total that can be emitted and still keep global warming under 2 °C relative to the reference period 1861-1880 [SPM].

Air quality on continental scales. Future surface ozone (air pollution) decreases over most continents for RCP2.6, RCP4.5 and RCP6.0; but it increases for RCP8.5 due to rising CH_4 [11]. Changes in air quality for the RCPs are driven primarily by pollutant emissions and secondarily by climate change [11]. Air pollution is less under RCP scenarios than under SRES scenarios [11].

Surface Temperatures. Global mean surface temperature increased by 0.85 [0.65 to 1.06] °C over the period 1880–2012 (linear trend) [SPM] and by 0.72°C over the period 1951–2012 [2]. Each of the last three decades (from 1983 to 2012) has been successively warmer than any preceding decade since 1850 [SPM]. The decade 2003-2012 has been the warmest over the instrumental record, even though the rate of warming over 1998–2012 is smaller than the average rate since 1951 (0.05°C vs. 0.12°C per decade) [2]. For the Northern Hemisphere, the period 1983–2012 was the warmest of the last 1400 years [5]. The slower surface warming trend over the period 1998–2012 vs. 1951–2012 is due in roughly equal measure to a reduced trend in radiative forcing and a cooling contribution from internal, possibly oceanic variability [SPM]. Models reproduce the overall 1951-2012 warming trend, but not the smaller trend for 1998-2012 [9]. More than half of the 1951-2010 temperature increase is due to the observed anthropogenic increase in GHG [10]. The projected near term (2016-2035) mean surface temperature increase is 0.9–1.3 °C [11], and the long term (2081-2100) ranges from 0.9–2.3 °C (RCP2.6) to 3.2–5.4 °C (RCP8.5) (values are relative to 1850-1900, the earliest period for which global mean surface temperatures have been measured, and include the 0.6°C offset from that period to the model reference period 1986-2005) [SPM, 2, 12].

Global temperatures during the last interglacial period (~120,000 years ago) were never more than 2°C higher than pre-industrial levels [5]. By 2050 the global warming range is 1.5°C to 2.3°C above the 1850-1900 period based on the range across all RCPs and models [11.3.6]. Near the end of the century (2081-2100) warming above 4°C is typical of RCP8.5, while that of RCP2.6 remains below 2°C [12]. Orbital forcing will not trigger widespread glaciation during the next 1,000 years [5].

Climate models reproduce observed continental-scale mean surface temperature patterns; on sub-continental and smaller scales model capability is reduced, but is better than in AR4 [9]. Regional downscaling provides climate information at the smaller scales needed for impact studies and adds value in regions with highly variable topography and for various small-scale phenomena [9]. Anthropogenic warming in the 21st century will proceed more rapidly over land areas than over oceans, and the Arctic region is projected to warm most [11, 12].

Precipitation. Observed trends in global land-average precipitation have *low confidence* prior to 1950 and *medium confidence* thereafter [2]. Simulation of large-scale precipitation patterns has improved somewhat since AR4, but precipitation at regional scales is not well simulated [9]. Precipitation (global annual averages) will increase as temperatures increase, and the contrast between dry and wet regions and that between wet and dry seasons will increase over most of the globe [12]. By 2100 under RCP8.5, high latitudes will experience more precipitation;

many moist mid latitude regions will also experience more; while many mid latitude and subtropical arid and semi-arid regions will experience less [12]. These patterns are also typical of near-term climate change [11]. Trends will not be apparent in all regions, especially in the near term, because of natural variability and possible influences of aerosols and land use change [11].

Extreme temperatures and precipitation. Since 1950, the numbers of cold days/nights have decreased and the numbers of warm days/nights have increased globally [2]; and model simulation of these extreme events has improved since AR4 [9]. Since 1950, anthropogenic forcing has contributed to the observed changes in daily temperature extremes on the global scale [10]. In most regions the frequency of warm days/nights will increase in the next decades, while that of cold days/nights will decrease [11]. Increases in the frequency, duration and magnitude of hot extremes along with heat stress are expected, however occasional cold winter extremes will occur [12]. Extreme high temperatures (20-year return values) are projected to increase at a rate similar to or greater than the rate of increase of summer mean temperatures in most regions [12].

There is *no confidence* level assigned to projected near-term increases in the duration, intensity, and spatial extent of heat waves and warm spells [11], but in the long term heat waves will occur at higher frequency and longer duration in response to increased seasonal mean temperatures [12.4.3]. Since 1950, the frequency or intensity of heavy precipitation events has in North America and Europe [2, SPM]. Trends in small-scale severe weather events (e.g., hail, thunderstorms) have *low confidence* [2]. With global warming, the frequency and intensity of heavy/extreme precipitation events will increase over most mid latitude land and over wet tropical regions [12], and extreme daily precipitation rates will increase faster than the mean time average [7]. Most models underestimate the sensitivity of extreme precipitation to temperature variability/trends, and thus projections may underestimate these extremes [9].

Floods and droughts. In many regions, historical droughts (last 1000 years) and historical floods (last 500 years) have been more severe than those observed since 1900 [5]. Global-scale trends in drought or dryness since 1950 have *low confidence* due to lack of direct observations, methodological uncertainties and geographical inconsistencies; and hence confidence levels in global drought trends since the 1970s as reported in AR4 are overstated [2]. Regional trends are found: the frequency and intensity of drought has increased in the Mediterranean and West Africa, and it has decreased in central North America and north-west Australia since 1950 [2, 2.6.2.2]. There is low confidence in attributing drought changes to human influence [10]. Projected changes in soil moisture and surface runoff have *low confidence* in the near term [11], but by 2100 under RCP8.5, annual runoff will: decrease in parts of southern Europe, Middle East, and southern Africa; and increase in high northern latitudes [12]. Decreases in soil moisture with increased risk of agricultural drought are projected in presently dry regions [12].

Tropical cyclones, storms, and wave heights. Observed changes in tropical cyclone activity on a centennial scale as well as attribution to human influence have *low confidence* [2, 10]; however, the frequency and intensity of the strongest tropical cyclones in the North Atlantic has increased since the 1970s [2]. In a few studies, high-resolution atmospheric models have reproduced the year-to-year variability of Atlantic hurricane counts [9]. Future changes in intensity and frequency of tropical cyclones will vary by region, but basin-specific projections have *low confidence* [11, 14]. The maximum wind speed and precipitation rates of tropical cyclones will increase [14].

Circulation features have moved poleward since the 1970s, including a poleward shift of storm tracks and jet streams [2], and model simulation of these patterns has improved since AR4 [9]. Large-scale trends in storminess over the last century have *low confidence* [2, 2.6.4]. Projections of the position and strength of Northern Hemisphere storm tracks, especially for the North Atlantic basin, have *low confidence* [11, 12, 14]. With global warming, a shift to more intense individual storms and fewer weak storms is projected [12].

Mean significant wave height has increased over much of the Atlantic north of 45°N since 1950, with winter season trends of up to 20 cm/decade (*medium confidence*) [3, 3.4.5]. Wave heights and the duration of the wave season will increase in the Arctic Ocean as a result of reduced sea-ice extent [13]. Wave heights will increase in the Southern Ocean as a result of enhanced wind speeds [13].

Ocean warming, stratification, and circulation. Overall, the ocean has warmed throughout most of its depth over some periods since 1950, and this warming accounts for about 93% of the increase in Earth's energy inventory between 1971 and 2010 [3]. The upper ocean above 700 m has warmed from 1971 to 2010, and the thermal stratification has increased by about 4% above 200 m depth [3]. Anthropogenic forcings have made a substantial contribution this upper ocean warming [10]. Measurement errors in the temperature data sets have been corrected since the AR4 [10]. The global ocean continues to warm in all RCP scenarios [11, 12]. To date there is no observational evidence of a long-term trend in Atlantic Meridional Overturning Circulation [3]; and over the 21st century it is projected to weaken but not undergo an abrupt transition or collapse [12].

Ocean acidification and low-oxygen. Oceanic uptake of anthropogenic CO_2 results in gradual acidification of the ocean [3]. Since 1750 the pH of seawater has decreased by 0.1 (a 26% increase in hydrogen ion concentration) [3]. Increased storage of carbon by the oceans over the 21st century will increase acidification, decreasing pH further by 0.065 for RCP2.6 and 0.31 for RCP8.5 [6]. Aragonite under-saturation becomes widespread in parts of the Arctic and Southern Oceans and in some coastal upwelling systems at atmospheric CO_2 levels of 500–600 ppm [6]. Oxygen concentrations have decreased since the 1960s in the open ocean thermocline of many regions (*medium confidence*) [3]. By 2100, the oxygen content of the ocean will decrease by a few percent [6]. There is no consensus on projection of the very low oxygen (hypoxic or suboxic) waters in the open ocean [6].

Sea ice. Continuing the trends reported in AR4, the annual Arctic sea ice extent decreased at rate of 3.5 to 4.1 %/decade between 1979 and 2012 [4]. Over the past three decades, Arctic summer sea ice retreat was unprecedented and Arctic sea surface temperatures were anomalously high, compared with the last 1,450 years [SPM]. The Arctic average winter sea ice thickness decreased between 1980 and 2008 [4]. Current climate models reproduce the seasonal cycle and downward trend of Arctic sea-ice extent [9]. Anthropogenic forcings have contributed to Arctic sea ice loss since 1979 [10]. With global warming, further shrinking and thinning of Arctic sea ice cover is projected, and the Arctic Ocean will be nearly ice-free in September before 2050 for the high-warming scenarios like RCP8.5 [11, 12]. There is little evidence in climate models of an Arctic Ocean tipping point, i.e. the transition from a perennially ice-covered to a seasonally ice-free beyond which further sea ice loss is unstoppable and irreversible [12]. Annual Antarctic sea ice extent increased by 1.2 to 1.8 %/decade between 1979 and 2012 [4]. The scientific understanding of this observed increase has *low confidence* [10]. With global warming, Antarctic sea ice extent and volume is expected to decrease (*low confidence*) [12].

Ice sheets, glaciers, snow cover and permafrost. During periods over the past few million years that were globally warmer than present, the Greenland and West Antarctic Ice Sheets were smaller [5]. The Antarctic and Greenland Ice Sheets have on average lost ice during the last two decades, and the rate of loss has increased over the most recent decade to a sea-level rise equivalent of 0.6 mm/y for Greenland and 0.4 mm/yr for Antarctica [4]. Anthropogenic influences have contributed to Greenland ice loss since 1990 and to the retreat of glaciers since the 1960s, but there is *low confidence* in attributing the causes of Antarctic ice loss [10]. With global warming, model studies agree that the Greenland Ice Sheet will significantly decrease in area and volume, while the Antarctic Ice Sheet increases in most projections (*confidence* not assessed) [12, 13.4.4]. Global warming above a certain threshold (e.g., 2°C to 4°C above the 1850-1900 period) would lead to the near-complete loss of the Greenland Ice Sheet over a millennium or more (*confidence* not assessed) [13]. There is *low confidence* and little consensus on the likelihood of abrupt or nonlinear changes in components of the climate system over the 21st century [12].

Multiple lines of evidence support very substantial Arctic warming since the mid-20th century [SPM]. Almost all glaciers world-wide have continued to shrink since AR4 [4]. Over the last decade, most ice was lost from glaciers in Alaska, Canadian Arctic, Greenland Ice Sheet periphery, Southern Andes, and Asian Mountains [4]. Current glacier extents are out of balance with current climate, and glaciers will continue to shrink even without further warming [4]. Snow cover extent has decreased in the Northern Hemisphere, particularly in spring [4]; and reductions since 1970 have an anthropogenic component [10]. Permafrost temperatures have increased in most regions since the early 1980s: observed warming was up to 3°C in parts of Northern Alaska and 2°C in parts of the Russian European North [4, SPM]. With global warming, Northern Hemisphere snow cover extent and permafrost extent will decrease further [11, 12]. By 2100 the decrease in near-surface permafrost area ranges from 37% (RCP2.6) to 81% (RCP8.5) (*medium confidence*) [12].

Sea level rise. During the last interglacial period, when global mean temperatures were no more than 2°C above pre-industrial values (*medium confidence*), maximum global mean sea level was, for several thousand years, 5 m to 10 m higher than present [SPM, 5, 5.3.4, 5.6.1, 5.6.2, 13, 13.2.1] with substantial contributions from Greenland and Antarctic Ice Sheets [5, 13]. The rate of sea level rise since the mid-19th century has been larger than the mean rate during the previous two millennia [SPM]. Global mean sea level has risen at an average rate of 1.7 mm/yr from 1901 to 2010 and at a faster rate, 3.2 mm/yr, from 1993 to 2010 [3]. There is a substantial anthropogenic contribution to the global mean sea level rise since the 1970s [10]. The rate of global mean sea level rise during the 21st century will exceed that observed during 1971–2010 for all RCP scenarios [13]. For the period 2081–2100 compared to 1986–2005, process-based models project a global mean sea level rise ranging from 0.26 to 0.55 m (RCP2.6) up to 0.45 to 0.82 m (RCP8.5) [13]. By 2100 for RCP8.5, this rise is 0.52 to 0.98 m with a rate of rise reaching 8 to 16 mm/yr [SPM, 13]. Only collapse of marine-based sectors of the Antarctic Ice Sheet could cause global mean sea level to rise substantially above these projections, probably not exceeding several tenths of a meter (*medium confidence*) by 2100 [13]. Semi-empirical projections of 2100 sea level rise have a wide spread across models, some overlapping with the process-based models and some twice as large; however there is *low confidence* in these projections [13, 13.5.2-3]. If global warming exceeds a certain threshold resulting in near-complete loss of the Greenland Ice Sheet over a millennium or more (*confidence* not assessed), global mean sea level would rise about 7 m [13]. Future sea level change will vary regionally, but about 70% of the global coastlines are projected to experience a sea level change within 20% of the global mean [13].

The magnitude of extreme high sea level events has increased since 1970 [3]. Future sea level extremes will become more frequent beyond 2050, primarily as a result of increasing mean sea level [13]. By 2100 the frequency of current sea level extremes will increase by large factors in some regions [13, 13.7.2]. Region-specific projections of storminess and associated storm surges have *low confidence* [13].

<u>Climate patterns</u>. The El Niño-Southern Oscillation (ENSO) system has remained highly variable throughout the past 7,000 years with no discernible evidence of orbital modulation [5]. The observed variability of the ENSO in the tropical Pacific is now reproduced in most climate models [9]. Models project an eastward shift in the ENSO teleconnection patterns of temperature and precipitation variations over the North Pacific and North America [14]. ENSO remains the dominant mode of interannual climate variability in the future, and the ENSO precipitation anomalies will intensify due to increased moisture [14]. Aggregated over all monsoon systems and over the 21st century, the monsoon will increase in area and intensity while its circulation weakens [14]. Monsoon onset dates become earlier or do not change and monsoon retreat dates delay, lengthening the monsoon season [14]. Reduced warming and decreased precipitation is projected in the eastern tropical Indian Ocean, with increased warming and precipitation in the western, influencing East Africa and Southeast Asia precipitation [14].

1.3.4. Relevant Findings from IPCC Working Group III Fifth Assessment Report

The WGIII report assesses scientific research related to the mitigation of climate change. Because mitigation lowers the effects of climate change as well as the risks of extreme impacts, it is part of a broader policy strategy that includes adaptation to climate impacts. Both mitigation (WGIII) and adaptation (WGII) involve risk management in the context of many prevailing uncertainties. Uncertainties arise not only in the natural but also in human and social systems, including responses of these to policy interventions. It is possible that extreme climate impacts could play a central role in determining the level of mitigation, adaptation, and other policy responses to climate change [WGIII-2].

Over the last two WGIII assessment reports, one of the most important shifts in the scientific literature reflects underlying changes in the structure of the world economy: the underlying determinants of emissions – such as technologies, investment patterns, resource use, lifestyles, and development pathways in general – have not substantially shifted toward a low-GHG pattern despite the adoption of the UNFCCC and the Kyoto Protocol. In 2010, GHG emissions surpassed 50 Gt CO_2-eq (13.6 GtC), higher than in any previous year since 1750. Most of the emission growth between 2000 and 2010 came from fossil-fuel use in the energy and industry sectors, and took place in emerging economies. This emission growth was not met by significant GHG emission cuts in the industrialized country group, which continued to dominate historical long-term contributions to global CO_2 emissions. In 2010, median per capita GHG emissions in high income countries were roughly ten times higher than in low-income countries [WGIII-1, WGIII-5].

One of the central messages of AR5 WGIII is that technological and behavioural options exist that would allow the world's economies to follow pathways to much lower future emissions of GHGs. Since AR4 a substantial scenario literature has emerged on the technological, economic, and institutional conditions needed to achieve different long-term pathways leading to a stabilization of atmospheric GHG concentrations at different levels. A continuation of current trends of technological change in the absence of explicit climate change mitigation policies is not sufficient to bring about stabilization of greenhouse gases. Scenarios, which are more likely than not, to limit temperature increase to 2° C are becoming increasingly challenging, and most of these include a temporary overshoot of this concentration goal requiring net negative CO_2 emissions after 2050 and thus large-scale application of carbon dioxide removal technologies (CDR) [WGIII-6]. CDR methods are not mature and have biogeochemical and technological limitations to their potential on a global scale and carry side effects and long-term consequences on a global scale [WGI-SPM, WGIII g]. The increasing dependence of pathways on CDR options reduces the ability of policymakers to hedge risks freely across the mitigation technology portfolio [WGIII 6]. The literature highlights the importance of a systemic, cross-sectoral approach to mitigation. Approaches that emphasize only a subset of sectors or a subset of actions may miss synergies between sectors, raise the costs of mitigation, cause unexpected consequences, and prove insufficient to meet long-term mitigation goals [WGIII 6-11]. The costs of mitigation grow over-proportionally with the stringency of the stabilization target. Delays in mitigation and the unavailability of individual mitigation technologies increase the cost of mitigation and negatively affect the probability of meeting ambitious long-term atmospheric stabilization goals [WGIII 6].

Mitigation policies involve multiple actors and institutions at the international, regional, national and sub-national scales—from global treaties to firms and individual households. Since AR4 a body of literature has been emerging to explain how this multiplicity of actors and levels, focused on a multiplicity of interacting goals, affects the design and evolution of mitigation policy [WGIII-13, WGIII- 14, WGIII- 15]. Approaches to international cooperation in climate policies have increased and become more diverse ranging from strong multi-lateralism to harmonized national and regional policies [WGIII-13]. Linkages among regional, national, and sub-national programs may complement international cooperation. Carbon markets have been the focus of regional policy due, in part, to the greater opportunities for trade as carbon markets expand [WGIII-13, WGIII-14]. A combination of policies that address providing a price signal, removing barriers, and promoting long-term investments could be most effective. If there is no coordination within an integrated perspective then results in one area may be undone by results in another area, for instance through leakage and rebound effects [WGIII-15].

While mitigation efforts generate costs and trade-offs, they also offer possible synergies because many of the policies that can mitigate GHGs also help address other policy goals, such as managing air pollution, water scarcity, or energy security. Since AR4 a substantial literature has emerged on this topic, underscoring the link of mitigation to a wide range of societal goals, often designated sustainable development [WGIII-3, WGIII-4, WGIII-15].

Frequently Asked Questions

FAQ 1.1: On what information is the new assessment based, and how has that information changed since the last report, the IPCC Fourth Assessment Report in 2007? *[to be placed in Section 1.1.1, near Figure 1-1]*
Thousands of scientists from around the world contribute voluntarily to the work of the IPCC, which was established by the United Nations Environment Programme (UNEP) and the World Meteorological Organization (WMO) in 1988 to provide the world with a clear scientific assessment of the current scientific literature about climate change and its potential human and environmental impacts. Those scientists critically assess the latest scientific, technical, and socio-economic information about climate change from many sources. Priority is given to peer-reviewed scientific, technical, and social-economic literature, but other sources such as reports from government and industry can be crucial for IPCC assessments.

The body of scientific information about climate change from a wide range of fields has grown substantially since 2007, so the new assessment reflects the large amount that has been learned in the past six years. To give a sense of how that body of knowledge has grown, between 2005 and 2010 the total number of publications just on climate change impacts, the focus of Working Group II, more than doubled. There has also been a tremendous growth in the proportion of that literature devoted to particular countries or regions.

FAQ 1.2: How is the state of scientific understanding and uncertainty communicated in this assessment?
[to be placed in Section 1.1.2.2]

While the body of scientific knowledge about climate change and its impacts has grown tremendously, future conditions cannot be predicted with absolute certainty. Future climate change impacts will depend on past and future socioeconomic development, which influences emissions of heat-trapping gases, the exposure and vulnerability of society and ecosystems, and societal capacity to respond.

Ultimately, anticipating, preparing for, and responding to climate change is a process of risk management informed by scientific understanding and the values of stakeholders and society. The Working Group II assessment provides information to decisionmakers about the full range of possible consequences and associated probabilities, as well as the implications of potential responses. To clearly communicate well-established knowledge, uncertainties, and areas of disagreement, the scientists developing this assessment report use specific terms, methods, and guidance to characterize their degree of certainty in assessment conclusions.

FAQ 1.3: How has our understanding of the interface between human, natural,and climate systems expanded since the 2007 IPCC Assessment? *[to be placed in Section 1.1.4]*

Advances in scientific methods that integrate physical climate science with knowledge about impacts on human and natural systems have allowed the new assessment to offer a more comprehensive and finer-scaled view of the impacts of climate change, vulnerabilities to those impacts, and adaptation options, at a regional scale. That's important because many of the impacts of climate change on people, societies, infrastructure, industry, and ecosystems are the result of interactions between humans, nature, and specifically climate and weather, at the regional scale.

In addition, this new assessment from Working Group II greatly expands the use of the large body of evidence from the social sciences about human behavior and the human dimensions of climate change. It also reflects improved integration of what is known about physical climate science, which is the focus of Working Group I of the IPCC, and what is known about options for mitigating greenhouse gas emissions, the focus of Working Group III. Together this coordination and expanded knowledge inform a more advanced and finer-scaled, regionally detailed assessment of interactions between human and natural systems, allowing more detailed consideration of sectors of interest to Working Group II such as water resources, ecosystems, food, forests, coastal systems, industry, and human health.

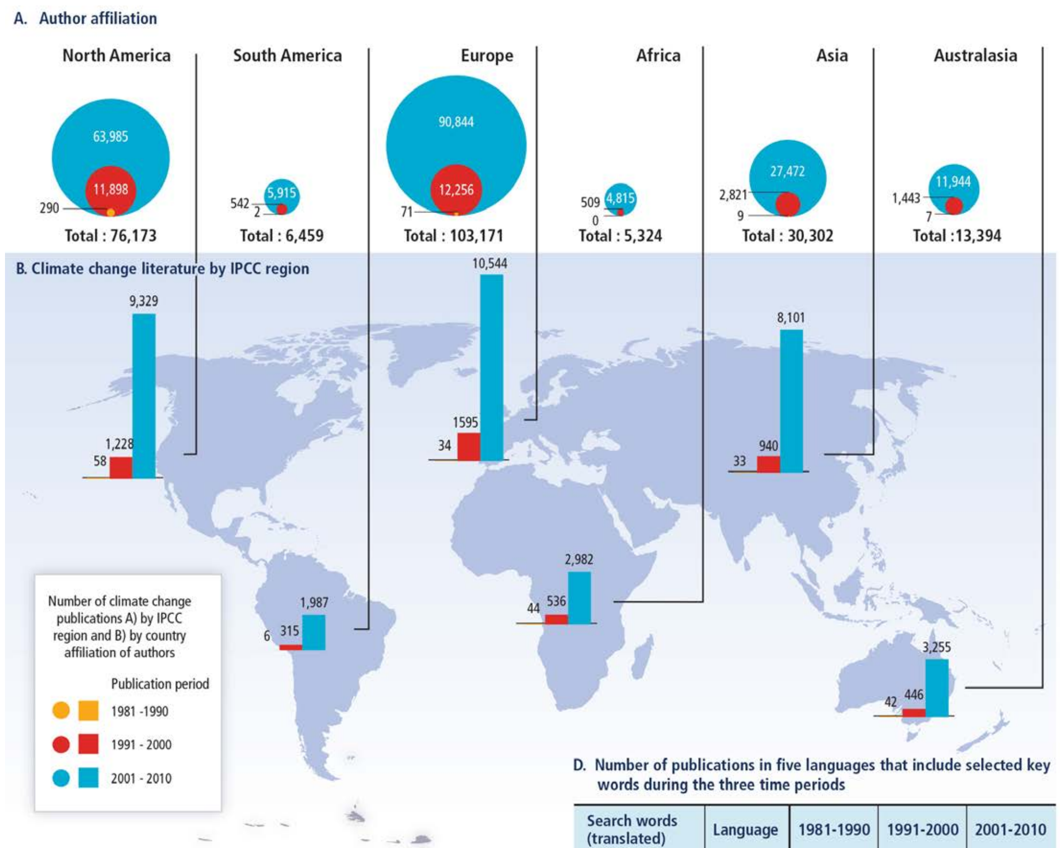
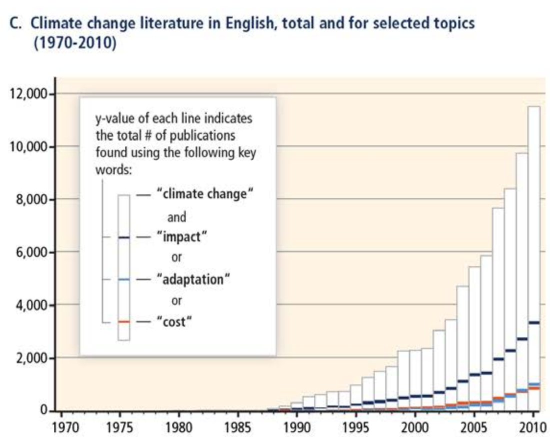
Table 1-3: Examples of linkages between the SRREN and the AR5 WGII with chapter references in parentheses.

SRREN findings	**WGII-AR5 findings**
Water resources	
Water availability limits the development of water cooled thermal power and hydropower. Environmental issues will continue to affect hydropower opportunities. (5.1, 5.6, 9.3)	Climate change is predicted affect surface and groundwater supplies. Development of water-dependent energy resources can also affect freshwater ecosystems. (4.4, 19.3)
Ocean systems	
Most ocean energy technologies are at the conceptual phase. Potential technologies include submarine turbines for tidal currents, ocean thermal energy conversion, and devices that harness energy of waves and salinity gradients. (6.2, 6.3, 6.5)	Offshore renewable energy introduces additional drivers of change for near- and offshore coastal and marine ecosystems and species. Ocean geoengineering approaches may have large environmental footprints. (5.5, 6.4)
Land cover changes	
The sustainability of bioenergy (i.e. lifecycle GHG emissions) is influenced by land and biomass resource management practices. (2.2, 2,8, 9.3)	Land cover change associated with biofuel production has food security implications; related land use change can alter ecosystems, species, and carbon storage. (19.4, 19.4, 27.2)
Resilient pathways	
Higher energy prices associated with transitions from fossil fuels to biofuels and other renewable energy sources may have adverse effects on socio-economic development. (9.4, 10.5)	The challenge is to identify and implement mixes of technological options that reduce net carbon emissions and support sustained economic and social growth. (20.3)
Regional effects	
Latin America is second to Africa for technical potential in producing bioenergy from rain-fed lignocellulosic feedstocks on unprotected grassland and woodlands. (2.2)	Bioenergy production requires large areas with risk of environmental degradation and may involve strong economic teleconnections (e.g., Latin America). (27.2, 27.3)
The quantity of water resources availability in Central and South America is the largest in the world. The region has the largest proportion of electricity generated through hydropower facilities. (5.2)	Hydropower, the main source of renewable energy available in Central and South America, is prone to serious effects of climate change. Altered river flows affect development in this region and use of land for biofuel production (27.3, 27.6, 27.8)





D. Number of publications in five languages that include selected key words during the three time periods

Search words (translated)	Language	1981-1990	1991-2000	2001-2010

Figure 1-1: Number of climate-change publications listed in the Scopus bibliographic database and results of literature searches conducted in four other languages. (a) Number of publications in English (as of July, 2011) summed by country affiliation of all authors of climate change publications and binned into IPCC regions. Each publication can be counted multiple times (i.e., the number of different countries in the author affiliation list). (b Number of climate change publications in English with individual countries mentioned in title, abstract, or key words (as of July, 2011) binned into IPCC regions for the decades 1981-1990, 1991-2000, and 2001-2010. Each publication can be counted multiple times if more than one country is listed.) (c) Annual global number of publications in English on climate change and related topics: impacts, adaptation, and costs for the years 1970-2010, as of September 2013. (d) Number of publications in five languages that include the words "climate change" and "climate change" plus "adaptation", "impact", and "cost" (translated) in the title, abstract or key words during the three decades ending in 2010. The following individuals conducted these literature searches during January, 2012-March, 2013: Valentin Przyluski (French), Huang Huanping (Chinese), Peter Zavialov and Vasily Kokore (Russian), and Saúl Armendáriz Sánchez (Spanish).

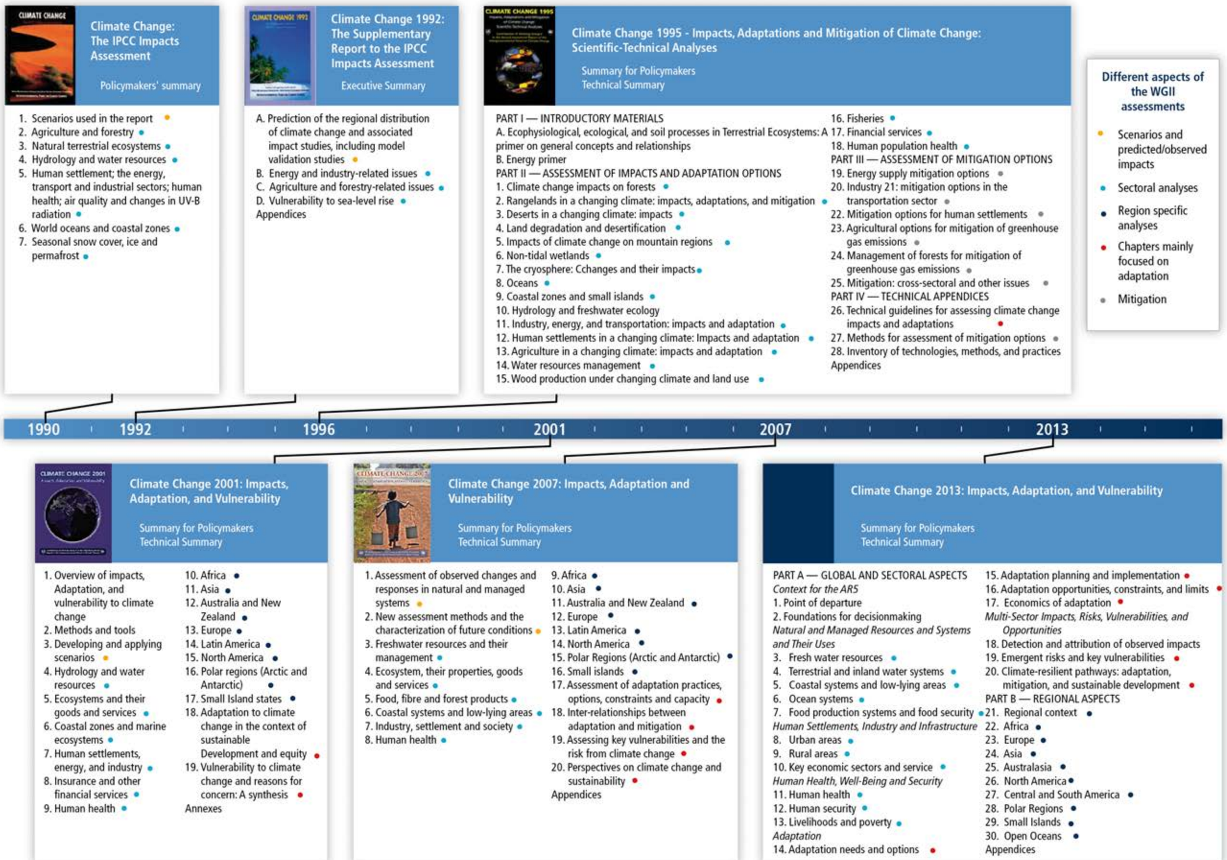

Figure 1-2: Tables of Contents for the Working Group II contributions to the IPCC Assessments since 1990. The FAR (IPCC, 1990) of IPCC Working Group II (WGII) focused on the impacts of climate change. For the SAR (IPCC, 1996) the WGII contribution included mitigation and adaptation with the impacts assessment. With the TAR (IPCC, 2001) and AR4 (IPCC, 2007) climate change mitigation reverted to WGIII, and WG II remained focused on impacts, adaptation, and vulnerability with an expanded effort on the regional scale.

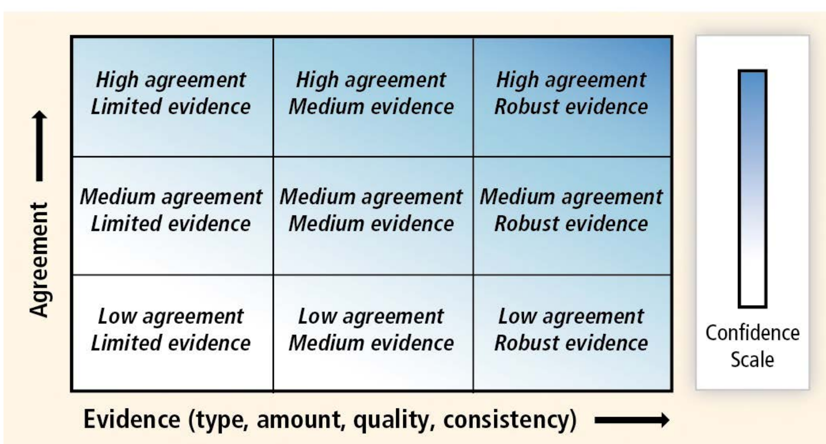

Figure 1-3: Evidence and agreement statements and their relationship to confidence. The coloring increasing towards the top-right corner indicates increasing confidence. Generally, evidence is most robust when there are multiple, consistent independent lines of high-quality evidence.

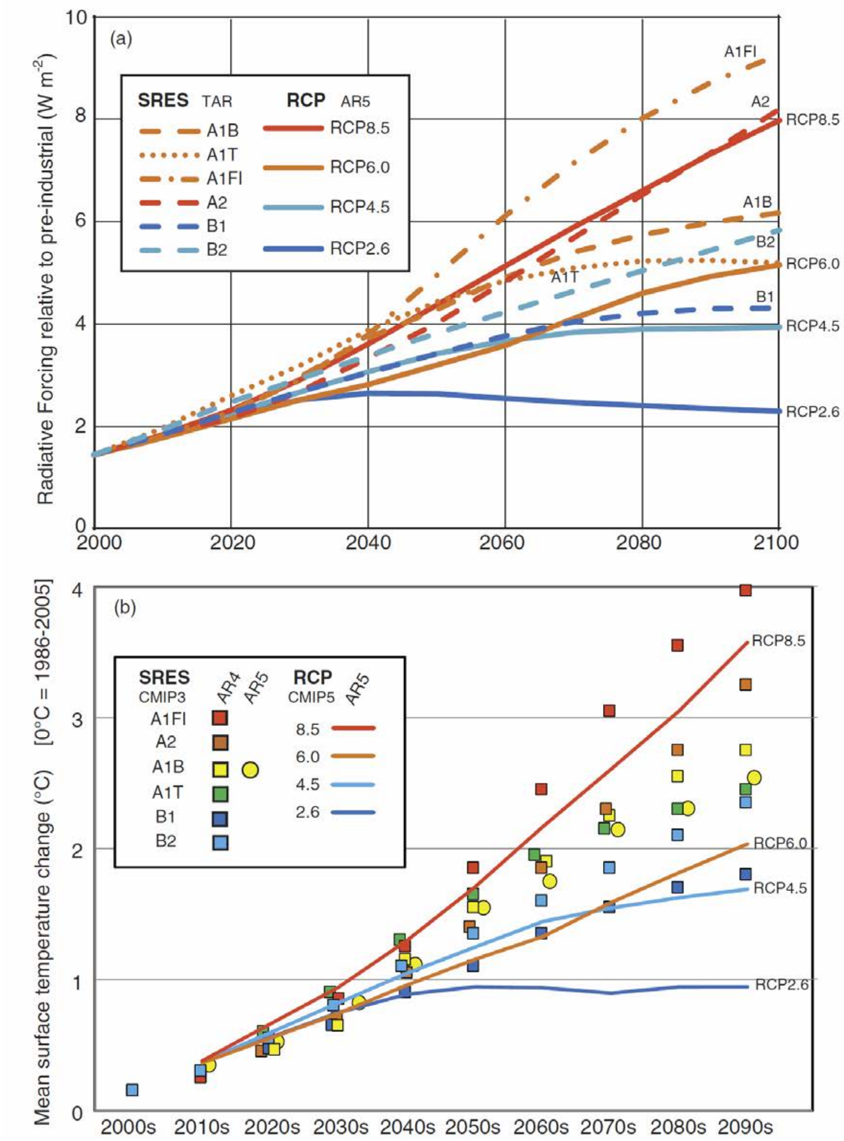

Figure 1-4: (a) Projected RF (W m^{-2}) and (b) global mean surface temperature change (°C) over the 21st century from the SRES and RCP scenarios. RF for the RCPs are taken from their published CO_2-equivalent (Meinshausen et al., 2011), and RF for SRES are from the TAR Appendix II (Table II.3.11). For RF derived from the CMIP5 models see WGI (Chapter 12.3, Tables AII.6.9-10). The ensemble total effective RF at 2100 for CMIP5 concentration-driven projections are 2.2, 3.8, 4.8 and 7.6 W m^{-2} for RCP2.6, RCP4.5, RCP6.0 and RCP8.5, respectively. The SRES RF are shifted upward by 0.12 W m^{-2} to match the RCPs at year 2000 since (i) the climate change over the 21st century is driven primarily by the changes in RF and (ii) the offset is due primarily to improvements in model physics including the aerosol RF. For more details and comparison with pre-SRES scenarios, see WGI Chapter 1 (Figure 1-15). Temperature changes are decadal averages (e.g., 2020s = 2016-2025) based on the model ensemble mean CMIP5 data for the RCPs (colored lines). The same analysis is applied to CMIP3 SRES A1B (yellow circles). See AR5 WGI Chapters 11, 12, Table AII.7.5. The colored squares show the temperature change for all six SRES scenarios based on a simple climate model tuned to the CMIP3 models (AR4 WG1 Figure 10.26). The difference between the yellow circles and yellow squares reflects differences between the simple model and analysis of the CMIP3 model ensemble in parallel with the CMIP5 data. For an assessment of uncertainties and *likely* ranges of temperature change see WGI Figures 11.24-25, 12.4-5, 12.40.
[Illustration to be redrawn to conform to IPCC publication specifications.]

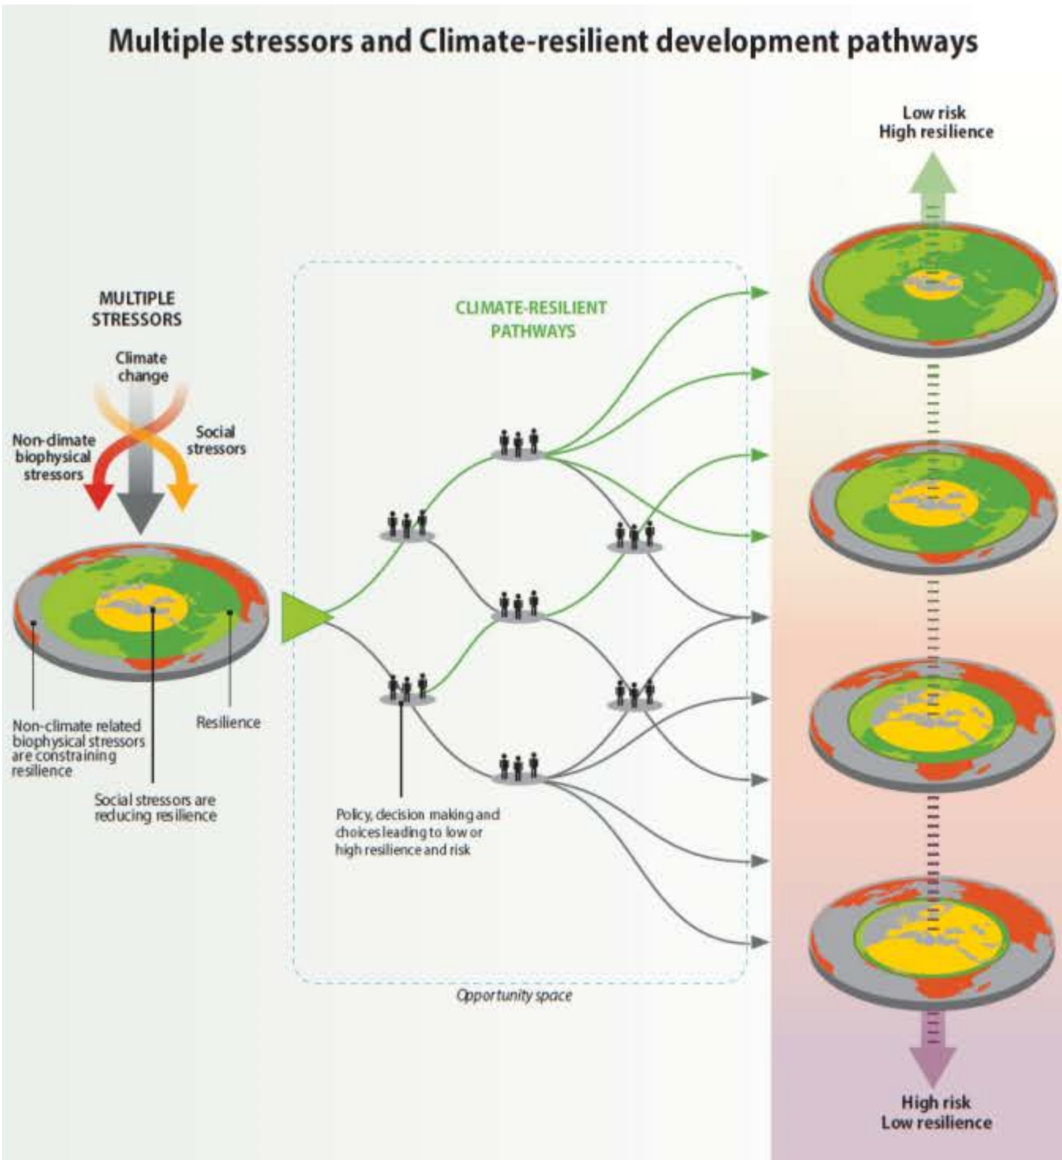

Figure 1-5: Multiple stressors and climate resilient pathways. The literature assessed in this report shows that climate change is just one of the many stressors that influence resilience. Climate-related risks interact with other biophysical stressors (such as biodiversity loss, soil erosion, and water contamination) and with social stressors (such as inequalities, poverty, gender discrimination, and lack of institutions). Rapid advances in knowledge about climate change and its impacts along with experience and other factors provide policy relevant information for decision making that can lead to climate-resilient development pathways. The decisions that societies make within this opportunity space can increase resilience and lower risks. Such decisions and choices are core elements of an iterative risk management process.
[Illustration to be redrawn to conform to IPCC publication specifications.]

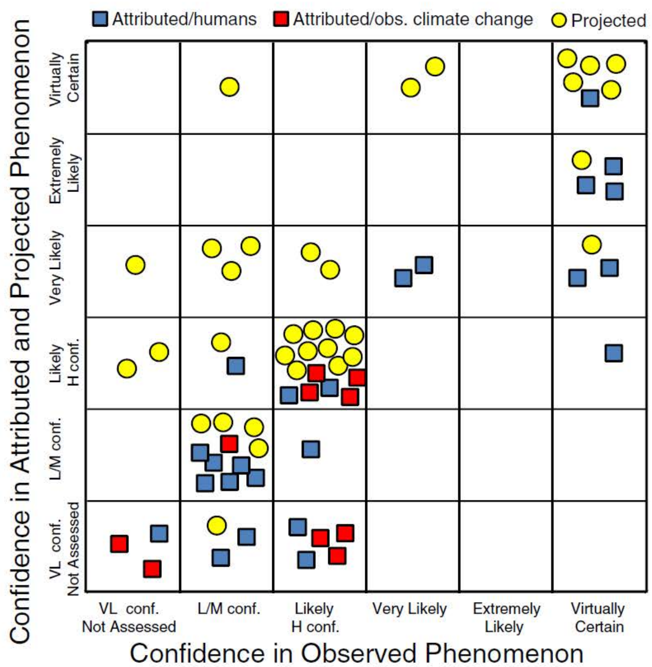

Figure 1-6: Confidence in the attributed (squares) and projected 21st century (yellow circles) changes in climate system phenomena plotted as a function of confidence in their detection to date. Phenomena and sources (AR4, SREX, AR5 WGI) are given in Table 1-2. Strength of confidence is sorted into the six bins as noted on the axes (very low confidence or not assessed; low or medium confidence; high confidence (no quantification) or likely; very likely; extremely likely; virtually certain). Attribution is to either human influence (blue squares, as used by WGI) or observed local/regional climate change (red squares, as used by WGII). Projections assume global warming exceeding 2°C. For AR5 WGII results see, *inter alia*, Chapters 18 and 19.
[Illustration to be redrawn to conform to IPCC publication specifications.]

Executive Summary

Decision support for impacts, adaptation and vulnerability is expanding from science-driven linear methods to a wide range of methods drawing from many disciplines *(high agreement, robust evidence)*. [2.1] This chapter introduces new material from disciplines including behavioural science, ethics and cultural and organizational theory, thus providing a broader perspective on climate change decision-making. Previous assessment methods and policy advice have been framed by the assumption that better science will lead to better decisions. [2.1.1] Extensive evidence from the decision sciences shows that while good scientific and technical information is necessary, it is not sufficient, and decisions require context-appropriate decision-support processes and tools *(high agreement, robust evidence)*. [2.1.2, 2.1.3, 2.2, 2.3] There now exists a sufficiently rich set of available methods, tools, and processes to support effective CCIAV decisions in a wide range of contexts *(medium agreement, medium evidence)*, although they may not always be appropriately combined or readily accessible to decision makers. [2.1.2, 2.1.3, 2.3]

Risk management provides a useful framework for most climate change decision making. [2.1.2] Iterative risk management is most suitable in situations characterised by large uncertainties, long time frames, the potential for learning over time, and the influence of both climate as well as other socio-economic and bio-physical changes *(high agreement, robust evidence)*. [2.1.2, 2.4.3] Complex decision-making contexts will ideally apply a broad definition of risk, address and manage relevant perceived risks, and assess the risks of a broad range of plausible future outcomes and alternative risk management actions *(medium agreement, robust evidence)*. [2.3] The resulting challenge is for people and organisations to apply CIAV decision-making processes in ways that address their specific aims. [2.2.1]

Decision support is situated at the intersection of data provision, expert knowledge and human decision-making at a range of scales from the individual to the organization and institution. Decision support is defined as a set of processes intended to create the conditions for the production of decision-relevant information and its appropriate use. [2.1.3, 2.2.1, 2.2, 2.3] Such support is most effective when it is context-sensitive, taking account of the diversity of different types of decisions, decision processes, and constituencies *(high agreement, robust evidence)*. [2.3.1, 2.3.3, 2.3.4] Boundary organizations, including climate services, play an important role in climate change knowledge transfer and communication, including translation, engagement and knowledge exchange *(high agreement, medium evidence)*. [2.2.2.1, 2.4.1, 2.4.2, 2.4.3]

Scenarios are a key tool for addressing uncertainty *(high agreement, robust evidence)*. They can be divided into those that explore how futures may unfold under various drivers (problem exploration) and those that test how various interventions may play out (solution exploration). [2.2.1.3][2.3.2] Historically, most scenarios used for CIAV assessments have been of the former type, though the latter are becoming more prevalent *(high agreement, medium evidence)*. The new RCP scenario process can address both problem and solution framing in ways that previous IPCC scenarios have not been able to *(medium agreement, limited evidence)*. [2.3.2]

CIAV decision making involves ethical judgments expressed at a range of institutional scales; the resulting ethical judgements are a key part of risk governance *(medium agreement, robust evidence)*. [2.2.1.1, 2.2.1.2, 2.2.1.4] Recognition of local and indigenous knowledge, and diverse stakeholder interests, values and expectations is fundamental to building trust within decision-making processes *(high agreement, robust evidence)* [2.2.1.2, 2.2.1.3, 2.4, 2.4.1].

Climate services aim to make knowledge about climate accessible to a wide range of decision makers. [2.4.1] In doing so they have to consider information supply, competing sources of knowledge and user demand. Knowledge transfer is a negotiated process that takes a variety of cultural values, orientations and alternative forms of knowledge into account *(high agreement, medium evidence)*. [2.4.1, 2.4.2]

Climate change response can be linked with sustainable development through actions that enhance resilience, the capacity to change in order to maintain the same identity while also maintaining the capacity to adapt, learn and transform. Mainstreamed adaptation, disaster risk management, and new types of governance and institutional arrangements are being studied for their potential to support the goal of enhanced resilience *(high agreement, medium evidence)*. [2.5.2]

Transformational adaptation may be required if incremental adaptation proves insufficient *(high agreement, medium evidence)*. This process may require changes in existing social structures, institutions, and values, which can be facilitated by iterative risk management and triple-loop learning that considers a situation and its drivers, along with the underlying frames and values that provide the situation context. **[2.1.2, 2.5.3]**

2.1. Introduction and Key Concepts

This chapter addresses the foundations of decision making with respect to climate impact, adaptation and vulnerability (CIAV). The Fourth Assessment Report (AR4) summarized methods for assessing CIAV (Carter et al., 2007), which we build on by surveying the broader literature relevant for decision making.

Decision making under climate change has largely been modelled on the scientific understanding of the cause-and-effect process whereby increasing greenhouse gas emissions cause climate change, resulting in changing impacts and risks, potentially increasing vulnerability to those risks. The resulting decision-making guidance on impacts and adaptation follows a rational-linear process that identifies potential risks then evaluates management responses (e.g., Carter et al., 1994; Feenstra et al., 1998; Parry and Carter, 1998; Fisher et al., 2007). This process has been challenged on the grounds that it does not adequately address the diverse contexts within which climate decisions are being made, often neglects existing decision-making processes, and overlooks many cultural and behavioural aspects of decision-making (Smit and Wandel, 2006; Sarewitz and Pielke Jr, 2007; Dovers, 2009; Beck, 2010). While more recent guidance on CIAV decision-making typically accounts for sectoral, regional and socio-economic characteristics (21.3), the broader decision-making literature is still not fully reflected in current methods. This is despite an increasing emphasis on the roles of societal impacts and responses to climate change in decision-making methodologies *(high confidence)* (1.1, 1.2, 21.2.1).

The main considerations that inform the decision-making contexts addressed here are knowledge generation and exchange, who makes and implements decisions, the issues being addressed and how these can be addressed. These decisions occur within a broader social and cultural environment. Knowledge generation and exchange includes knowledge generation, development, brokering, exchange and application to practice. Decision makers include policy-makers, managers, planners and practitioners, and range from individuals to organizations and institutions (Table 21-1). Relevant issues include all areas affected directly and indirectly by climate impacts or by responses to those impacts, covering diverse aspects of society and the environment. These issues include consideration of values, purpose, goals, available resources, the time over which actions are expected to remain effective and the extent to which the objectives being pursued are regarded as appropriate. The purpose of the decision in question; e.g., assessment, strategic planning or implementation, will also define the framework and tools needed to enable the process. This chapter does not provide any standard template or instructions for decision-making, nor does it endorse particular decisions over others.

The remainder of this chapter is organized as follows. Section 2.1.2 addresses risk management, which provides an overall framework suitable for CIAV decision-making; Section 2.1.3 introduces decision support, Section 2.2 discusses contexts for decision-making, Section 2.3 methods, tools and process, Section 2.4 support for and application of decision-making and Section 2.5 describes some of the broader contexts influencing CIAV decision making.

2.1.1. Decision-Making Approaches in this Report

The overarching theme of the chapter and the AR5 report is managing current and future climate risks (1.2.4, 16.2, 19.1), principally through adaptation (Chapters 14–17), but also through resilience and sustainable development informed by an understanding of both impacts and vulnerability (19.2). The International Standard ISO:31000 defines risk as *the effect of uncertainty on objectives* (ISO, 2009) and the Working Group II glossary defines risk as: *The potential for consequences where something of human value (including humans themselves) is at stake and where the outcome is uncertain* (Rosa, 2003). However, the glossary also refers to a more operational definition for assessing climate-related hazards: *risk is often represented as probability of occurrence of hazardous events or trends multiplied by the consequences if these events occur.* Risk can also refer to an uncertain opportunity or benefit (see 2.2.1.3). This chapter takes a broader perspective than the latter by including risks associated with taking action (e.g., will this adaptation strategy be successful?) and the broader socially-constructed risks that surround 'climate change' (e.g., fatalism, hope, opportunity and despair).

Because all decisions on CIAV are affected by uncertainty and focus on valued objectives, all can be considered as decisions involving risk (e.g., Giddens, 2009)*(high confidence)*. AR4 endorsed iterative risk management as a suitable decision-support framework for CIAV assessment because it offers formalized methods for addressing uncertainty, involving stakeholder participation, identifying potential policy responses, and evaluation of those responses (Carter et al., 2007; IPCC, 2007a; Yohe et al., 2007). The literature shows significant advances on all these topics since AR4 (1.1.4), greatly expanding methodologies for assessing impacts, adaptation and vulnerability in a risk context (Agrawala and Fankhauser, 2008; Hinkel, 2011; Jones and Preston, 2011; Preston et al., 2011).

Many different risk methodologies, such as financial, natural disaster, infrastructure, environmental health and human health risk methodologies are relevant for CIAV decision-making *(very high confidence)*. Each methodology utilizes a variety of different tools and methods. For example, the standard CIAV methodology follows a top-down cause and effect pathway as outlined above. Others follow a bottom-up pathway, starting with a set of decision-making goals that may be unrelated to climate and consider how climate may affect those goals (see also 15.2.1, 15.3.1). Some methodologies such as vulnerability, resilience and livelihood assessments are often considered as being different from traditional risk assessment, but may be seen as dealing with particular stages within a longer term iterative risk management process. For example, developing resilience can be seen as managing a range of potential risks that are largely unpredictable; and sustainable development aims to develop a social-ecological system robust to climate risks.

A major aim of decision-making is to make good or better decisions. Good and better decisions with respect to climate adaptation are frequently mentioned in the literature but no universal criterion exists for a good decision, including a good climate-related decision (Moser and Ekstrom, 2010). This is reflected in the numerous framings linked to adaptation decision making, each having its advantages and disadvantages (Preston et al., 2013; 15.2.1). Extensive evidence from the decision sciences shows that good scientific and technical information alone is rarely sufficient to result in better decisions (Bell and Lederman, 2003; Jasanoff, 2010; Pidgeon and Fischhoff, 2011) *(high confidence)*. Aspects of decision-making that distinguish climate change from most other contexts are the long time scales involved, the pervasive impacts and resulting risks and the 'deep' uncertainties attached to many of those risks (Kandlikar et al., 2005; Ogden and Innes, 2009; Lempert and McKay, 2011). These uncertainties include not only future climate but also socio-economic change and potential changes in norms and values within and across generations.

2.1.2. Iterative Risk Management

Iterative risk management involves an ongoing process of assessment, action, reassessment, and response (Kambhu et al., 2007; IRGC, 2010) that will continue – in the case of many climate-related decisions – for decades if not longer (Committee on America's Climate Choices National Research Council, 2011). This development is consistent with an increasing focus on risk governance (Power, 2007; Renn, 2008), the integration of climate risks with other areas of risk management (Hellmuth et al., 2011; Measham et al., 2011) and a wide range of approaches for structured decision-making involving process uncertainty (Ohlson et al., 2005; Wilson and McDaniels, 2007; Ogden and Innes, 2009; Martin et al., 2011).

[INSERT FIGURE 2-1 HERE
Figure 2-1: Iterative risk management framework depicting the assessment process, and indicating multiple feedbacks within the system and extending to the overall context. Adapted from Willows and Connell (2003).]

Two levels of interaction can be recognised within the iterative risk management process: one internal and one external (Figure 2-1). External factors are present through the entire process and shape the process outcomes. The internal aspects describes the adaptation process itself. The first major internal iteration (in yellow) reflects the interplay with the analysis phase by addressing the interactions between evolving risks and their feedbacks (not shown) and during the development and choice of options. This process may also require a revision of criteria and objectives. This phase ends with decisions on the favoured options being made. A further internal iteration covers the implementation of actions and their monitoring and review (in orange). Throughout all stages the process is reflexive, in order to enable changes in knowledge, risks or circumstances to be identified and responded to. At the end of the implementation stage, all stages are evaluated and the process starts again with the scoping phase. Iterations can be successive, on a set timetable, triggered by specific criteria or informally by new information informing risk or a change in the policy environment. An important aspect of this process is to recognise emergent risks and respond to them (19.2.3–5, 19.3).

Complexity is an important attribute for framing and implementing decision-making processes *(very high confidence)*. Simple, well-bounded contexts involving cause and effect can be addressed by straightforward linear methods. Complicated contexts require greater attention to process but can generally be unravelled providing an ultimate solution (Figure 2-2). However, when complex environments interact with conflicting values they become associated with wicked problems. Wicked problems are not well bounded, are framed differently by various groups and individuals, harbour large scientific to existential uncertainties and have unclear solutions and pathways to those solutions (Rittel and Webber, 1973; Australian Public Service Commission, 2007). Such ‘deep uncertainty’ cannot easily be quantified (Dupuy and Grinbaum, 2005; Kandlikar et al., 2005). Another important attribute of complex systems is *reflexivity*, where cause and effect feed back into each other (see glossary). For example, actions taken to manage a risk will affect the outcomes, requiring iterative processes of decision-making *(very high confidence)*. Under climate change, calculated risks will also change with time as new knowledge becomes available (Ranger et al., 2010).

[INSERT FIGURE 2-2 HERE
Figure 2-2: Hierarchy of simple, complicated, and complex risks, showing how perceived risks multiply and become less connected with calculated risk with increasing complexity. Also shown are major characteristics of assessment methods for each level of complexity.]

In complex situations, socio-cultural and cognitive-behavioural contexts become central to decision-making. This requires combining the scientific understanding of risk with how risks are framed and perceived by individuals, organisations and institutions (Hansson, 2010). For that reason, formal risk assessment is moving from a largely technocratic exercise carried out by experts to a more participatory process of decision support (Fiorino, 1990; Pereira and Quintana, 2002; Renn, 2008), although this process is proceeding slowly (Christoplos et al., 2001; Pereira and Quintana, 2002; Bradbury, 2006; Mercer et al., 2008).

Different traditional and modern epistemologies, or 'ways of knowing' exist for risk (Hansson, 2004; Althaus, 2005; Hansson, 2010), vulnerability (Weichselgartner, 2001; O'Brien et al., 2007) and adaptation assessments (Adger et al., 2009) affecting the way they are framed by various disciplines and are also understood by the public (Garvin, 2001; Adger, 2006; Burch and Robinson, 2007). These differences have been identified as a source of widespread misunderstanding and disagreement. They are also used to warn against a uniform epistemic approach (Hulme, 2009; Beck, 2010), a critique that has been levelled against previous IPCC assessments (e.g., Hulme and Mahony, 2010).

The following three types of risk have been identified as important epistemological constructs (Thompson, 1986; Althaus, 2005; Jones, 2012):

1) Idealized risk: the conceptual framing of the problem at hand. For example, dangerous anthropogenic interference with the climate system is how climate change risk is idealized within the UNFCCC.
2) Calculated risk: the product of a model based on a mixture of historical (observed) and theoretical information. Frequentist or recurrent risks often utilize historical information whereas single-event risks may be unprecedented, requiring a more theoretical approach.
3) Perceived risk: the subjective judgement people make about an idealized risk (see also 19.6.1.4).

These different types show risk to be partly an objective threat of harm and partly a product of social and cultural experience (Kasperson et al., 1988; Kasperson, 1992; Rosa, 2008). The aim of calculating risk is to be as objective as possible, but the subjective nature of idealized and perceived risk reflects the division between positivist (imposed norms) and constructivist (derived norms) approaches to risk from the natural and social sciences respectively (Demeritt, 2001; Hansson, 2010). Idealized risk is important for framing and conceptualising risk and will often have formal and informal status in the assessment process, contributing to both calculated and perceived risk. These types of risk combine at the societal scale as socially constructed risk, described and assessed in a wide range of research literature such as psychology, anthropology, geography, ethics, sociology and political science (2.2.1.2, 19.6.1.4).

Acceptance of the science behind controversial risks is strongly influence by social and cultural values and beliefs (Leiserowitz, 2006; Kahan et al., 2007; Brewer and Pease, 2008). Risk perceptions can be amplified socially where events pertaining to hazards interact with psychological, social, institutional, and cultural processes in ways that heighten or attenuate individual and social perceptions of risk and shape risk behaviour (Kasperson et al., 1988; Renn et al., 1992; Pidgeon et al., 2003; Rosa, 2003; Renn, 2011). The media have an important role in propagating both calculated and perceived risk (Llasat et al., 2009), sometimes to detrimental effect (Boykoff and Boykoff, 2007; Oreskes and Conway, 2010; Woods et al., 2012).

Understanding how these perceptions resonate at an individual and collective level can help overcome constraints to action (Renn, 2011). Science is most suited to calculating risk in areas where it has predictive skill and will provide better estimates than may be obtained through more informal methods (Beck, 2000), but an assessment of what is at risk generally needs to be accepted by stakeholders (Richard Eiser et al., 2012). Therefore, the science always sits within a broader social setting (Jasanoff, 1996; Demeritt, 2001; Wynne, 2002; Demeritt, 2006), often requiring a systems approach where science and policy are investigated in tandem, rather than separately (Pahl-Wostl, 2007; Ison, 2010) *(very high confidence)*. These different types of risk give rise to complex interactions between formal and informal knowledge that cannot be bridged by better science or better predictions but require socially and culturally mediated processes of engagement *(high confidence)*.

2.1.3. Decision Support

The concept of *decision support* provides a useful framework for understanding how risk-based concepts and information can help enhance decision-making (McNie, 2007; National Research Council (US) Panel on Design Issues for the NOAA Sectoral Applications Research Program et al., 2007; Moser, 2009; Romsdahl and Pyke, 2009; Kandlikar et al., 2011; Pidgeon and Fischhoff, 2011) The concept also helps situate methods, tools, and processes intended to improve decision-making within appropriate institutional and cultural contexts.

Decision support is defined as "a set of processes intended to create the conditions for the production of decision-relevant information and its appropriate use" (National Academy of Sciences, 2009). Information is decision-relevant if it yields deeper understanding of, or is incorporated into making a choice that improves outcomes for decision makers and stakeholder or precipitates action to manage known risks. Effective decision support provides users with information they find useful because they consider it credible, legitimate, actionable, and salient (e.g., Jones et al., 1999; Cash et al., 2003; Mitchell, 2006; Reid et al., 2007). Such criteria can be used to evaluate decision support and such evaluations lead to common principles of effective decision support, which have been summarized in (National Research Council, 2009) as:

1) Begins with user's needs, not scientific research priorities. Users may not always know their needs in advance, so user needs are often developed collaboratively and iteratively among users and researchers.
2) Emphasizes processes over products. While the information products are important, they are likely to be ineffective if they are not developed to support well-considered processes.
3) Incorporates systems that link users and producers of information. These systems generally respect the differing cultures of decision makers and scientists, but provide processes and institutions that effectively link individuals from these differing communities
4) Builds connections across disciplines and organizations, in order to provide for the multidisciplinary character of the needed information and the differing communities and organizations in which this information resides
5) Seeks institutional stability, either through stable institutions and/or networks, which facilitates building the trust and familiarity needed for effective links and connections among information users and producers in many different organizations and communities.
6) Incorporates learning, so that all parties recognize the need for and contribute to the implementation of decision support activities structured for flexibility, adaptability, and learning from experience.

These principles can lead to different decision support processes depending on the stage and context of the decision in question. For instance, decision support for a large water management agency operating an integrated system serving millions of people will have different needs than a small town seeking to manage its ground water supplies. A community in the early stages of developing a response to climate change may be more focused on raising awareness of the issue among its constituents, while a community with a well-developed understanding of its risks may be more focused on assessing trade-offs and allocating resources.

2.2. Contexts for Decision-Making

This section surveys aspects of decision-making that relate to context setting. Social context addresses cultural values, psychology, language and ethics (2.2.1) and institutional context covers institutions and governance (2.2.2).

2.2.1. Social Context

Decision support for CIAV must recognize that diverse values, language uses, ethics and human psychological dimensions play a crucial role in the way that people use and process information and take decisions (Kahan and Braman, 2006; Leiserowitz, 2006). As illustrated in Figure 2-1, the context defines and frames the space in which decision-making processes operate.

2.2.1.1. Cultural Values and Determinants

Cultural differences allocate values and guide socially mediated change. Five value dimensions that show significant cross-national variations are: power distance, individualism/collectivism, uncertainty avoidance, long/short term orientation and masculinity/femininity (Hofstede, 1980; Hofstede and Hofstede, 2001; Hofstede et al., 2010). Power distance and individualism/collectivism both show a link to climate via latitude; the former relates to willingness to conform to top-down directives, whereas the latter relates to the potential efficacy of market/community-based strategies. Uncertainty avoidance and long-term orientation show considerable variation between countries (Hofstede et al., 2010) potentially producing significant differences in risk perception and agency.

Environmental values have also been linked to cultural orientation. Schultz et al. (2004) identified the association between self and nature in people as being implicit – informing actions without specific awareness. A strong association was linked to a more connected self and a weaker association with a more egoistic self. Explicit environmental values can substantially influence climate change-related decision-making processes (Nilsson et al., 2004; Milfont and Gouveia, 2006; Soyez et al., 2009) and public behaviour toward policies (Stern and Dietz, 1994; Xiao and Dunlap, 2007). Schaffrin (2011) concludes that geographical aspects, vulnerability and potential policy benefits associated with a given issue can influence individual perceptions and willingness to act (De Groot and Steg, 2007, 2008; Shwom et al., 2008; Milfont et al., 2010). Cultural values can interrelate with specific physical situations of climate change (Corraliza and Berenguer, 2000), or seasonal and meteorological factors influencing people's implicit connections with nature (Duffy and Verges, 2010). Religious and sacred values are also important (Goloubinoff et al., 1998; Katz et al., 2002; Lammel et al., 2008), informing the perception of climate change and risk, as well as the actions to adapt (Crate and Nuttal, 2009; 16.3.1.3). The role of protected values (values that people will not trade off, or negotiate) can also be culturally and spiritually significant (Baron and Spranca, 1997; Baron et al., 2009; Hagerman et al., 2010). Adger et al. (2013) emphasise the importance of cultural values in assessing risks and adaptation options, suggesting they are at least as important as economic values in many cases, if not more so. These aspects are important for framing and conceptualizing CIAV decision-making. Cultural and social barriers are described in Chapter 16.3.2.7.

Two distinct ways of thinking – holistic and analytical thinking – reflect the relationship between humans and nature and are cross-culturally and even intra-culturally diverse (Gagnon Thompson and Barton, 1994; Huber and Pedersen, 1997; Atran et al., 2005; Ignatow, 2006; Descola, 2010; Ingold, 2011). Holistic thinking is primarily gained through experience and is dialectical, accepting contradictions and integrating multiple perspectives. Characteristic of collectivist societies, the holistic conceptual model considers that social obligations are reciprocal and individuals take an active part in the community for the benefit of all (Peng and Nisbett, 1999; Nisbett et al., 2001; Lammel and Kozakai, 2005; Nisbett and Miyamoto, 2005). Analytical thinking isolates the object from its broader context, understanding its characteristics through categorization, and predicting events based on intrinsic rules. In the analytic conceptual model, individual interests take precedence over the collective; the self is independent and communication comes from separate fields. These differences influence the understanding of complex systemic phenomena such as climate change (Lammel et al., 2011; Lammel et al., 2012; Lammel et al., 2013) and decision making practices (Badke-Schaub and Strohschneider, 1998; Strohschneider and Güss, 1999; Güss et al., 2010).

The above models vary greatly across the cultural landscape, but neither model alone is sufficient for decision making in complex situations *(high confidence)*. At a very basic level, egalitarian societies may respond more to community based adaptation in contrast to more individualistic societies that respond to market-based forces *(medium confidence)*. In small-scale societies, knowledge about climate risks are often integrated into a holistic view of community and environment (e.g., Katz et al., 2002; Strauss and Orlove, 2003; Lammel et al., 2008). Many studies highlight the importance of integrating local, traditional knowledge with scientific knowledge when assessing CIAV (Magistro and Roncoli, 2001; Krupnik and Jolly, 2002; Vedwan, 2006; Nyong et al., 2007; Dube and Sekhwela, 2008; Crate and Nuttal, 2009; Mercer et al., 2009; Roncoli et al., 2009; Green and Raygorodetsky, 2010; Orlove et al., 2010; Crate, 2011; Nakashima et al., 2012; Chapter 12.3, 12.3.1, 12.3.2, 12.3.3, 12.3.4, 14.4.5, 14.4.7, 15.3.2.7, 25.8.2, 28.2.6.1, 28.4.1). For example, a case study in Labrador (Canada) demonstrated the need to account for local material and symbolic values because they shape the relationship to the land, underlie the way of life, influence the intangible effects of climate change, and can lead to diverging views on adaptations (Wolf et al., 2012). In Kiribati, the integration of local cultural values attached to resources/assets is fundamental to adaptation planning and water management, otherwise technology will not be properly utilised (Kuruppu, 2009).

2.2.1.2. Psychology

Psychology plays a significant role in climate change decision-making (Gifford, 2008; Swim et al., 2010; Anderson, 2011). Important psychological factors for decision-making include: perception, representation, knowledge acquisition, memory, behaviour, emotions and understanding of risk (Böhm and Pfister, 2000; Leiserowitz, 2006; Lorenzoni et al., 2006; Oskamp and Schultz, 2006; Sterman and Sweeney, 2007; Gifford, 2008; Kazdin, 2009; Sundblad et al., 2009; Reser et al., 2011; Swim et al., 2011).

Psychological research contributes to understanding on both risk perception and the process of adaptation. Several theories, such as multi-attribute utility theory (Keeney, 1992), prospect theory (Kahneman and Tversky, 1979; Hardman, 2009), and cumulative prospect theory relate to decision making under uncertainty (Tversky and Kahneman, 1992), especially to risk perception and agency. Adaptation in complex situations pits an unsure gain against an unsure loss, so creates an asymmetry in preference that magnifies with time as gains/losses are expected to accrue in future. Decisions focusing on values and uncertainty are therefore subject to framing effects. Recent cognitive approaches include the one-reason decision process that uses limited data in a limited time period (Gigerenzer and Goldstein, 1996) or decision by sampling theory that samples real-world data to account for the cognitive biases observed in behavioural economics (Stewart et al., 2006; Stewart and Simpson, 2008). Risk perception is further discussed in Chapter 19.6.1.4.

Responses to new information can modify previous decisions, even producing contradictory results (Grothmann and Patt, 2005; Marx et al., 2007). Although knowledge about climate change is necessary (Milfont, 2012), understanding such knowledge can be difficult (Rajeev Gowda et al., 1997; Boyes et al., 1999; Andersson and Wallin, 2000). Cognitive obstacles in processing climate change information include psychological distances with four theorized dimensions: temporal, geographical, social distance and uncertainty (Spence et al., 2012, see also 25.4.3). Emotional factors also play an important role in climate change perception, attitudes, decision making and actions (Meijnders et al., 2002; Leiserowitz, 2006; Klöckner and Blöbaum, 2010; Fischer and Glenk 2011; Roeser, 2012) and even shape organizational decision making (Wright and Nyberg, 2012). Other studies on attitudes and behaviours relevant to climate change decision-making, include place attachment (Scannell and Gifford, 2013; chapter 25.4.3), political affiliation (Davidson and Haan, 2011), and perceived costs and benefits (Tobler et al., 2012). Time is a critical component of action-based decision making (Steel and König, 2006). As the benefits of many climate change actions span multiple temporal scales, this can create a barrier to effective motivation for decisions through a perceived lack of value associated with long term outcomes.

Protection Motivation Theory (Rogers, 1975; Maddux and Rogers, 1983), which proposes that a higher personal perceived risk will lead to a higher motivation to adapt, can be applied to climate change-related problems (e.g., Grothmann and Reusswig, 2006; Cismaru et al., 2011). The Person-relative-to-event approach predicts human coping strategies as a function of the magnitude of environmental threat (Mulilis and Duval, 1995; Duval and Mulilis, 1999; Grothmann et al., 2013). People’s responses to environmental hazards and disasters are represented in the multistage Protective Action Decision Model (Lindell and Perry, 2012). This model helps decision makers to respond to long-term threat and apply it in long-term risk management. Grothmann and Patt (2005) developed and tested a socio-cognitive model of proactive private adaptation to climate change showing that perceptions of adaptive capacities were important as well as perceptions of risk. If a perceived high risk is combined with a perceived low adaptive capacity (see 2.4.2.2; Glossary), the response is fatalism, denial and wishful thinking.

Best-practice methods for incorporating and communicating information about risk and uncertainties into decisions about climate change (Climate Change Science Program, 2009; Pidgeon and Fischhoff, 2011) suggests that effective communication of uncertainty requires products and processes that: i) closes psychological distance, explaining why this information is important to the recipient; ii) distinguishes between and explains different types of uncertainty; iii) establishes self-agency, explaining what the recipient can do with the information and ways to make decisions under uncertainty (e.g., precautionary principle, iterative risk-management); iv) recognizes that each person's view of risks and opportunities depends on their values; v) recognizes that emotion is a critical part of judgment; vi) provides mental models that help recipients to understand the connection between cause and effect. Information providers also need to test their messages, since they may not be communicating what they think they are.

2.2.1.3. Language and Meaning

Aspects of decision-making concerned with language and meaning include framing, communication, learning, knowledge exchange, dialogue and discussion. Most IPCC-related literature on language and communication deals with definitions, predictability and incomplete knowledge, with less emphasis given to other aspects of decision-support such as learning, ambiguity, contestedness and complexity. Three important areas assessed here are definitions, risk language and communication, and narratives.

Decision-making processes need to accommodate both specialist and non-specialist meanings of the concepts they apply. Various disciplines often have different definitions for the same terms or use different terms for the same action or object, which is a major barrier for communication and decision-making (Adger, 2003; Chapter 21). For example, adaptation is defined differently with respect to biological evolution, climate change and social adaptation. Budescu et al. (2012) found that people prefer imprecise wording but precise numbers when appropriate. Personal lexicons vary widely, leading to differing interpretations of uncertainty terms (Morgan et al., 1990); in the IPCC's case leading to uncertainty ranges often being interpreted differently than intended (Patt and Schrag, 2003; Patt and Dessai, 2005; Budescu et al., 2012). Addressing both technical and everyday meanings of key terms can help bridge the analytic and emotive aspects of cognition. For example, words like danger, disaster, uncertainty and catastrophe have technical and emotive aspects (Britton, 1986; Carvalho and Burgess, 2005). Terms where this issue is especially pertinent include adaptation, vulnerability, risk, dangerous, catastrophe, resilience and disaster. Other words have definitional issues because they contain different epistemological frames; sustainability and risk being key examples (Harding, 2006; Hamilton et al., 2007). Many authors advocate that narrow definitions focused solely on climate need to be expanded to suit the context in which they are being used (Huq and Reid, 2004; O'Brien et al., 2007; Schipper, 2007). This is a key role for risk communication, ensuring that different types of knowledge are integrated within decision context and outlining the different values – implicit and explicit – involved in the decision process (e.g., Morgan, 2002; Lundgren and McMakin, 2013).

The language of risk has a crucial role in framing and belief. Section 2.1.2 described over-arching and climate-specific definitions but risk enters into almost every aspect of social discourse, so is relevant to how risk is framed and communicated (e.g., Hansson, 2004). Meanings of risk range from its ordinary use in everyday language to power and political discourse, health, emergency, disaster and seeking benefits, ranging from specific local meanings to broad-ranging concepts such as the risk society (Beck and Ritter, 1992; Beck, 2000; Giddens, 2000). Complex framings in the word risk (Fillmore and Atkins, 1992; Hamilton et al., 2007) feature in general English as both a noun and a verb, reflecting harm and chance with negative and positive senses (Fillmore and Atkins, 1992). Problem analysis applies risk as a noun (at-risk), whereas risk management applies risk as a verb (to-risk) (Jones, 2011). For simple risks, this transition is straightforward because of agreement around values and agency (Figure 2-2). In complex situations, risk as a problem and as an opportunity can compete with each other, and if socially amplified can lead to action paralysis (Renn, 2011). For example, unfamiliar adaptation options that seem to be risky themselves will force a comparison between the risk of maladaptation and future climate risks, echoing the risk trap where problems and solutions come into conflict (Beck, 2000). Fear-based dialogues in certain circumstances can cause disengagement (O'Neill and Nicholson-Cole, 2009), by emphasising risk aversion. Young (2013) proposes framing adaptation as a solution to overcome the limitations of framing through the problem, and links it to innovation, which provides established pathways for the implementation of actions, proposing a problem-solution framework linking decision-making to action. Framing decisions and modelling actions on positive risk-seeking behaviour can help people to address uncertainty as opportunity (e.g., Keeney, 1992).

Narratives are accounts of events with temporal or causal coherence that may be goal directed (László and Ehmann, 2012) and play a key role in communication, learning and understanding. They operate at the personal to societal scales, are key determinants of framing and have a strong role in creating social legitimacy. Narratives can also be non-verbal: visualization, kinetic learning by doing and other sensory applications can be used to communicate science and art, and to enable learning through play (Perlovsky, 2009; Radford, 2009). Narratives of climate change have evolved over time and invariably represent uncertainty and risk (Hamblyn, 2009) being characterised as tools for analysis, communication and engagement (Cohen, 2011; Jones et al., 2013; Westerhoff and Robinson, 2013) by:

1) Providing a social and environmental context to modelled futures (Arnell et al., 2004; Kriegler et al., 2012; O'Neill et al., 2013), by describing aspects of change that drive or shape those futures as part of scenario construction (Cork et al., 2012).
2) Communicating knowledge and ideas to increase understanding and increase agency framing it in ways so that actions can be implemented (Juhola et al., 2011) or provide a broader socio-ecological context to specific knowledge (Burley et al., 2012). These narratives bridge the route between scientific knowledge and local understandings of adaptation, often by working with multiple actors in order to creatively explore and develop collaborative potential solutions (Turner and Clifton, 2009; Paton and Fairbairn-Dunlop, 2010; Tschakert and Dietrich, 2010).
3) Exploring responses at an individual/institutional level to an aspect of adaptation, and communicate that experience with others. (Bravo, 2009; Cohen, 2011). For example, a community that believes itself to be resilient and self-reliant is more likely to respond proactively, contrasted to a community that believes itself to be vulnerable (Farbotko and Lazrus, 2012). Bravo (2009) maintains that narratives of catastrophic risk and vulnerability demotivate indigenous peoples whereas narratives combining scientific knowledge and active citizenship promote resilience (2.5.2).

2.2.1.4. Ethics

Climate ethics can be used to formalize objectives, values (2.2.1.1), rights and needs into decisions, decision-making processes and actions (see also 16.7). Principal ethical concerns include: intergenerational equity; distributional issues; the role of uncertainty in allocating fairness or equity; economic and policy decisions; international justice and law; voluntary and involuntary levels of risk; cross-cultural relations; and human relationships with nature, technology and the socio-cultural world. Climate change ethics have been developing over the last 20 years (Jamieson, 1992, 1996; Gardiner, 2004; Gardiner et al., 2010), resulting in a substantial literature (Garvey, 2008; Harris, 2010; O'Brien et al., 2010; Arnold, 2011; Brown, 2012; Thompson and Bendik-Keymer, 2012). Equity, inequity and responsibility are fundamental concepts in the United Nations Framework Convention on Climate Change (United Nations, 1992) and therefore are important considerations in policy development for CIAV. Climate ethics examine effective responsible and 'moral' decision-making and action, not only by governments but also by individuals (Garvey, 2008).

An important discourse on equity is that industrialized countries have, through their historical emissions, created a natural debt (Green and Smith, 2002). Developing nations experience this debt through higher impacts and greater vulnerability combined with limited adaptive capacity. Regional inequity is also of concern (Green and Smith, 2002), particularly indigenous or marginalized populations exposed to current climate extremes, who may become more vulnerable under a changing climate (Tsosie, 2007; 12.3.3). With respect to adaptation assessment, cost-benefit or cost effectiveness methods combined with transfer of funds will not satisfy equity considerations (Broome, 2008; 17.3.1.4) and modifications such as equity weighting (Kuik et al., 2008) and cost-benefit under uncertainty (17.3.2.1), have not been widely used. Adaptation measures need to be evaluated by considering their equity implications (17.3.1.4) especially under uncertainty (Hansson, 2004).

Intergenerational issues are frequently treated as an economic problem, with efforts to address them through an ethical framework proving to be controversial (Nordhaus, 2007; Stern and Treasury of Great Britain, 2007; Stern, 2008). However, future harm may make the lives of future generations difficult or impossible, dilemmas that involve ethical choices (Broome, 2008), therefore discount rates matter (17.4.4.4). Some authors question whether the rights and interests of future people should even be subject to a positive discount rate Caney (2009). Future generations cannot defend themselves within current economic frameworks (Gardiner, 2011) nor can these frameworks properly account for the dangers, interdependency and uncertainty under climate change (Nelson, 2011), even though peoples' values may change over time (16.7). The limits to adaptation raise questions of irreversible loss and the loss of unique cultural values that cannot necessarily be easily transferred (16.7), contributing to key vulnerabilities and informing ethical issues facing mitigation (see 19.7.1).

Environmental ethics considers the decisions humans may make concerning a range of biotic impacts (Schalow, 2000; Minteer and Collins, 2010; Nanda, 2012; Thompson and Bendik-Keymer, 2012). Intervention in natural systems through 'assisted colonization' or 'managed relocation' raises important ethical and policy questions (Minteer and Collins, 2010)(4.4.2.4) that include the risk of unintended consequences (4.4.4). Various claims are made for a more pragmatic ethics of ecological decision-making (Minteer and Collins, 2010), consideration of moral duties toward species (Sandler, 2009) and ethically explicit and defendable decision-making (Minteer and Collins, 2005b, a).

Cosmopolitan ethics and global justice can lead to successful adaptation and sustainability (Caney, 2006; Harris, 2010) and support collective decision-making on public matters through voting procedures (Held, 2004). Ethics also concerns the conduct and application of research, especially research involving stakeholders. Action-based and participatory research requires that a range of ethical guidelines be followed, taking consideration of the rights of stakeholders, respect for cultural and practical knowledge, confidentiality, dissemination of results and development of intellectual property (Macaulay et al., 1999; Kindon et al., 2007; Daniell et al., 2009; Pearce et al., 2009). Ethical agreements and processes are an essential part of participatory research, whether taking part as behavioural change processes promoting adaptation or projects of collaborative discovery *(High confidence)*. Although the climate change ethics literature is rapidly developing, the related practice of decision-making and implementation needs further development. Ethical and equity issues are discussed in WG III, Chapter 3 *Social, Economic, and Ethical Concepts and Methods*.

2.2.2. Institutional Context

2.2.2.1. Institutions

Institutions are rules and norms held in common by social actors that guide, constrain, and shape human interaction (North, 1990; Glossary). Institutions can be formal, such as laws and policies, or informal, such as norms and conventions. Organizations – such as parliaments, regulatory agencies, private firms, and community bodies – develop and act in response to institutional frameworks and the incentives they frame (Young et al., 2008). Institutions can guide, constrain, and shape human interaction through direct control, through incentives, and through processes of socialization (Glossary). Virtually all CIAV decisions will be made by or influenced by institutions because they shape the choices made by both individuals and organizations (Bedsworth and Hanak, 2012). Institutional linkages are important for adaptation in complex and multi-layered social and biophysical systems such as coastal areas (5.5.3.2) and urban systems (8.4.3.4), and are vital in managing health (11.6), human security (12.5.1, 12.6.2) and poverty (13.1). Institutional development and interconnectedness are vital in mediating vulnerability in social-ecological systems to changing climate risks, especially extremes (Chapters 5, 7–9, 11–13).

The role of institutions as actors in adaptation are discussed in Chapter 14.4, in planning and implementing adaptation in Chapter 15.5 and in providing barriers and opportunities in Chapter 16.3. Their roles can be very diverse. Local institutions usually play important roles in accessing resources and in structuring individual and collective responses (Agarwal, 2010; 14.4.2) but Madzwamuse (2010) found that in Africa, state level actors had significantly more influence on formal adaptation policies than did civil society and local communities. This suggests a need for greater integration and cooperation among institutions of all levels (15.5.1.2). Chapter 14 identifies four institutional design issues: flexibility; potential for integration into existing policy plans and programs; communication, coordination and cooperation; and the ability to engage with multiple stakeholders (14.2.3).

Institutions are instrumental in facilitating adaptive capacity, by utilising characteristics such as variety, learning capacity, room for autonomous change, leadership, availability of resources and fair governance (Gupta et al., 2008). They play a key role in mediating the transformation of coping capacity into adaptive capacity and in linking short and long-term responses to climate change and variability (Berman et al., 2012). Most developing countries have weaker institutions that are less capable of managing extreme events, increasing vulnerability to disasters (Lateef, 2009; Biesbroek et al., 2013). Countries with strong functional institutions are generally assumed to have a greater capacity to adapt to current and future disasters. However, Hurricane Katrina of 2005 in the USA and the European heat wave of 2003 demonstrate that strong institutions and other determinants of adaptive capacity do not necessarily reduce vulnerability if the mechanisms are not translated to actions (IPCC, 2007b; Box 2-1, 2.4.2.2).

To facilitate adaptation under uncertainty, institutions need to be flexible enough to accommodate adaptive management processes such as evaluation, learning and refinement (Agarwal, 2010; Gupta et al., 2010; 14.2.3). Organizational learning can lead to significant change in organizations' purpose and function (Bartley, 2007), for example where non-governmental organizations have moved from advocacy to program delivery with local stakeholders (Ziervogel and Zermoglio, 2009; Kolk and Pinkse, 2010; Worthington and Pipa, 2010).

Boundary organisations are increasingly being recognised as important to CIAV decision support (Guston, 2001; Cash et al., 2003; McNie, 2007; Vogel et al., 2007). A boundary organization is a bridging institution, social arrangement, or network that acts as an intermediary between science and policy (Glossary). Its functions include facilitating communication between researchers and stakeholders, translating science and technical information, and mediating between different views of how to interpret that information. It will also recognize the importance of location-specific contexts (Ruttan et al., 1994), provide a forum in which information can be co-created by interested parties (Cash et al., 2003), and develop boundary objects, such as scenarios, narratives and model-based decision support systems (White et al., 2010). Adaptive and inclusive management practices are considered to be essential, particularly in addressing wicked problems such as climate change (Batie, 2008). Boundary organisations also link adaptation to other processes managing global change and sustainable development.

Boundary organizations already contributing to regional CIAV assessments include in the US, the Great Lakes Integrated Sciences and Assessments Center – GLISA (GLISA web site: http://www.glisa.umich.edu/), part of the Regional Integrated Sciences and Assessment s (RISA) Program of the US Government (Pulwarty et al., 2009), the UK Climate Impacts Program – UKCIP (UK Climate Impacts Program, 2011), the Alliance for Global Water Adaptation – AGWA (AGWA web site: http://alliance4water.org) and institutions working on water issues in the U.S., Mexico and Brazil (Kirchhoff et al., 2012; Varady et al., 2012).

2.2.2.2. Governance

Effective climate change governance is important for both adaptation and mitigation and is increasingly being seen as a key element of risk management *(high confidence)* (Renn, 2008; Renn et al., 2011). Some analysts propose that governance of adaptation requires knowledge of anticipated regional and local impacts of climate change in a more traditional planning approach (e.g., Meadowcroft, 2009), whereas others propose governance consistent with sustainable development and resilient systems (Adger, 2006; Nelson et al., 2007; Meuleman and in 't Veld, 2010). Quay (2010) proposes 'anticipatory governance'- a flexible decision framework based on robustness and learning (2.3.3, 2.3.4). Institutional decisions about climate adaptation are taking place within a multi-level governance system (Rosenau, 2005; Kern et al., 2008). Multi-level governance could be a barrier for successful adaptation if there is insufficient coordination as it is comprised of different regulatory, legal and institutional systems (16.3.1.4), but is required to manage the 'adaptation paradox' (Local solutions to a global problem), unclear ownership of risks and the adaptation bottleneck linked to difficulties with implementation (14.5.3). Lack of horizontal and vertical integration between organizations and policies leads to insufficient risk governance in complex social-ecological systems such as coasts (5.5.3.2) and urban areas (8.4), including in the management of compound risks (19.3.2.4).

Legal and regulatory frameworks are important institutional components of overall governance, but will be challenged by the pervasive nature of climate risks *(high confidence)*(Craig, 2010; Ruhl, 2010a, b). Changes proposed to better manage these risk under uncertainty include integration between different areas of law, jurisdictions and scale, changes to property rights, greater flexibility with respect to adaptive management and a focus on ecological processes rather than preservation (Craig, 2010; Ruhl, 2010a; Abel et al., 2011; Macintosh et al., 2013). With respect to human security, this report does not see them as an issue of rights alone, given that a minimum set of universal rights exists but they are not always exercised (Box 12-1) but instead investigates a wide range of forces. Internationally, sea level rise could alter the maritime boundaries of many nations that may lead to new claims by affected nations or loss of sovereignty (Barnett and Adger, 2003). New shipping routes, such as the North West Passage, will be opened up by losses in Arctic sea ice (6.4.1.6, 28.2.6). Many national and international legal institutions and instruments need to be updated to face climate related challenges and decision implementation *(medium confidence)* (Verschuuren, 2013).

2.3. Methods, Tools, and Processes for Climate-Related Decisions

This section deals with methods, tools and processes that deal with uncertainties (2.3.1), describe scenarios (2.3.2), cover trade-offs and multi-metric valuation (2.3.3) and learning review and reframing (2.3.4).

2.3.1. Treatment of Uncertainties

Most advice on uncertainty, including the latest guidance from the IPCC (Mastrandrea et al., 2010; 1.1.2.2), deals with uncertainty in scientific findings and to a lesser extent confidence. While this is important, uncertainty can invade all aspects of decision making, especially in complex situations. Whether embodied in formal analyses or in the training and habits of decision makers, applied management is often needed because unaided human reasoning can produce mismatches between actions and goals (Kahneman, 2011). A useful high-level distinction is between ontological uncertainty – what we know – and epistemological uncertainty – how different areas of knowledge and 'knowing' combine in decision making (van Asselt and Rotmans, 2002; Walker et al., 2003). Two other areas of relevance are ambiguity (Brugnach et al., 2008) and contestedness (Klinke and Renn, 2002; Dewulf et al., 2005), commonly encountered in wicked problems/systemic risks (Renn and Klinke, 2004; Renn et al., 2011).

Much of this uncertainty can be managed through framing and decision-processes. For example, a predict-then-act framing is different to an assess-risk-of-policy framing (IPCC SREX 6.3.1 and Fig 6.2; Lempert et al., 2004). In the former, also known as 'top-down'; model or impacts-first; science-first; or standard approach, climate or impact uncertainty is described independently of other parts of the decision problem. For instance, probabilistic climate projections (see Chapter 21, Fig. 21-4 or IPCC WG1 Chapters 11 and 12; Murphy et al., 2009) are generated for wide application, thus are not tied to any specific choice. This follows the cause and effect model described in Section 2.1. The basic structure of IPCC Assessment Reports follows this pattern, with WGI laying out what is known and uncertain about current and future changes to the climate system. Working Groups II and III then describe impacts resulting from and potential policy responses to those changes (Jones and Preston, 2011).

In contrast, the 'assess-risk-of-policy' framing (Lempert et al., 2004; UNDP, 2005; Carter et al., 2007; Dessai and Hulme, 2007) starts with the decision-making context. This framing is also known as 'context-first' (Ranger et al., 2010), 'decision scaling' (Brown et al., 2011), 'bottom-up'; vulnerability, tipping point (Kwadijk et al., 2010), critical threshold (Jones, 2001), or policy-first approaches (IPCC SREX 6.3.1). In engaging with decision-makers, the 'assess-risk-of-policy' approach often requires that information providers work closely with decision makers to understand their plans and goals, before customizing the uncertainty description to focus on those key factors. This can be very effective, but often needs to be individually customized for each decision context (Lempert and Kalra, 2011; Lempert, 2012) requiring collaboration between researchers and users (see Box 2-1). A 'predict-then-act' framing is appropriate when uncertainties are shallow, but when uncertainties are deep, an 'assess-risk-of-policy' framing is more suitable (Dessai et al., 2009).

The largest focus on uncertainty in CIAV has been on estimating climate impacts such as streamflow or agricultural yield changes and their consequent risks. Since AR4, the treatment of these uncertainties has advanced considerably. For example, multiple models of crop responses to climate change have been compared to estimate intermodel uncertainty (Asseng et al., 2013). Although many impact studies still characterise uncertainty by using a few climate scenarios, there is a growing literature that uses many climate realisations and also assesses uncertainty in the impact model itself (Wilby and Harris, 2006; New et al., 2007). Some studies propagate uncertainties to evaluate adaptation options locally (Dessai and Hulme, 2007) by assessing the robustness of a water company's plan to climate change uncertainties or regionally (Lobell et al., 2008) by identifying which regions are most in need of adaptation to food security under a changing climate. Alternatively, the critical threshold approach, where the likelihood of a given criterion can be assessed as a function of climate change, is much less sensitive to input uncertainties than assessments estimating the 'most likely' outcome (Jones, 2010). This is one of the mainstays of robustness assessment discussed in Section 2.3.3.

2.3.2. Scenarios

A scenario is a story or image that describes a potential future, developed to inform decision making under uncertainty (1.1.3). A scenario is not a prediction of what the future will be but rather a description of how the future might unfold (Jäger et al., 2008). Scenario use in the CIAV research area has expanded significantly beyond climate into broader socio-economic areas as it has become more mainstream *(high confidence)* (1.1.3, 2.4.2.1). Climate change has also become a core feature of many scenarios used in regional and global assessments of environmental and socio-economic change (Carpenter et al., 2005; Raskin et al., 2005). Scenarios can be used at a number of stages within an assessment process or can underpin an entire assessment. They serve a variety of purposes, including informing decisions under uncertainty, scoping and exploring poorly understood issues, and integrating knowledge from diverse domains (Parson et al., 2007; Parson, 2008).

Scenarios also contribute to learning and discussion, facilitate knowledge exchange and can be expressed using a range of media. Local scale visualization of impacts and adaptation measures, depicted on realistic landscapes, is an emerging technology that is being tested to support dialogue on adaptation planning at the local scale (Schroth et al., 2011; Sheppard, 2012). Although visual representations of scenario-based impact assessments may be available for a location, scenario-based adaptation assessments are usually not. Artistic depictions of potential adaptation measures and outcomes are being negotiated and assessed with local stakeholders in communities within Metro Vancouver, Canada (Shaw et al., 2009; Burch et al., 2010; Sheppard et al., 2011).

Climate, socio-economic or other types of scenarios are widely used to assess the impacts of climate change. Fewer studies report on the use of scenarios as participatory tools to enable decision-making on adaptation (e.g., Harrison et al., 2013). However, the scenario literature emphasises the importance of process over product. The new generation of climate and socio-economic scenarios being developed from the representative concentration pathways (RCP; 1.1.3.1) and Shared Socioeconomic Pathways (SSP; 1.1.3.2), which are storylines corresponding to the new RCPs (Moss et al., 2010; Kriegler et al., 2012) have yet to be applied within CIAV studies in any substantive way (Ebi et al., 2013; van Ruijven et al., 2013).

By separating risks into simple and systemic or wicked-problem risks, scenario needs for decision-making can be better identified *(medium confidence)*. For simple risks, if probabilities cannot be easily calculated then scenarios can be used to explore the problem, test for acceptable or unacceptable levels of risk and illustrate alternative solutions for evaluation and testing. Wicked problems will need to be thoroughly scoped to select the most suitable decision-making process, with scenarios playing an important role. They may require separate applications of problem (exploratory or descriptive) and solution-based (normative or positive) scenarios or the development of reflexive scenarios, the latter being updated with new knowledge over time that may re-examine values and goals (van Notten, 2006; Wilkinson and Eidinow, 2008; Jones, 2012); these categories can also be structured as top-down, bottom-up and interactive (Berkhout et al., 2013). Even if conditional probabilities can be used to illustrate climate futures, scenarios are needed to explore the solutions space involving strategic actions, options planning and governance using both process and goal-oriented methods *(high confidence)*.

2.3.3. Evaluating Trade-Offs and Multi-Metric Valuation

Decision makers bring diverse aims, interests, knowledge and values to CIAV decision-making. With effective decision support, parties to a decision can manage competing views by more clearly articulating their goals, understanding how various options affect trade-offs between goals, and making informed choices that participants regard as legitimate, salient, and credible *(high confidence)* (Cash et al., 2003). The decision theory, risk governance, and ethical reasoning literatures use two broad sets of criteria for decision making: outcome-based criteria focus on whether a decision is likely to meet specified goals; process-based criteria compare alternative actions according to the process by which a decision is arrived. In particular, decision process aims to help stakeholders choose between the risks, costs, and obligations being proposed (Morgan et al., 1990), including specified levels of risk tolerance. Such choices around risk tolerance, including acceptable levels of risk, are ethical choices (DesJardins, 2012; Nanda, 2012). Selection strategies informing context and process are described in

Section 14.3.5. Decision criteria inform the discussions of adaptation options, planning, and economics in Chapters 14–17 and WG III Chapter 2.

Multi-attribute decision theory (Keeney and Raiffa, 1993), or multi-criteria decision analysis (MCDA), provides the most general framework for assessing outcomes-based criteria. MCDA concepts and tools organize and display the implications of alternative decisions on differing objectives (e.g., cost and environmental quality), order and test preferences among trade-offs between potentially incommensurate objectives, and show how alternative processes for choosing options can lead to different decisions. Cost-benefit analysis under uncertainty, one key tool for evaluating trade-offs, is described in Chapter 17.3.2.1. Simple MCDA tools include scorecards that graphically display how alternative policy choices affect different goals. For example the 'burning embers' diagram displays how risks to various attributes (e.g., health of unique systems, extreme weather events) depend on targets for a given global mean temperature increase (Figure 19-5). More sophisticated MCDA tools can optimise a portfolio of choices in a variety of ways; for example, one recent method applies scenarios representing significant uncertainty to optimise between four or more choices in order to identify robust combinations and system vulnerabilities (e.g., Kasprzyk et al., 2013). Successfully use of MCDA in CIAV decisions, include the U.S. Bureau of Reclamation helping stakeholders with diverse interests and values to consider 26 alternative performance measures for the Colorado River system, agree on potential climate-related risks and consider options for reducing those risks. Trade-offs also occur where adaptation measures produce negative impacts in other areas of value; e.g., where adaptation in agricultural and urban areas negatively affect ecosystems (4.3.3.3). Korteling et al. (2013) assess the robustness of adaptation options for six criteria including risk of water shortage, environmental impact, local self-sufficiency, cost, carbon footprint and social acceptability. Chapter 17 describes many criteria commonly used in MCDA analyses.

Robustness is often nominated as the most appropriate criterion for managing large decision uncertainty. It is a satisficing (sufficient rather than optimal) criteria (Rosenhead, 1989) that seeks decisions likely to perform well over a wide range of plausible climate futures, socio-economic trends, and other factors (Dessai and Hulme, 2007; Groves et al., 2008; Wilby and Dessai, 2010; WUCA, 2010; Brown et al., 2011; Lempert and Kalra, 2011). Robust decisions often perform better than other methods if the future turns out differently than expected. Testing for robustness can often illuminate trade-offs that help decision makers achieve consensus even when they have different future expectations. Robust choices often trade some optimality for being able to manage unanticipated outcomes. Many forms of the precautionary principle are consistent with robustness criteria (Lempert and Collins, 2007). Flexible and reversible options are often needed to manage situations with significant potential for unanticipated outcomes and differences in values and interests among decision makers (Gallopín, 2006; Hallegatte, 2009; 2.3.4, 5.5.3.1). Flexibility is signalled by reaching of specific management thresholds, critical control points or design states (Box 5-1). The literature disagrees on the relationship between robustness and resilience (Folke, 2006). Chapter 20 describes resilience as a property of systems that might be affected by decision makers' choices, while robustness is a property of the choices made by those decision makers (SREX, Chapter 1).

Process-based criteria focus on the credibility and legitimacy of a decision process. Institutional (2.2.2) and cultural and ethical (2.2.1) contexts will strongly influence the appropriateness and importance of such criteria in a given situation *(high confidence)*. Process criteria provide institutional rules, and governance for decision-making in a wide range of circumstances (Dietz and Stern, 2008; Sen, 2009). For instance, many environmental laws require advanced notice and periods of public comment before any regulations are issued. Water rights can be made tradable, giving users extra flexibility during times of water shortage or oversupply. Participants may regard any decision that fails to respect such rights as illegitimate. In complex situations of a collaborative nature, both outcome and process-related criteria will be needed in a decision-making process *(high confidence)*.

Stakeholder involvement is a central process for climate-related decision making and since the AR4 has grown in importance, particularly for adaptation decision-making (e.g., Lebel et al., 2010), covering methods (Debels et al., 2009; Gardner et al., 2009; Salter et al., 2010; André et al., 2012) and reflecting concrete experiences with stakeholder involvement in CIAV assessments and adaptation processes (de la Vega-Leinert et al., 2008; Ebi and Semenza, 2008; Posthumus et al., 2008; Raadgever et al., 2008; Tompkins et al., 2008a; Tompkins et al., 2008b; Preston et al., 2009). Lebel et al. (2010) differentiate six advantages of social learning and stakeholder involvement for adaptation to climate change: i) reducing informational uncertainty; ii) reducing normative uncertainty; iii) helps to build consensus on criteria for monitoring and evaluation; iv) can empower stakeholders to influence adaptation and take appropriate actions themselves by sharing knowledge and responsibility in participatory processes; v) can reduce conflicts and identify synergies between adaptation activities of various stakeholders, thus improving overall chances of success; and vi) can improve the likely fairness, social justice and legitimacy of adaptation decisions and actions by addressing the concerns of all relevant stakeholders. Complex settings will require a detailed mapping of stakeholder roles and responsibilities (André et al., 2012).

2.3.4. Learning, Review, and Reframing

Effective decision support processes generally includes learning (Figure 2-1), where learning and review become important to track decision progress (National Research Council, 2009; see Box 2-1). This can be achieved by developing an ongoing monitoring and review process during the scoping stage of a project or program. If circumstances change so much that desired outcomes may not be achieved, then reframing of the decision criteria, process and goals may be required. This iterative approach begins with the many participants to a decision working together to define its objectives and other parameters, working with experts to generate and interpret decision-relevant information, and then revisiting the objectives and choices based on that information (Figure 2-1). Again, process is important. Pelling et al. (2008) found that accounting for different personal values in both an official and informal capacity could enhance social learning and therefore adaptive capacity. Measuring progress on adaptation and adaptive capacity, though tracking impacts, vulnerability and related adaptation metrics, and process indicators is discussed in Chapter 14.6. Such metrics are needed to transfer wider learning on adaptation to new situations.

Learning and review can range from periodic reporting through to adaptive management. Adaptive management refers to a choice of policy required to generate reliable new information (Holling, 1978, 1996) and involves a process of adjusting approaches in response to observations of their effect and changes in the system brought on by resulting feedback effects and other variables (Glossary). Adaptive strategies are designed to be robust over a wide range of futures by evolving over time in response to new information (Rosenhead, 1989; Walker et al., 2001; Lempert and Schlesinger, 2002; Swanson et al., 2006). Necessary components include: separating immediate actions from those that can be deferred (and that may require additional information); an explicit process to generate new information; institutional mechanisms for incorporating and acting on new information; and some understanding of the policy limits that, if exceeded, should lead to its re-evaluation (Swanson et al., 2012; Box 5-1). As indicated by Fig 2-1, effective decision making not only requires flows of appropriate information but people willing and able to act on it. While most policies change over time, very few follow the steps of an intentional adaptive strategy *(high confidence)*. For instance, McCray et al. (2010) survey 32 examples of U.S. environmental, health, and safety regulations – all legally required to be adaptive – and find only five instances where any policy change occurred as intended.

Reframing of an action can occur when an existing set of decisions and actions are failing to adequately manage risks (See Box 2-1).

_____ START BOX 2-1 HERE _____

Box 2-1. Managing Wicked Problems with Decision Support

A well-designed decision support process, combined with favourable political conditions, can effectively address ‘wicked’ (Section 2.1) decision challenges. The State of Louisiana faces a serious problem of coastal land loss, exposing the region’s fisheries and heightening the risk of storm surge damage to the City of New Orleans, one of the United States’ largest ports with facilities that account for about 20% of U.S. oil and gas production (Coastal Protection and Restoration Authority, 2007). Previous efforts at comprehensive coastal protection had been stymied by, among other factors, numerous competing jurisdictions and stakeholders with a wide range of conflicting interests.

In the aftermath of Hurricane Katrina, the state embarked on a new coastal planning effort, this time with extensive decision support. The Louisiana state Coastal Protection and Restoration Authority organized an extension decision support effort with a network of about a dozen research institutions interacting with a 33-member stakeholder group consisting of representatives from business and industry, federal, state, and local governments, nongovernmental organizations and coastal institutions. In dozens of workshops over the course of two years, these stakeholders influenced the development of and interacted with a decision support system consisting of two parts: 1) a regional model that integrated numerous strands of scientific data into projections of future flood risk (Fischbach et al., 2012) and 2) a multi-attribute planning tool that allowed stakeholders to explore the implications of alternative portfolios of hundreds of proposed risk reduction projects over alternative sea level rise scenarios (Groves et al., 2012). This decision support system allowed decision makers and stakeholders to first formulate alternative risk reduction plans and then to visualize outcomes and trade-offs up to fifty years into the future.

The resulting Master Plan for a Sustainable Coast passed the state legislature on a unanimous vote in May 2012. Deviating strongly from past practice, the plan allocates far more resources to restoring natural barriers than to structural measures such as levees. The plan balances between the interests of multiple stakeholders and contains some projects that offer near-term benefits and some whose benefits will be largely felt decades from now. Many participants and observers of this process credited the extensive analytic decision support for significant contributions to this plan.

_____ END BOX 2-1 HERE _____

Based on experience to date, there now exists a sufficiently rich set of available methods, tools, and processes to support effective CCIAV decisions in a wide range of contexts *(medium confidence)*, although they may not be combined appropriately, accessible or readily used by decision makers (Webb and Beh, 2013). Tools for decision-making, planning and development, transfer and diffusion are discussed in Chapter 15.4.

2.4. Support for Climate-Related Decisions

Growing understanding of the aspects of decision-making (2.2) and methods and tools (2.3) have led to improved support for CIAV decisions as shown by the provision of climate information and services (2.4.1), methods for impacts and vulnerability assessments (2.4.2) action, and decision support in practice (2.4.3). Figure 2-3 divides the decision-making process into four stages: scoping, analysis, implementation and review, outlining institutional, leadership, knowledge and information characteristics for each stage. Most effort in CIAV research has been put into the first two stages, whereas decision implementation and follow-up have been minimal. This does not imply that the analysis stage is discounted. Problem analysis and solution evaluation are significant undertakings in any decision process, but that is where most current climate change assessments stop. Note that each of these stages can be divided into other quite distinct process elements.

[INSERT FIGURE 2-3 HERE
Figure 2-3. Four-stage process of decision making. Note that while adaptive management is located in the decision review quadrant here, when applied it will influence the entire process.]

2.4.1. Climate Information and Services

Climate Services are institutions that bridge the generation and application of climate knowledge. Their history and concepts are described in 2.4.1.1; how they apply decision support in 2.4.1.2, and the policy implications of climate services as a global practice in 2.4.1.3. They supply climate information on local, regional, national and global scales for the monitoring of risks, mitigation and adaptation planning “as an important component of sustainable development” (Sivakumar et al., 2011). The Global Framework for Climate Services (Hewitt et al., 2012) aims to “enable better management of the risks of climate variability and change and adaptation to climate change, through the development and incorporation of science-based climate information and prediction into planning, policy and practice on the global, regional and national scale” (http://www.wmo.int/pages/gfcs/index_en.php). Climate services focus on the connection between climate science and the public demand for information, however their development and deployment needs support from many other disciplines (Miles et al., 2006). This extended reach requires measures such as case-specific communication, engagement and knowledge exchange skills *(high confidence)*.

While many countries have already established national and regional climate services or are on the way to doing so, they show significant differences. The development of Regional Climate Services in the US and parts of Europe, with their increasing focus on communication and decision support, is well documented (DeGaetano et al., 2010; von Storch et al., 2011). Developing countries are becoming increasingly aware of the need for climate services (Semazzi, 2011), which is in part reflected in the migration of regional climate models into those countries. In 2001 only around 21 (mostly OECD) countries were running regional climate models (RCMs), but today over 100 countries are trained in using the PRECIS RCM (Jones et al., 2004; Edwards, 2010). Regional Climate Services are expanding geographically, shifting from simple understandings of climate cause and effect to ever more complex and wicked problem situations and are becoming more interdisciplinary.

2.4.1.1. Climate Services: History and Concepts

Early climate services in North America were seen as an expansion of weather services, mainly dealing with forecasts, seasonal outlooks, risk assessment in a mostly stationary but variable climate (Changnon et al., 1990; Miles et al., 2006; DeGaetano et al., 2010). This mainly technical outlook had limited effectiveness; for example, decision makers had difficulties understanding and using climate data for planning purposes (Changnon et al., 1990; Miles et al., 2006; Visbeck, 2008) and the data were slow to access and of poor quality (Changnon et al., 1990). As these services developed, formal definitions of their mission and scope shifted to being user-centric, focusing on active research, data stewardship and effective partnership (National Research Council, 2001). Climate services were understood as a clearinghouse and technical access point to stakeholders, providing education and user access to experts; the latter informing the climate forecast community of information needs, largely to inform adaptation (Miles et al., 2006).

Downscaling is a key product demanded by users for decision making (21.3.3.2). For example, in Africa, regional climate models play an increasing role in Regional Climate Outlook Forums arranged by WMO. The Global Framework for Climate Services was created in order to coordinate and strengthen activities and develop new infrastructure where needed, focusing on developing countries (World Meteorological Organization, 2011; Hewitt et al., 2012). From initially being supply-focused and static, public climate services increasingly need communication skills, engagement and knowledge exchange in a highly challenging environment of technical and institutional networks, monitoring systems, and collaborations with other institutions, stakeholders and decision-makers (DeGaetano et al., 2010).

2.4.1.2. Climate Services: Practices and Decision Support

Decision support is generally acknowledged as an integral part of climate services *(high confidence)* (Miles et al., 2006; DeGaetano et al., 2010). Depending on the stage and context in question (see 2.1.3.), ‘best’ data as framed by experts should be reconciled with user needs in order to produce scientific information that is relevant and suitable for decision making. Social and cultural determinants have to be taken into account (see 2.2.) and require the communication of scientific data to be context specific. Decision support for climate services consists of “processes of interaction, different forms of communication, potentially useful data sets or models, reports and training workshops, data ports and websites, engaging any level of governance, at any stage in the policy- or decision-making process” (Moser, 2009). The climate service is a “process of two-way communication” and “involves providing context that turns data into information” (Shafer, 2004). Capacity building is required on all sides of the communication process. For Regional Climate Services, a successful learning process, engages both users and providers of knowledge in knowledge exchange. For example, the uptake and utility of climate forecasts in rural Africa is described in Box 9-4.

As knowledge brokers, climate services have to establish an effective dialogue between science and the public (von Storch et al., 2011). This dialogue undertakes two main tasks: One is to understand the range of perceptions, views, questions, needs, concerns and knowledge in the public and among stakeholders about climate, climate change and climate risks. The other task is to convey the content of scientific knowledge to the public, media and stakeholders.

This includes communicating the limitations of such knowledge, the known uncertainties and the unknowable, as well as the appropriate role of science in complex decision processes (von Storch et al., 2011).

2.4.1.3. The Geo-Political Dimension of Climate Services

Climate knowledge is continually being documented and assessed by the social sciences within a policy-relevant context (Yearley, 2009; Grundmann and Stehr, 2010). One focus is on the spread of climate knowledge into developing countries. Climate models distributed to users with no in-house capacity for model development build capacity in regional climate science, producing high resolution data for local decision-making. This mobility of knowledge has far-reaching implications for how climate knowledge is produced; strengthening the influence of epistemic communities such as the IPCC and other global governance mechanisms (Mahony and Hulme, 2012). Thus, while regional climate models play an increasingly important role in decision making processes, critics argue that climate monopolises planning and development strategies, rendering other forms of knowledge subordinate to this ‘climate reductionism’ (Dessai et al., 2009; Hulme, 2011).

Indigenous forms of knowledge – including the specialized knowledge of any stakeholder – are becoming increasingly relevant for climate services *(high confidence)* (Strauss and Orlove, 2003; Crate and Nuttal, 2009; Crate, 2011; Ulloa, 2011; Krauss and von Storch, 2012). Local forms of knowledge and scientific climate models are not necessarily mutually exclusive; individual case studies show how both forms of knowledge contribute jointly to place-based adaptation (Strauss and Orlove, 2003; Orlove and Kabugo, 2005; Orlove, 2009; Strauss, 2009; Orlove et al., 2010). Indigenous knowledge in the form of oral histories and other traditional knowledge are being compared or combined with remote sensing technologies and model-based scenarios to co-produce new knowledge, and to create a new discourse on adaptation planning (Nakashima et al., 2012; Table 15.1). The challenge will be to collaborate in a way that enables their integration into a shared narrative on future adaptation choices.

These examples show that adaptation needs both to be implemented locally and to be informed by larger scale (inter-) national policies and directions. One strategy will not suit every location. Endfield (2011) argues for a ‘reculturing and particularizing of climate discourses’ in order to successfully localize global and scientific meta-narratives. Climate service development combines very different types of knowledge and the social, cultural and communication sciences play a decisive role in this process (Pidgeon and Fischhoff, 2011; von Storch et al., 2011). To position itself and to react according to the diverse demands, science-based climate services have to become “rooted in society” (Krauss, 2011). The climate science community does not necessarily take the lead, but becomes part of an inter- and trans-disciplinary process, where politics, culture, religion, values and so forth become part of climate communication *(medium confidence)*.

2.4.2. Assessing IAV on a Range of Scales

CIAV assessments address the ‘adapt to what’ question, which can enable a dialogue among practitioners, stakeholders, and the public on planning and implementation of adaptation measures within prevailing mechanisms for governance. To date, however, assessments have focused more on I than A (see Chapter 1, Figure 1-1d). A number of global initiatives are taking place to enable knowledge generation, transfer and use, including the Programme of Research on Climate Change Vulnerability, Impacts and Adaptation – PROVIA (http://www.provia-climatechange.org/), the Nairobi Work Programme on impacts, vulnerability and adaptation to climate change (http://unfccc.int/adaptation/nairobi_work_programme/items/3633.php), and work by the World Bank and regional development banks (http://climatechange.worldbank.org/).

2.4.2.1. Assessing Impacts

For scenario-based impact assessments to contribute to vulnerability and risk assessment, a series of translations need to be performed. Scenarios of projected greenhouse gas concentrations are converted to changes in climate, impacts are assessed, perhaps with autonomous adaptation, leading to the evaluation of various adaptation options.

This series of translations requires the transformation of data across various scales of time and space, between natural and social sciences, utilizing a wide variety of analytical tools representing areas such as agriculture, forestry, water, economics, sociology, and social-ecological systems. Climate scenarios are translated into scenarios or projections for biophysical and socio-economic impact variables such as river flow, food supply, coastal erosion, health outcomes and species distribution (e.g., European Climate Adaptation Platform, http://climate-adapt.eea.europa.eu). Climate services help establish and support the translation process (Section 2.4.1).

The resulting climate impacts and risks are then subject to decision making on risk management and governance. Assessments of observed events combine biophysical and socioeconomic assessments of the past and present (Table 2-1, top row). Most scenario-based assessments superimpose biophysical 'futures' onto present-day socio-economic conditions (Table 2-1, middle row). This is useful for assessing the how current socio-economic conditions may need to change in response to biophysical impacts but raises inconsistencies when future socio-economic states are out of step with biophysical states. This will hamper assessments of future adaptation responses in coupled social-ecological systems (see Chapter 16). An important challenge, therefore, is to construct impact assessments in which biophysical futures are coupled with socioeconomic futures (Table 2-1, bottom row). A new set of socioeconomic futures, known as Shared Socioeconomic Pathways (SSP), which are storylines corresponding to the new RCPs (Moss et al., 2010; Kriegler et al., 2012) are being developed to assist this process (1.1.3.2).

[INSERT TABLE 2-1 HERE
Table 2-1: Nature of published IAV assessments.]

A new generation of assessments links biophysical, economic and social analysis tools in order to describe the interactions between projected biophysical changes and managed systems. For example, Ciscar et al. (2011) estimated the costs of potential climate change impacts, without public adaptation policies, in four European market sectors (agriculture, river floods, coastal areas, and tourism) and one nonmarket sector (human health). A similar study in the UK was conducted for tourism, health and transportation maintenance, buildings and transportation infrastructure, and residential water supplies (Hunt, 2008). In the US, Backus et al. (2013) assessed national and state level GDP and employment impacts, incorporating direct impacts on water resources, secondary impacts on agriculture and other water interests, and indirect impacts through interstate migration of affected populations. Decision support tools are being integrated into scenario-based impact and adaptation assessments. For example, the Water Evaluation and Planning System model has been used to assess a community water system in British Columbia, Canada (Harma et al., 2012). Incorporation of stakeholder dialogue processes within scenario construction (Parson, 2008), and Participatory Integrated Assessment (Salter et al., 2010), enables inclusion of local knowledge as part of scenario-based assessments.

2.4.2.2. Assessing Vulnerability, Risk, and Adaptive Capacity

The adaptation to climate change, disaster risk management, and resilience literatures all address the concept of vulnerability, defined as a susceptibility to loss or damage (Adger, 2006; Füssel, 2007), or, the propensity or predisposition to be adversely affected (glossary). Within IPCC AR4, Schneider et al. (2007) identified vulnerabilities that might be considered 'key', and therefore potentially 'dangerous' (see glossary). Criteria denoting a key vulnerability include its magnitude and timing, persistence and reversibility, and the likelihood and confidence that the contributing event(s) would occur (Sections 19.2.5, 19.6). Other criteria include the importance of a location or activity to society, society's exposure to potential loss and its capacity to adapt. Adaptive capacity has been defined as the ability to adjust, to take advantage of opportunities, or to cope with consequences (Adger et al., 2007; glossary). However, adaptive capacity is context specific, related to both availability of resources, capacity to learn, and governance measures (Gupta et al., 2010; 14.5); Section 14.5). Actions that illustrate how adaptive capacity and climate resilience can be mutually reinforcing include disaster risk management (2.5.2, 15.3.2, 16.7.2) and 'triple-win' interventions where adaptation, mitigation, and sustainable development goals are integrated so as to find climate-resilient pathways (20.3.3, 20.4.2).

The concept of an 'adaptation deficit' (Burton and May, 2004) is applicable to cases such as Hurricane Katrina (Committee on New Orleans Regional Hurricane Protection Projects, 2009; Freudenberg et al., 2009; Box 2-1) or the 2003 European heat wave (Haines et al., 2006) where substantial vulnerability follows a climate event. An adaptation deficit represents a gap between an existing state of adaptation and an idealized state of adaptation where adverse impacts are avoided (Chapter 17, Glossary). The adaptation deficit has also been related to 'residual impacts', which occur due to insufficient adaptation to current or future climate (IPCC, 2007b). Within developing countries, Narain et al. (2011) consider the adaptation deficit as being part of a larger 'development deficit'. Cardona et al. (2012) cite other 'deficit' indicators, including a Disaster Deficit Index (extreme event impact combined with financial ability to cope), structural deficit (low income, high inequality, lack of access to resources, etc.), and a risk communication deficit. Maladaptation occurs where a short-term response inadvertently leads to an increase in future vulnerability (Glantz, 1988; Barnett and O'Neill, 2010; McEvoy and Wilder, 2012). Barriers unrelated to scientific knowledge can hamper effective decision making (Adger and Barnett, 2009; Berrang Ford et al., 2011). This may help to explain why some extreme events create surprising levels of damage within developed countries. The adaptation deficit has also been related to 'residual impacts', which occur due to insufficient adaptation to current or future climate (IPCC, 2007b).

The assessment of potential future damages and loss requires approaches that link bio-physical and socio-economic futures. An example is the assessment of climate change effects on human health, including research-to-decision pathways, monitoring of social vulnerability indicators and health outcomes (English et al., 2009; Portier et al., 2010), and tools for enabling adaptive management (Hess et al., 2012). Examples of regional scale scenario-based vulnerability assessments are case studies for North Rhine-Westphalia in Germany (Holsten and Kropp, 2012) and agriculture in Mexico (Monterroso et al., 2012). An example of a larger scale study is a vulnerability assessment of ecosystem services for Europe, in which future adaptive capacity was based on indicators from the SRES storylines (Metzger and Schröter, 2006). Difficulty in separating the relative influences of changing climate and development patterns hampers assessments of observed trends in property damage caused by atmospheric extreme events. Recent increases in economic losses may be due to changes in probabilities of extreme events, changes in human development patterns (more people in harm's way) without changes in climatic extremes, or a combination of both (Pielke, 1998; Mills, 2005; Munich Re Group, 2011). IPCC (2012) concluded that increasing exposure has been the major cause, but a role for climate change has not been excluded.

Development choices taken in the current or near term can potentially influence future vulnerability to projected climate change, hence the interest in the study of emergent risks (Sections 19.3, 19.4). Interactions between development pathways, and climate change impacts and responses, could create situations with little or no precedent. Assessments based on gradual shifts in mean conditions could underestimate future risk and consequent damage, suggesting the need for process-based methodologies that focus on enhancing resilience (Jones et al., 2013; Sections 2.5.2, 20.2.3). An example of assessing this type of risk, and the costs and benefits of potential adaptation responses, is a resilience assessment framework for infrastructure networks (Vugrin et al., 2011; Turnquist and Vugrin, 2013).

2.4.3. Climate-Related Decisions in Practice

Implementation of adaptation actions, resilience strategies and capacity building can take place as stand-alone actions or be integrated into other management plans and strategies. Recent literature on potential climate change effects on natural resources, public health and community planning and management is reviewed in Chapters 3–12. As the complexity of management challenges increases due to climate change, development and other pressures, a range of reflexive decision-making processes are emerging under the general topics of adaptive management, iterative risk management and community-based adaptation (e.g., 5.5.4.1). However, there are few assessments of adaptation delivery and effectiveness (15.6). Cross-sectoral integrated approaches such as Integrated Water Resources Management (IWRM), sustainable forestry management (SFM) and Integrated Coastal Zone Management (ICZM) are viewed as being more effective than stand-alone efforts (16.5.1).

Adaptive approaches to water management can potentially address uncertainty due to climate change (3.6.1) but there is a limited number of examples in practice (3.6.4). Examples of recent strategies include an IWRM roadmap prepared for the state of Orissa, India (Jønch-Clausen, 2010) and seven cases in the US (Bateman and Rancier, 2012) some of which are applying adaptive water management using a scenario-based experimental approach intending to align with IWRM and promote resilience. Adaptations in urban systems following integrated urban water management principles are becoming widespread (8.3.3.4) and in rural systems are more advanced in developed countries and less so in developing countries, especially those within transboundary basins (9.4.3.2, 24.4.1.5, 24.4.2.5, 25.5.3, 26.3.3, 27.3.1.2, 27.3.2.2).

Adaptation in agriculture ranges from small adjustments made to current activities through to transformative adaptations across whole systems. (7.5.1, 9.4.3.1, 22.4.5.7, 23.4.1, 24.4.4.5, 25.7.2, 26.5.4, 27.3.4.2). Diversified systems are more resilient with some diversification coming from off farm sources (9.4.3.1). There are few unequivocal adaptations to climate, but the development of adaptive capacity is more widespread (7.5.1.2). Adaptation in forestry has expanded since the AR4 (9.4.3.3) and is aiming to develop towards SFM by focusing on biological diversity, productive and protective functions of forests, maintenance of their social and economic benefits, and governance (McDonald and Lane, 2004; Wijewardana, 2008; Montréal Process, 2009). Although SFM is still largely an abstract concept (Seppälä et al., 2009), managing climate change risks is seen as necessary for achieving its objectives (Montréal Process, 2009). Governments and companies are also considering assisted migration of forest species as an adaptation strategy (Pedlar et al., 2012) and payment for ecosystem services is becoming more common (9.4.3.3). Sustainable Fisheries Management has long-term ecological and productivity goals (FAO, 2013) but climate change has generally not been included in strategic guidance for fisheries management (Brander, 2010). Ecosystem-based approaches to management e.g., (Zhou et al., 2010) and transformative approaches will be required (7.5.1.1.2, 9.4.3.4). Sustainable livelihoods approaches are also being applied for populations dependent on marine resources (9.4.3.4, 30.6.2.1, Table 30-2).

National Adaptation Programmes of Action (NAPA) for least developed countries (LDCs) are designed to be flexible, action-oriented and country-driven (UNFCCC, 2009). Key preparatory steps include the synthesis of available information on vulnerability and impacts via extensive public participation (see Chapter 14). The NAPA process has assisted least-developed countries to assess climate sensitive sectors and prioritize projects to address the most urgent adaptation issues (Lal et al., 2012; UNFCCC, 2012). Integrating NAPAs with other socio-economic programs can help develop resilience. However, although many countries have linked their NAPAs with development programs, Hardee and Mutunga (2010) argue that they have had limited success in aligning the NAPA priorities with existing national priorities such as population growth. To this end, scaling up and institutionalization of the NAPA process has commenced. Under the Cancun Adaptation Framework, a process was established that enables LDCs to formulate and implement National Adaptation Plans (NAPs) building upon the NAPA experience (UNFCCC, 2013). The NAP's main objectives are to identify vulnerabilities, medium- and long-term adaptation needs and to develop and implement strategies and programmes to address those needs and also to mainstream climate change risks. The NAPs are also an opportunity to align with other global initiatives such as the Millennium Development Goals and Hyogo Framework for Action.

Many developed countries are developing adaptation strategy documents at different scales of governance (European Environmental Agency, 2013). Biesbroek et al. (2010) analysed National Adaptation Strategies (NAS) of nine European nations, examining their decision making aspects and finding both 'top-down' and 'bottom-up' (delegation of authorities to local governments) approaches. Dissemination of information on weather, climate, impacts, vulnerability and scenarios was found to be a critical element for adaptation decision making.

Climate risk is being increasingly factored into existing decision-making processes (15.2.1). For example, learning from the 2003 heat waves that killed some 35,000 people across Europe, many European countries have implemented health-watch warning systems (Alcamo et al., 2007; WHO, 2008). Vietnam has initiated large-scale mangrove restoration and rehabilitation programs with the support of international institutions to protect coastal settlements and aquaculture industry (World Resources Institute et al., 2011). The Tsho Rolpa glacier lake in Nepal was at the risk of outburst due to glacial melt (Adger et al., 2007) so the Government of Nepal introduced both short- and long-term measures to prevent the outburst flood event (World Resources Institute et al., 2011). In many ways, local government is at the coal face of adaptation decision making (Pelling et al., 2008; Measham et al., 2011; Roberts et al., 2012). Municipal governments are incorporating climate change adaptation planning within municipal planning instruments, including energy and water system design, disaster risk reduction and sustainability plans (Ford and Berrang-Ford, 2011; Rosenzweig et al., 2011). In human health, two main areas of benefit are occurring through improvements in current health patterns being exacerbated by changing climate and in reducing pollutants associated with co-pollutants of greenhouse gas emissions (11.7, 11.9). Climate is being increasingly recognised as a component of human conflict and insecurity, so is becoming a factor in governance arrangements affecting security and peace building programs (12.5).

Details of adaptation planning within urban and rural settlements are addressed in Chapters 8 and 9, respectively. In urban settlements, adaptations are occurring in areas of energy, water, transport, housing and green infrastructure (8.3.3) but opportunities for broader integration into planning and the urban economy are largely being missed (8.4). The overall status of adaptation implementation is assessed in Chapter 15. Although there is a rapidly growing list of adaptation plans being generated at multiple scales, an evaluation of adaptation plans from Australia, United Kingdom and the United States suggests they are under-developed (Berrang Ford et al., 2011). These plans reflect a preference for capacity building over the delivery of specific vulnerability-reduction measures, indicating that current adaptation planning is still informal and ad hoc (Preston et al., 2011; Bierbaum et al., 2013). Capacity barriers have hampered the transition from planning to implementation, so only a small number of jurisdictions have been successful at implementing adaptation measures (15.2). However, there has been growth in community-based adaptation initiatives (Baer and Risbey, 2009; Rudiak-Gould, 2011; 15.1, 15.2, 15.5, 15.6)

Various enabling factors for implementation have been identified in stakeholder engagement processes. Such factors include access to resources, sharing observations, language specific information and ICT tools (e.g., wireless sensor networks, geographic information systems and Web-based tools) that increase local awareness, allowing for good public understanding of stresses, risks and trade-offs (15.4.2). These factors allow new strategies to be explored, evaluated and implemented (Shepherd et al., 2006; Hewitt et al., 2013). Enabling factors also include customized impact and vulnerability assessments for communities of interest and local practitioners who would serve as champions for adaptation planning, and the existence of local social influences/networks and capacity that enable long term strategic planning and mainstreaming (Gardner et al., 2009; Cohen, 2010). These factors are further discussed in Chapters 15 and 16. Local government officials often lack training on climate change adaptation and require capacity to be built in a number of areas. To assist this process, guidebooks have been produced, framing the process of adaptation planning as both a team-building and project management exercise, activities that are already part of usual practice (Snover et al., 2007; Bizikova et al., 2008; ICLEI Oceania, 2008; CARE International in Vietnam, 2009; Ayers et al., 2012). Practitioner engagement in decision ‘games’ can offer another training resource (Black et al., 2012).

2.5. Linking Adaptation with Mitigation and Sustainable Development

2.5.1. Assessing Synergies and Trade-offs with Mitigation

Capacities to adapt to and mitigate climate change are broadly similar. Opportunities for synergies are particularly relevant for the agriculture, forestry, urban infrastructure, energy and water sectors (Chapters 3, 4, 7–10). The IPCC AR4 (Klein et al., 2007) concluded that a lack of information made it difficult to assess these synergies. Assessing the synergies and trade-offs that face both adaptation and mitigation is an important goal of the new IPCC scenario process (Kriegler et al., 2012; O'Neill et al., 2013). These synergies and trade-offs between adaptation and mitigation are illustrated in Figure 2-4. The negatives associated with ‘adaptive emissions’ or ‘new vulnerabilities’ arising from mitigation do not necessarily mean that such measures should not be contemplated, but they do need to be assessed within a larger portfolio of actions where losses and gains have been sufficiently well quantified (19.7). Limits of adaptation emphasise the different reach of adaptation and mitigation in managing climate risks (16.6, 19.7.5).

Mitigation can affect, for example, the water (3.7.2.1), terrestrial and freshwater ecosystems (4.4.4, 19.3.2.2), agriculture (19.3.2.2, 19.4.1) and livelihoods and poverty (13.3.1) sectors and will in turn be affected by the water sector (3.7.3.2), terrestrial ecosystems (4.3.3.1, 4.2.4.1). Adaptation actions for agriculture generally tend to reduce emissions (7.5.1.4). Potential losses of human security associated with climate policy are discussed in 12.5.2 and 19.4.2.2. Recent literature on potential interactions between mitigation and adaptation is reviewed in Sections 16.4.3, 19.7.1–5. Chapter 20 discusses the relationship between adaptation, mitigation, and sustainable development including sustainable risk management (20.3.3).

[INSERT FIGURE 2-4 HERE
Figure 2-4: Examples of adaptation (A) – mitigation (M) trade-offs and synergies (adapted from Cohen and Waddell, 2009). The upper right quadrant (sustainable win-win) illustrates synergies in which actions enable the achievement of both adaptation and mitigation goals. The lower left quadrant (unsustainable) shows the opposite condition. The upper left (adaptive emissions) and lower right (new vulnerabilities) quadrants illustrate trade-offs that can result from actions within particular local-regional circumstances.]

2.5.2. Linkage with Sustainable Development – Resilience

The idea that climate change response and sustainable development should be integrated within a more holistic decision framework was assessed in IPCC AR4 (Robinson et al., 2006; Klein et al., 2007; Yohe et al., 2007). Practical aspects of this integration are being tested as decision makers endeavour to incorporate adaptation measures within official long-term development plans (15.3.3). A typical example is the engagement of researchers and practitioners (planners, engineers, water managers, etc.) in scenario-based exercises to build local capacity to plan for a wide range of climate outcomes (Bizikova et al., 2010). Development can yield adaptation co-benefits if climate change is factored into its design (17.2.7.2, 20.3, 20.4).

Resilience is the capacity to change in order to maintain the same identity (see Glossary) and can be assessed through participatory research (Tyler and Moench, 2012) or through system modelling. Chapter 20 examines climate-resilient pathways, which are development trajectories of combined mitigation and adaptation to realize the goal of sustainable development while meeting the goals of the UNFCCC (Box 20-1). An example of resilience assessment at the landscape scale is in the Arctic, where local sources of important productivity and biodiversity are being mapped and their future capacity in supporting larger ecoregions under climate change is being assessed (Christie and Sommerkorn, 2012). An industry example covers the resilience analysis of supply chains, specifically petrochemical supply chains exposed to a hurricane in south-eastern United States (Vugrin et al., 2011). For urban areas, Leichenko (2011) categorize four types of urban resilience studies: i) urban ecological resilience, ii) urban hazards and disaster risk reduction, iii) resilience of urban and regional economies, and iv) urban governance and institutions. Boyd et al. (2008) promote resilience as a way of guiding future urbanization that would be better ‘climatized’. The Asian Cities Climate Change Resilience Network is applying a resilience planning framework, with attention given to the role of agents and institutions (Tyler and Moench, 2012).

Adaptive capacity is seen as an important component of resilience on a range of scales (Sections 2.1.1, 2.2.3, 2.3.4, 2.4.2, 20.3). Local cases, such as King County (Seattle) USA, illustrate the importance of researcher–practitioner collaboration for knowledge exchange (Snover et al., 2007) and iterative and reflexive processes that enable local ownership, and adjustment to new information and evaluation of actions taken (Saavedra and Budd, 2009). However, in regions with high and chronic poverty, coupled with low awareness of global change drivers, adaptation as a process is not well understood and tools that enable anticipatory learning are lacking (Tschakert and Dietrich, 2010).

The normative concept of sustainable adaptation has been proposed to manage adaptation’s unintended consequences (Eriksen et al., 2011). It considers effects on social justice and environmental integrity, challenging current (unsustainable) development paths rather than seeking adjustments within them. This concept recognizes the role of multiple stressors in vulnerability, the importance of values in affecting adaptation outcomes (Section 2.2.1), and potential feedbacks between local and global processes. Little is known about the long-term effects of adaptation on livelihoods and poverty (13.3.2) although focussing on poverty alleviation as part of adaptation is thought to build capacity (13.4.1, 13.4.2).

The Hyogo Framework for Action on disaster risk reduction considers climate change as an underlying risk factor, and promotes the integration of risk reduction and climate change adaptation (UNISDR, 2007; 2011; 15.3.2). Social development is being integrated with disaster risk management in order to enhance adaptive capacity and address the structural causes of poverty, vulnerability and exposure.. In small island states, this integration is being enabled through focused institutional coordination, greater stakeholder engagement and promotion of community-based adaptation and resilience-building projects (UNISDR, 2012b). Similar initiatives are underway in urban areas (UNISDR, 2012a; 15.3.2, 15.3.3, 15.5 and Chapter 24, Box CC-TC).

Resilience is also being explored as an outcome of social contracts that underpin governance. O'Brien et al. (2009) use examples from Norway, New Zealand and Canada to illustrate how resilience thinking on climate does not easily fit into existing social contracts, and that new types of arrangements may better serve the goals of resilience and sustainable development within the context of climate change. Chapter 20 describes climate-resilient development pathways as being an explicit objective of long-term planning and decision making and considers the need for transformational adaptation aiming to achieve sustainable development (20.5).

2.5.3. Transformation – How Do We Make Decisions Involving Transformation?

Much of the existing adaptation literature examines gradual adjustment or accommodation to change. But a growing literature highlights the importance of transformative adaptation (14.3.5, 16.4.2), both in the context of a world where global temperature raise above 2°C (Kates et al., 2012; PIK, 2012) and in the context of climate resilient pathways that manage risk through combinations of adaptation and mitigation (20.5).

In concluding this chapter, we therefore reflect on some emerging, though still sparse literature that examines such transformational adaptation, how it differs from incremental adaptation (O'Brien, 2012; Park et al., 2012), and how it might occur in specific sectors and systems (Rickards and Howden, 2012). This early literature suggests that many themes raised in this chapter may prove important to transformational adaptation, including: iterative risk management with a broad view of risk, adaptive management, robustness and resilience and deliberation (McGray et al., 2007; Leary et al., 2008; Hallegatte, 2009; Tschakert and Dietrich, 2010; Hallegatte et al., 2011; Stafford Smith et al., 2011). For instance, Irvin and Stansbury (2004) identify situations where participatory processes may be most effective for bringing about positive social and environmental change. Recently, Park et al. (2012) have proposed the Adaptation Action Cycles concept as a means to delineate incremental and transformative adaptation and the role of learning in the decision-making process. Similarly to the learning process called 'triple-loop' that considers a situation, its drivers plus the underlying frames and values that provide the situation context (Argyris and Schön, 1978; Peschl, 2007; Hargrove, 2008), transformational adaptation may involve decision makers questioning deep underlying principles (Flood and Romm, 1996; Pelling et al., 2008) and seeking changes in institutions, such as legal and regulatory structures underlying environmental and natural resource management (Craig, 2010 ; Ruhl, 2010a), as well as in cultural values (O'Brien, 2012; O'Brien et al., 2013).

Frequently Asked Questions

FAQ 2-1: What constitutes a good (climate) decision? *[to be inserted after Section 2.1.1]*
No universal criterion exists for a good decision, including a good climate-related decision. Seemingly reasonable decisions can turn out badly, and seemingly unreasonable decisions can turn out well. However, findings from decision theory, risk governance, ethical reasoning and related fields offer general principles that can help improve the quality of decisions made.

Good decisions tend to emerge from processes in which people are explicit about their goals; consider a range of alternative options for pursuing their goals; use the best available science to understand the potential consequences of their actions; carefully consider the trade-offs; contemplate the decision from a wide range of views and vantages, including those who are not represented but may be affected; and follow agreed-upon rules and norms that enhance the legitimacy of the process for all those concerned. A good decision will be implementable within constraints such as current systems and processes, resources, knowledge and institutional frameworks. It will have a given lifetime over which it is expected to be effective, and a process to track its effectiveness. It will have defined and measurable criteria for success, in that monitoring and review is able to judge whether measures of success are being met, or whether those measures, or the decision itself, need to be revisited.

A good climate decision requires information on climate, its impacts, potential risks and vulnerability to be integrated into an existing or proposed decision-making context. This may require a dialogue between users and specialists to jointly ascertain how a specific task can best be undertaken within a given context with the current state of scientific knowledge. This dialogue may be facilitated by individuals, often known as knowledge brokers or extension agents, and boundary organizations, who bridge the gap between research and practice. Climate services are boundary organizations that provide and facilitate knowledge about climate, climate change and climate impacts for planning, decision making and general societal understanding of the climate system.

FAQ 2.2: Which is the best method for climate change decision-making/assessing adaptation?
[to be inserted in Section 2.3.4]
No single method suits all contexts, but the overall approach used and recommended by the IPCC is iterative risk management. The International Standards Organization defines risk as *the effect of uncertainty on objectives*. Within the climate change context, risk can be defined as the potential for consequences where something of human value (including humans themselves) is at stake and where the outcome is uncertain. Risk management is a general framework that includes alternative approaches, methodologies, methods and tools. Although the risk management concept is very flexible, some methodologies are quite prescriptive; for example, legislated emergency management guidelines and fiduciary risk. At the operational level, there is no single definition of risk that applies to all situations. This gives rise to much confusion about what risk is and what it can be used for.

Simple climate risks can be assessed and managed by the standard methodology of making up the 'adaptation deficit' between current practices and projected risks. Where climate is one of several or more influences on risk, a wide range of methodologies can be used. Such assessments need to be context-sensitive, involve those who are affected by the decision (or their representatives), use both expert and practitioner knowledge, and need to map a clear pathway between knowledge generation, decision-making and action.

FAQ 2.3: Is climate change decision-making different from other kinds of decision-making?
[to be inserted after Section 2.4.3]
Climate-related decisions have similarities and differences with decisions concerning other long-term, high consequence issues. Commonalities include the usefulness of a broad risk framework and the need to consider uncertain projections of various biophysical and socioeconomic conditions. However, climate change includes longer time-horizons and affects a broader range of human and earth systems as compared to many other sources of risk. Climate change impact, adaptation and vulnerability assessments offer a specific platform for exploring long term future scenarios in which climate change is considered along with other projected changes of relevance to long term planning.

In many situations, climate change may lead to non-marginal and irreversible outcomes, which pose challenges to conventional tools of economic and environmental policy. In addition, the realization that future climate may differ significantly from previous experience is still relatively new for many fields of practice (e.g., food production, natural resources management, natural hazards management, insurance, public health services and urban planning).

Nature of IAV assessments	Biophysical conditions	Socio-economic conditions
Stationarity and extrapolation	Continuation of current trends, no change in statistical properties	No change from current conditions
Transitional	Scenario-based projections of future biophysical conditions	No change from current conditions, sometimes sensitivity analysis with alternate futures
Coupled and interactive	Scenario-based projections of future biophysical conditions	Alternative futures from scenarios/storylines consistent with biophysical projections, sometimes with dynamic response

Table 2-1: Nature of published IAV assessments.

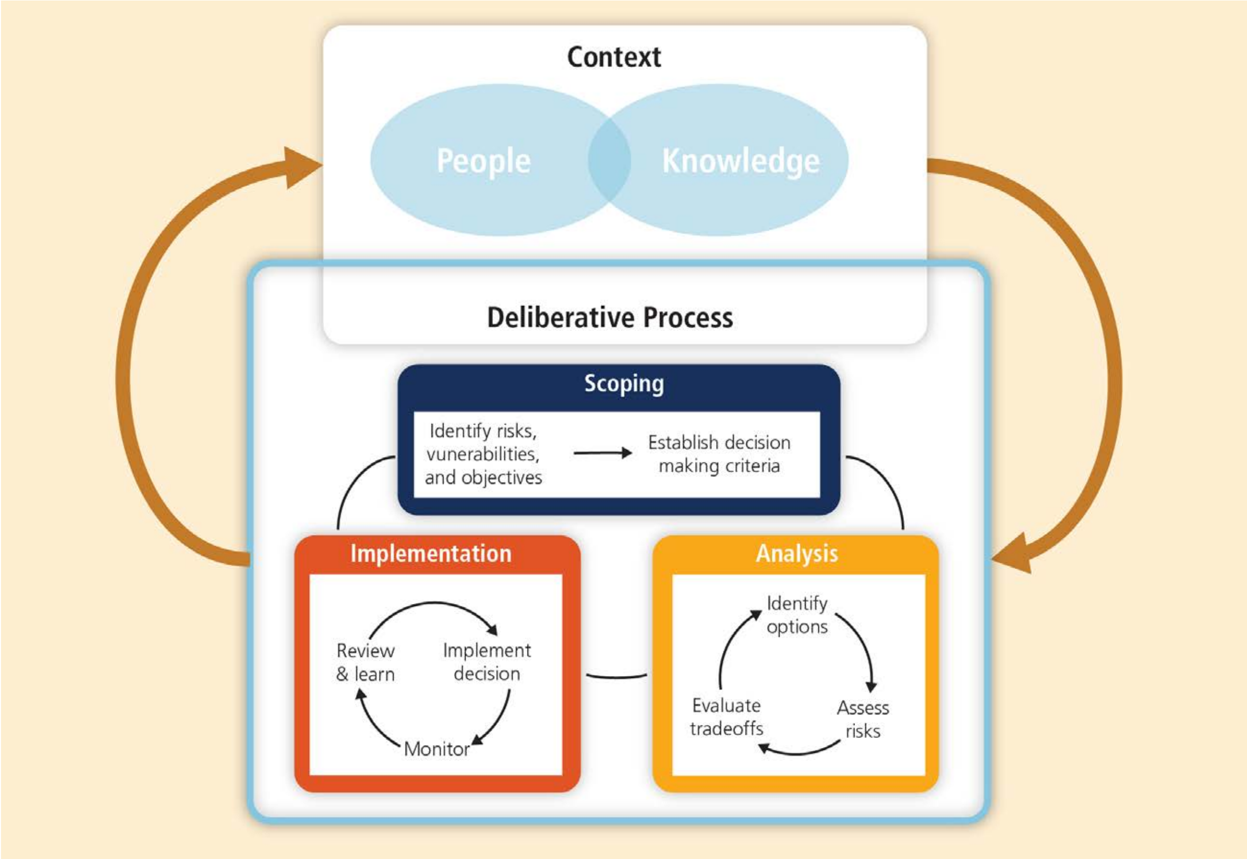

Figure 2-1: Iterative risk management framework depicting the assessment process, and indicating multiple feedbacks within the system and extending to the overall context. Adapted from Willows and Connell (2003).

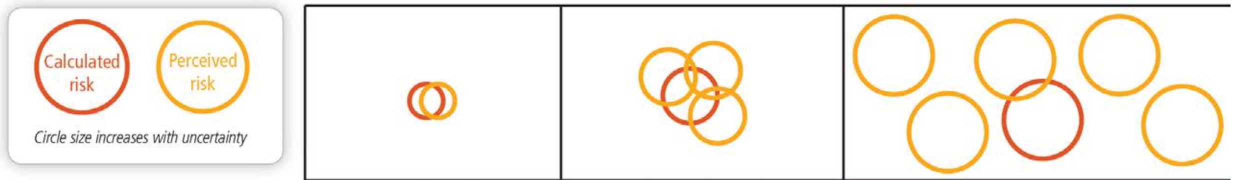

Characteristics of decision making	Simple risk	Complicated risk	Complex risk
Methodology	Linear, cause and effect	Top down and/or bottom up, iterative	Iterative and/or adaptive, ongoing and systemic
Approach	Analytic and technical	Collaborative process with technical input	Process driven. Frame and model multiple drivers and valued outcomes
Stakeholder strategy	Communication	Collaboration	Deliberation, creating shared understanding and ownership
Mental models	Common model	Negotiated and shared	Contested initially and negotiated over project
Values and outcomes	Widely accepted	Negotiated over project by user perspectives and calculated risk	Contested initially and negotiated over project
Monitoring	Straightforward	With review and trigger points	As real-time as possible, adaptive with management feedback and trigger points

Figure 2-2: Hierarchy of simple, complicated, and complex risks, showing how perceived risks multiply and become less connected with calculated risk with increasing complexity. Also shown are major characteristics of assessment methods for each level of complexity.

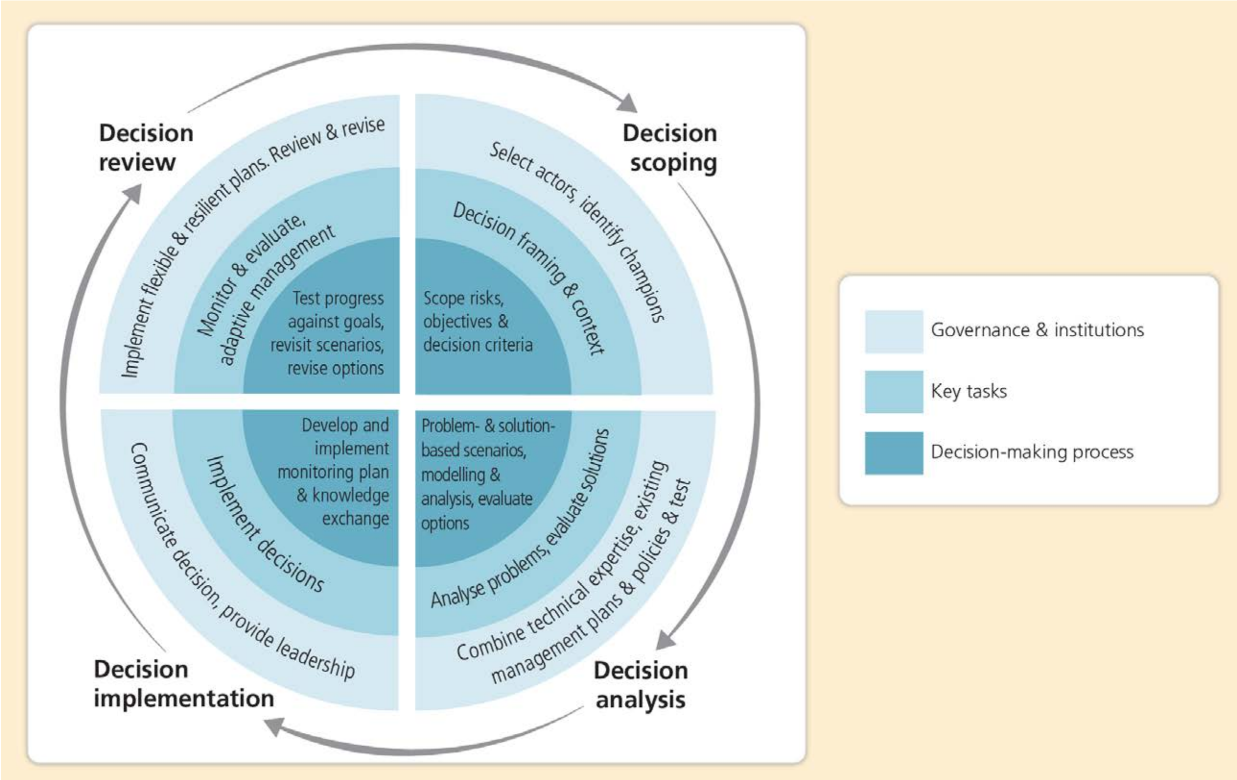

Figure 2-3. Four-stage process of decision making. Note that while adaptive management is located in the decision review quadrant here, when applied it will influence the entire process.

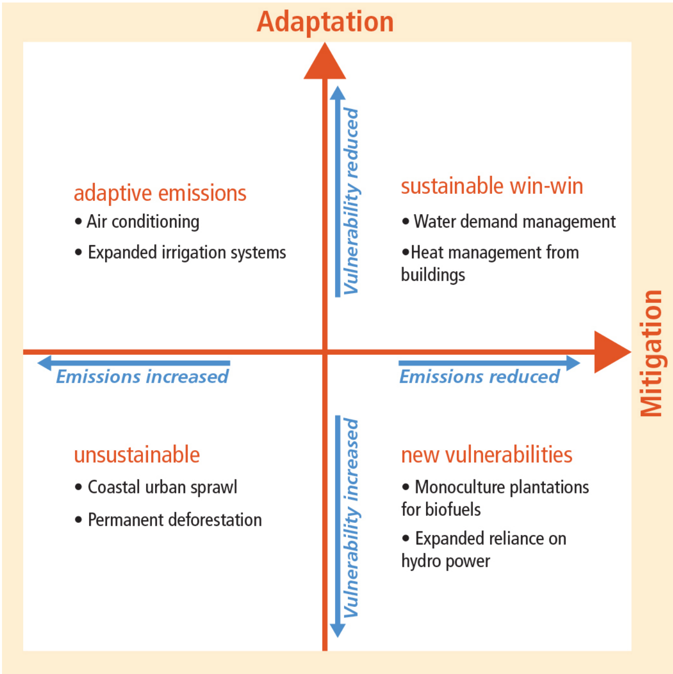

Figure 2-4: Examples of adaptation (A) – mitigation (M) trade-offs and synergies (adapted from Cohen and Waddell, 2009). The upper right quadrant (sustainable win-win) illustrates synergies in which actions enable the achievement of both adaptation and mitigation goals. The lower left quadrant (unsustainable) shows the opposite condition. The upper left (adaptive emissions) and lower right (new vulnerabilities) quadrants illustrate trade-offs that can result from actions within particular local-regional circumstances.

Executive Summary

Key risks at the global scale

Freshwater-related risks of climate change increase significantly with increasing greenhouse gas emissions (*high agreement, robust evidence*) [3.4; 3.5]. Modelling studies since AR4, with large but better quantified uncertainties, have demonstrated clear differences between global futures with higher emissions, which have stronger adverse impacts, and those with lower emissions, which cause less damage and cost less to adapt to [Table 3-2]. Each degree of warming is projected to decrease renewable water resources by at least 20% for an additional 7% of the global population. By the end of the 21st century, the number of people exposed annually to a 20th-century 100-year flood is projected to be three times greater for very high emissions (RCP8.5) than for very low emissions (RCP2.6) [Table 3-2; 3.4.8].

Climate change is projected to reduce renewable surface water and groundwater resources significantly in most dry subtropical regions (*high agreement, robust evidence*) [3.4; 3.5]. This will exacerbate competition for water among agriculture, ecosystems, settlements, industry and energy production, affecting regional water, energy and food security [3.5.1; 3.5.2; Box CC-WE]. In contrast, water resources are projected to increase at high latitudes. Proportional changes are typically one to three times greater for runoff than for precipitation. The effects on water resources and irrigation requirements of changes in vegetation due to increasing greenhouse-gas concentrations and climate change remain uncertain [Box CC-VW].

So far there are no widespread observations of changes in flood magnitude and frequency due to anthropogenic climate change, but projections imply variations in the frequency of floods (*medium agreement,*

***limited evidence*).** Flood hazards are projected to increase in parts of south, southeast and northeast Asia, tropical Africa, and South America (*medium agreement, limited evidence*). Since the mid-20th century, socio-economic losses from flooding have increased mainly due to greater exposure and vulnerability (*high confidence*). Global flood risk will increase in the future partly due to climate change (*medium agreement, limited evidence*) [3.2.7; 3.4.8].

Climate change is *likely* to increase the frequency of meteorological droughts (less rainfall) and agricultural droughts (less soil moisture) in presently dry regions by the end of this century under the RCP8.5 scenario (*medium confidence*) [WGI Ch12]. This is *likely* to increase the frequency of short hydrological droughts (less surface water and groundwater) in these regions (*medium agreement, medium evidence*) [3.4.8]. Projected changes in the frequency of droughts longer than 12 months are more uncertain, because these depend on accumulated precipitation over long periods. There is no evidence that surface water and groundwater drought frequency has changed over the last few decades, although impacts of drought have increased mostly due to increased water demand [3.5.1].

Climate change negatively impacts freshwater ecosystems by changing streamflow and water quality (*high agreement, medium evidence*). Quantitative responses are known in only a few cases. Except in areas with intensive irrigation, the streamflow-mediated ecological impacts of climate change are expected to be stronger than historical impacts due to anthropogenic alteration of flow regimes by water withdrawals and the construction of reservoirs [Box CC-RF; 3.5.2.4].

Climate change is projected to reduce raw water quality, posing risks to drinking water quality even with conventional treatment (*high agreement, medium evidence*). The sources of the risks are increased temperature, increases in sediment, nutrient and pollutant loadings due to heavy rainfall, reduced dilution of pollutants during droughts, and disruption of treatment facilities during floods [3.2.5; Figure 3-2; 3.4.6; 3.5.2.3].

In regions with snowfall, climate change has altered observed streamflow seasonality, and increasing alterations due to climate change are projected (*high agreement, robust evidence*) [Table 3-1; 3.2.3; 3.2.7; 3.4.5; 3.4.6; 26.2.2]. Except in very cold regions, warming in the last decades has reduced the spring maximum snow depth and brought forward the spring maximum of snowmelt discharge; smaller snowmelt floods, increased winter flows and reduced summer low flows have all been observed. River ice in Arctic rivers has been observed to break up earlier [3.2.3; 28.2.1.1].

Because nearly all glaciers are too large for equilibrium with the present climate, there is a committed water-resources change during much of the 21st century, and changes beyond the committed change are expected due to continued warming; in glacier-fed rivers, total meltwater yields from stored glacier ice will increase in many regions during the next decades but decrease thereafter (*high agreement, robust evidence*). Continued loss of glacier ice implies a shift of peak discharge from summer to spring, except in monsoonal catchments, and possibly a reduction of summer flows in the downstream parts of glacierized catchments [3.4.3].

There is little or no observational evidence yet that soil erosion and sediment loads have been altered significantly due to changing climate (*medium agreement, limited evidence*). However, increases in heavy rainfall and temperature are projected to change soil erosion and sediment yield, although the extent of these changes is highly uncertain and depends on rainfall seasonality, land cover, and soil management practices [3.2.6; 3.4.7].

Adaptation, mitigation, and sustainable development

Of the global cost of water-sector adaptation, most is necessary in developing countries where there are many opportunities for anticipatory adaptation (*high agreement, medium evidence*). There is limited published information on the water-sector costs of adaptation at the local level [3.6.1; 3.6.3].

An adaptive approach to water management can address uncertainty due to climate change (*high agreement, limited evidence*). Adaptive techniques include scenario planning, experimental approaches that involve learning from experience, and the development of flexible and low-regret solutions that are resilient to uncertainty. Barriers to progress include lack of human and institutional capacity, financial resources, awareness, and communication [3.6.1; 3.6.2; 3.6.4].

Reliability of water supply, which is expected to suffer from increased variability of surface water availability, may be enhanced by increased groundwater abstractions (*high agreement, limited evidence*). This adaptation to climate change is limited in regions where renewable groundwater resources decrease due to climate change [3.4.5; 3.4.8; 3.5.1].

Some measures to reduce greenhouse gas emissions imply risks for freshwater systems (*high agreement, medium evidence*). If irrigated, bioenergy crops make water demands that other mitigation measures do not. Hydropower has negative impacts on freshwater ecosystems which can be reduced by appropriate management. Carbon capture and storage can decrease groundwater quality. In some regions, afforestation can reduce renewable water resources but also flood risk and soil erosion [3.7.2.1; Box CC-WE].

3.1. Introduction

Changes in the hydrological cycle due to climate change can lead to diverse impacts and risks, and they are conditioned by and interact with non-climatic drivers of change and water-management responses (Figure 3-1). Water is the agent that delivers many of the impacts of climate change to society, for example to the energy, agriculture, and transport sectors. Even though water moves through the hydrological cycle, it is a locally variable resource, and vulnerabilities to water-related hazards such as floods and droughts differ between regions. Anthropogenic climate change is one of many stressors of water resources. Non-climatic drivers such as population increase, economic development, urbanization, and land-use or natural geomorphic changes also challenge the sustainability of resources by decreasing water supply or increasing demand. In this context, adaptation to climate change in the water sector can contribute to improving the availability of water.

[INSERT FIGURE 3-1 HERE
Figure 3-1: Framework (boxes) and linkages (arrows) for considering impacts of climatic and social changes on freshwater systems, and consequent impacts on and risks for humans and freshwater ecosystems. Both climatic (Section 3.3.1) and non-climatic (Section 3.3.2) drivers have changed natural freshwater systems (Section 3.2) and are expected to continue to do so (Section 3.4). They also stimulate adaptive measures (Section 3.6). Hydrological and water-management changes interact with each other and with measures to mitigate climate change (Section 3.7.2). Adaptive measures influence the exposure and vulnerability of human beings and ecosystems to water-related risks (Section 3.5).]

The key messages with *high* or *very high confidence* from the Working Group II Fourth Assessment Report (AR4; IPCC, 2007) in respect to freshwater resources were:

- The observed and projected impacts of climate change on freshwater systems and their management are mainly due to increases in temperature and sea level, local changes of precipitation, and changes in the variability of those quantities.
- Semi-arid and arid areas are particularly exposed.
- Warmer water, more intense precipitation, and longer periods of low flow reduce water quality, with impacts on ecosystems, human health, and reliability and operating costs of water services.
- Climate change affects water-management infrastructure and practice.
- Adaptation and risk-management practices have been developed for the water sector in some countries and regions.
- The negative impacts of climate change on freshwater systems outweigh its benefits.

This chapter assesses hydrological changes due to climate change, mainly based on research published since AR4. Current gaps in research and data are summarized in Section 3.8. For further information on observed trends in the water cycle, please see Chapter 2 of the Working Group I (WGI) contribution to this assessment. See WGI Chapter 4 for freshwater in cold regions and WGI Chapter 10 for detection and attribution, Chapter 11 for near-term projections, and Chapter 12 for long-term projections of climate change. In this Working Group II contribution, impacts on aquatic ecosystems are discussed in Chapter 4 (see also Section 3.5.2.4). Chapter 7 describes the impacts of climate change on food production (see also Section 3.5.2.1 for the impact of hydrological changes on the agricultural sector). The health effects of changes in water quality and quantity are covered in Chapter 11, and regional vulnerabilities related to freshwater in Chapters 21-30. Sections 3.2.7, 3.4.8 and 3.6.3 discuss impact costs and adaptation costs related to water resources; these costs are assessed more broadly in Chapter 10.

3.2. Observed Hydrological Changes due to Climate Change

3.2.1. Detection and Attribution

A documented hydrological change is not necessarily due to anthropogenic climate change. Detection entails showing, usually statistically, that part of the documented change is not due to natural variability of the water cycle (Chapter 18; WGI Chapter 10). For robust attribution to climatic change, all the drivers of the hydrological change must be identified, with confidence levels assigned to their contributions. Human contributions such as water withdrawals, land-use change and pollution mean that this is usually difficult. Nevertheless, many hydrological impacts can be attributed confidently to their climatic drivers (Table 3-1). End-to-end attribution, from human climate-altering activities to impacts on freshwater resources, is not attempted in most studies, because it requires experiments with climate models in which the external natural and anthropogenic forcing is “switched off”. However climate models do not currently simulate the water cycle at fine enough resolution for attribution of most catchment-scale hydrological impacts to anthropogenic climate change. Until climate models and impact models become better integrated, it is necessary to rely heavily on multi-step attribution, in which hydrological changes are shown to result from climatic changes that may in turn result partly from human activities.

[INSERT TABLE 3-1 HERE
Table 3-1: Selected examples, mainly from Section 3.2, of the observation, detection and attribution of impacts of climate change on freshwater resources. Observed hydrological changes are attributed here to their climatic drivers, not all of which are necessarily anthropogenic; in the diagram, symbols with borders represent end-to-end attribution of the impact on resources to anthropogenic climate change.
1: Gerten *et al*. (2008), Piao *et al.* (2010), Alkama *et al.* (2011); 2: Piao *et al*. (2010); 3: Shiklomanov *et al*. (2007); 4: Hidalgo *et al*. (2009); 5: Collins (2008); 6: Baraer *et al*. (2012); 7: Rosenzweig *et al*. (2007); 8: Min *et al*. (2011); 9: Pall *et al*. (2011); 10: Aguilera and Murillo (2009); 11: Jeelani (2008); 12: Evans *et al*. (2005); 13: Marcé *et al*. (2010); 14: Pednekar *et al*. (2005); 15: Paerl *et al*. (2006); 16: Tibby and Tiller (2007).]

Extreme hydrological events, such as floods, prompt speculation about whether they are “caused” by climate change. Climate change can indeed alter the probability of a particular event. However, to estimate the alteration reliably it is necessary to quantify uncertainties due to natural variability in the changed and the unchanged climates, and also – because of the need for model simulations – uncertainties due to limited ability to simulate the climate.

The probability or risk of the extreme event can be measured by recording the fraction of events beyond some threshold magnitude. Call this fraction r_{ctrl} in the simulated actual climate and r_{expt} in the simulated climate in which there is no anthropogenic forcing, and suppose there are many paired instances of r_{ctrl} and r_{expt}, with the ratio of risks in each pair given by $F = r_{expt}/r_{ctrl}$. The distribution of risk ratios F describes the likelihood that the climate change has altered the risk. Several thousand pairs of such simulations were run to estimate the risk ratio for the floods in England and Wales in autumn 2000 (Pall *et al.*, 2011). Each pair started from a unique initial state that differed slightly from a common reference state, and was obtained with a seasonal-forecast model driven by patterns of attributable warming found beforehand from four climate-model simulations of the 20th century. The forecast model was coupled to a model of basin-scale runoff and channel-scale hydraulics. It is not probable that such exercises will become routine for assessing single-event risks in, for example, the insurance industry, because the necessary amount of computation was so formidable. Nevertheless, the result was compelling: in each of the four sets of simulation pairs, the risk increased greatly on average in the runs forced by anthropogenic greenhouse radiation. In aggregate, the most probable amount of increase was two- to three-fold, and at most a few percent of the simulation pairs suggested that anthropogenic forcing actually decreased the risk. This summary is worded carefully: the thousands of simulation pairs were needed for quantifying the uncertainties, which led unavoidably to a spread of likelihoods, and thus to statements about uncertainty about risk that are themselves uncertain.

3.2.2. Precipitation, Evapotranspiration, Soil Moisture, Permafrost, and Glaciers

Global trends in precipitation from several different datasets during 1901-2005 are statistically insignificant (Bates *et al*., 2008; WGI Chapter 2). According to regional observations, most droughts and extreme rainfall events of the 1990s and 2000s have been the worst since the 1950s (Arndt *et al*., 2010) and certain trends in total and extreme precipitation amounts are observed (WGI Chapter 2). Most regional changes in precipitation are attributed either to internal variability of the atmospheric circulation or to global warming (Lambert *et al*., 2004; Stott *et al*., 2010). It was estimated that the 20th-century anthropogenic forcing contributed significantly to observed changes in global and regional precipitation (Zhang *et al*., 2007). Changes in snowfall amounts are indeterminate, as for precipitation; however, consistent with observed warming, shorter snowfall seasons are observed over most of the Northern Hemisphere, with snowmelt seasons starting earlier (Takala *et al*., 2009). In Norway, increased temperature at lower altitudes has reduced the snow water equivalent (Skaugen *et al*., 2012).

Steady decreases since the 1960s of global and regional actual evapotranspiration and pan evaporation have been attributed to changes in precipitation, in diurnal temperature range, aerosol concentration, (net) solar radiation, vapour pressure deficit, and wind speed (Fu *et al*., 2009; McVicar *et al*., 2010; Miralles *et al*., 2011; Wang A. *et al*., 2011). Regional downward and upward trends in soil moisture content have been calculated for China from 1950 to 2006, where longer, more severe and more frequent soil moisture droughts have been experienced over 37% of the land area (Wang A. *et al*., 2011). This is supported by detected increases since the 1960s in dry days and a prolongation of dry periods (Fischer *et al.*, 2013; Gemmer *et al*., 2011), and can be attributed to increases in warm days and warm periods (Fischer *et al.*, 2011).

Decreases in the extent of permafrost and increases in its average temperature are widely observed, for example in some regions of the Arctic and Eurasia (WGI Chapter 4) and the Andes (Rabassa, 2009). Active layer depth and permafrost degradation are closely dependent on soil ice content. In steep terrain, slope stability is highly affected by changes in permafrost (Harris *et al*., 2009). The release of GHGs (greenhouse gases) due to permafrost degradation can have unprecedented impacts on the climate, but these processes are not well represented in global climate models yet (Grosse *et al*., 2011). In most parts of the world glaciers are losing mass (Gardner *et al.*, 2013). For example, almost all glaciers in the tropical Andes have been shrinking rapidly since the 1980s (Rabassa, 2009; Rabatel *et al.*, 2013); similarly, Himalayan glaciers are losing mass at present (Bolch *et al.*, 2012).

3.2.3. Streamflow

Detected trends in streamflow are generally consistent with observed regional changes in precipitation and temperature since the 1950s. In Europe, streamflow (1962-2004) decreased in the south and east and generally increased elsewhere (Stahl *et al*., 2010; 2012), particularly in northern latitudes (Wilson *et al*., 2010). In North America (1951-2002), increases were observed in the Mississippi basin and decreases in the US Pacific Northwest and southern Atlantic-Gulf regions (Kalra *et al*., 2008). In China, a decrease in streamflow in the Yellow River (1960-2000) is consistent with a reduction of 12% in summer and autumn precipitation, whereas the Yangtze shows a small increase in annual streamflow driven by an increase in monsoon rains (Piao *et al*., 2010; see Table 3-1). These and other stream flow trends must be interpreted with caution (Jones, 2011) because of confounding factors such as land-use changes (Zhang and Schilling, 2006), irrigation (Kustu *et al*., 2010) and urbanization (Wang and Cai, 2010).

In a global analysis of simulated streamflows (1948-2004), about one-third of the top 200 rivers (including the Congo, Mississippi, Yenisei, Paraná, Ganges, Columbia, Uruguay and Niger) showed significant trends in discharge; 45 recorded decreases and only 19 recorded increases (Dai *et al*., 2009). Decreasing trends in low and mid latitudes are consistent with recent drying and warming in West Africa, southern Europe, south and east Asia, eastern Australia, western Canada and the USA and northern South America (Dai, 2013). The contribution to observed streamflow changes due to decreased stomatal opening of many plant species at higher CO_2 concentration remains disputed (Box CC-VW).

In regions with seasonal snow storage, warming since the 1970s has led to earlier spring discharge maxima (*high agreement, robust evidence*) and has increased winter flows because more winter precipitation falls as rain instead of snow (Clow, 2010; Korhonen and Kuusisto, 2010; Tan *et al*., 2011). There is *robust evidence* of earlier breakup of river ice in Arctic rivers (de Rham *et al*., 2008; Smith, 2000). Where streamflow is lower in summer, decrease in snow storage has exacerbated summer dryness (Cayan *et al*., 2001; Knowles *et al*., 2006).

3.2.4. Groundwater

Attribution of observed changes in groundwater level, storage or discharge to climatic changes is difficult due to additional influences of land use changes and groundwater abstractions (Stoll *et al*., 2011). Observed trends are largely attributable to these additional influences. The extent to which groundwater abstractions have already been affected by climate change is not known. Both detection of changes in groundwater systems and attribution of those changes to climatic changes are rare, due to a lack of appropriate observation wells and a small number of studies. Observed decreases of the discharge of groundwater-fed springs in Kashmir (India) since the 1980s were attributed to observed precipitation decreases (Jeelani, 2008; Table 3-1). A model-based assessment of observed decreases of groundwater levels in four overexploited karst aquifers in Spain led to the conclusion that groundwater recharge not only decreased strongly during the 20th century due to the decreasing precipitation but that groundwater recharge as a fraction of observed precipitation declined progressively, possibly indicating an increase in evapotranspiration (Aguilera and Murillo, 2009; Table 3-1).

3.2.5. Water Quality

Most observed changes of water quality due to climate change (Table 3-1; Figure 3-2) are known from isolated studies, mostly of rivers or lakes in high-income countries, of a small number of variables. In addition, even though some studies extend over as many as 80 years, most are short-term. For lakes and reservoirs, the most frequently reported change is more intense eutrophication and algal blooms at higher temperatures, or shorter hydraulic retention times and higher nutrient loads resulting from increased storm runoff (*high agreement, medium to robust evidence*). Greater runoff results in greater loads of salts, faecal coliforms, pathogens and heavy metals (Boxall *et al*., 2009; Paerl *et al.*, 2006; Pednekar *et al.*, 2005; Tibby and Tiller, 2007) (*medium to high agreement, robust evidence*, depending on the pollutant). In some cases there are associated impacts on health. For instance, hospital admissions for gastrointestinal illness in elderly people increased by 10% when turbidity increased in the raw water of a drinking water plant even when treated using conventional procedures (Schwartz *et al*., 2000). However, positive impacts were also reported. For example, the risk of eutrophication was reduced when nutrients were flushed from lakes and estuaries by more frequent storms and hurricanes (Paerl and Huisman, 2008). For rivers, all reported impacts on water quality were negative. Greater runoff, instead of diluting pollution, swept more pollutants from the soil into watercourses (*medium to high agreement, robust evidence*) (Benítez-Gilabert *et al*., 2010; Boxall *et al*., 2009; Gascuel-Odoux *et al.*, 2010; Howden *et al*., 2010; Loos *et al*., 2009; Macleod *et al*., 2012; Saarinen *et al*., 2010; Tetzlaff *et al.*, 2010). Increased organic matter content impaired the quality of conventionally treated drinking water (Weatherhead and Howden, 2009). In streams in semiarid and arid areas, temperature changes had a stronger influence on the increase of organic matter, nitrates and phosphorus than precipitation changes (Benítez-Gilabert *et al.*, 2010; Chang, 2004; Ozaki *et al.*, 2003) (*medium agreement, limited evidence*). Studies of impacts on groundwater quality are limited and mostly report elevated concentrations of faecal coliforms during the rainy season or after extreme rain events (*high agreement, medium evidence*), with varying response times (Auld *et al*., 2004; Curriero *et al*., 2001; Jean *et al*., 2006; Seidu *et al*., 2013; Tumwine *et al*., 2002; 2003). Given the widespread use of groundwater for municipal supply and minimal or lacking treatment of drinking water in poor regions, increased pollution is a source of concern (Jean *et al.*, 2006; Seidu *et al*., 2013). Another concern is the nonlinearity (except for temperature) of relationships between water quality and climatic variables (*medium agreement, limited evidence*). In general, the linkages between observed effects on water quality and climate should be interpreted cautiously and at the local level, considering the type of water body, the pollutant of concern, the hydrological regime and the many other possible sources of pollution (*high confidence*, Benítez-Gilabert *et al*., 2010; Howden *et al*., 2010; Kundzewicz and Krysanova, 2010; Senhorst and Zwolsman, 2005; Ventela *et al*., 2011; Whitehead *et al*., 2009a).

[INSERT FIGURE 3-2 HERE
Figure 3-2: Observations of the impacts of climate on water quality.]

3.2.6. Soil Erosion and Sediment Load

Precipitation extremes in many regions have increased since 1950 (Seneviratne *et al*., 2012), which suggests an increase in rainfall erosivity that would enhance soil erosion and stream sediment loads. A warmer climate may affect soil moisture, litter cover and biomass production, and can bring about a shift in winter precipitation from snow to more erosive rainfall (Kundzewicz *et al*., 2007) or, in semiarid regions, an increase in wildfires with subsequent rainfall leading to intense erosive events (Bussi *et al*., 2013; Nyman *et al*., 2011). The effects of climate change on soil erosion and sediment load are frequently obscured by human agricultural and management activities (Walling, 2009).

Only few studies have isolated the contribution of climate change to observed trends in soil erosion and sediment load. In the Yellow River basin, where soil erosion results mostly from heavy rainfall, reduced precipitation (~10%) contributed about 30% to a total reduction in stream sediment loads reaching the sea during 2000-2005, compared to 1950-1968, with the remaining 70% attributable to sediment trapping in reservoirs and soil conservation measures (Miao *et al*., 2011; Wang *et al*., 2007). Dai *et al*. (2008), analyzing the decrease in sediment load of the Yangtze River over 1956-2002, found that climate change was responsible for an increase of about 3±2%; most of the decline in its lower reaches was due to dam construction (Three Gorges Dam) and soil conservation measures.

Potential impacts of climate change on soil erosion and sediment production are of concern in regions with pronounced glacier retreat (Walling, 2009). Glacial rivers are expected to discharge more meltwater, which may increase sediment loads. However, the *limited evidence* is inconclusive for a global diagnosis of sediment load changes; there are both decreasing (e.g. Iceland, Lawler *et al*., 2003) and increasing trends (Patagonia, Fernandez *et al*., 2011). So far, there is no clear evidence that the frequency or magnitude of shallow landslides have changed over past decades (Huggel *et al*., 2012), even in regions with relatively complete event records (e.g. Switzerland, Hilker *et al*., 2009). Increased landslide impacts (measured by casualties or losses) in south and southeast Asia, where landslides are predominantly triggered by monsoon and tropical cyclone activity, are largely attributed to population growth leading to increased exposure (Petley, 2012).

In summary, there is *low agreement* and *limited evidence* that anthropogenic climate change has made a significant contribution to soil erosion, sediment loads and landslides. The available records are limited in space and time, and evidence suggests that, in most cases, the impacts of land-use and land-cover changes are more significant than those of climate change.

3.2.7. Extreme Hydrological Events and Their Impacts

There is *low confidence*, due to *limited evidence*, that anthropogenic climate change has affected the frequency and magnitude of floods at global scale (Kundzewicz *et al*., 2013). The strength of the evidence is limited mainly by lack of long-term records from unmanaged catchments. Moreover, in the attribution of detected changes it is difficult to distinguish the roles of climate and human activities (Section 3.2.1). However, recent detection of trends in extreme precipitation and discharge in some catchments implies greater risks of flooding at regional scale (*medium confidence*). More locations show increases in heavy precipitation than decreases (Seneviratne *et al*., 2012). Flood-damage costs worldwide have been increasing since the 1970s, although this is partly due to increasing exposure of people and assets (Handmer *et al*., 2012).

There is no strong evidence for trends in observed flooding in the USA (Hirsch and Ryberg, 2012), Europe (Benito and Machado, 2012; Hannaford and Hall, 2012; Mudelsee *et al*., 2003; Stahl *et al*., 2010), South America, and Africa (Conway *et al*., 2009). However, at smaller spatial scales, an increase in annual maximum discharge has been detected in parts of northwestern Europe (Giuntoli *et al*., 2012; Hattermann *et al*., 2012; Petrow and Merz, 2009), while a decrease was observed in southern France (Giuntoli *et al*., 2012). Flood discharges in the lower Yangtze basin increased over the last 40 years (Jiang *et al*., 2008; Zhang *et al*., 2009), and both upward and downward trends were identified in four basins in the northwestern Himalaya (Bhutiyani *et al*., 2008). In Australia, only 30% of 491 gauge stations showed trends at the 10% significance level, with decreasing magnitudes in southern regions and increasing magnitudes in the northern regions (Ishak *et al*., 2010). In Arctic rivers dominated by a snowmelt regime, there is no general trend in flood magnitude and frequency (Shiklomanov *et al*., 2007). In Nordic countries, significant changes since the mid-20th century are mostly towards earlier seasonal flood peaks, but flood magnitudes show contrasting trends, driven by temperature and precipitation, in basins with and without glaciers: increasing peaks in the former and decreasing peaks in the latter (Dahlke *et al*., 2012; Wilson *et al*., 2010). Significant trends at almost one fifth of 160 stations in Canada were reported, most of them decreases in snowmelt-flood magnitudes (Cunderlik and Ouarda, 2009). Similar decreases were found for spring and annual maximum flows (Burn *et al*., 2010).

Attribution has been addressed by Hattermann *et al*. (2012), who identified parallel trends in precipitation extremes and flooding in Germany, which for the increasing winter floods are explainable in terms of increasing frequency and persistence of circulation patterns favourable to flooding (Petrow *et al*., 2009). It is *very likely* that the observed intensification of heavy precipitation is largely anthropogenic (Min *et al.*, 2011; see also Section 3.2.1).

Socio-economic losses from flooding are increasing (*high confidence*), although attribution to anthropogenic climate change is established only seldom (Pall *et al.*, 2011). Reported flood damages (adjusted for inflation) have increased from an average of 7 billion US$ per year in the 1980s to about 24 billion US$ per year in 2011 (Munich Re, 2012; Kundzewicz *et al*., 2013). Economic, including insured, flood disaster losses are higher in developed countries, while fatality rates and economic losses expressed as a proportion of gross domestic product are higher in developing countries. Since 1980, the annual number of flood-related deaths has been in the thousands, with over 95% in developing countries and 75% in southern, southeastern and eastern Asia (Handmer *et al*., 2012). There is *high confidence* (*high agreement*, *medium evidence*) that greater exposure of people and assets, and societal factors related to population and economic growth, contributed to the increased losses (Handmer *et al*., 2012; Kundzewicz *et al*., 2013). When damage records are normalized for changes in exposure and vulnerability (Bouwer, 2011), most studies find no contribution of flooding trends to the trend in losses (Barredo, 2009; Benito and Machado, 2012; Hilker *et al*., 2009), although there are exceptions (Chang *et al*., 2009; Jiang *et al*., 2005).

Assessments of observed changes in 'drought' depend on the definition of drought (meteorological, agricultural or hydrological) and the chosen drought index (e.g. consecutive dry days, Standardised Precipitation Index (SPI), Palmer Drought Severity Index (PDSI), Standardised Runoff Index (SRI); see Seneviratne *et al.*, 2012). Meteorological (rainfall) and agricultural (soil moisture) droughts have become more frequent since 1950 (Seneviratne *et al*., 2012) in some regions, including southern Europe and western Africa, but in others (including the southern USA; Chen *et al*., 2012) there is no evidence of change in frequency (WGI Chapter 2).

Very few studies have considered variations over time in hydrological (streamflow) drought, largely because there are few long records from catchments without direct human interventions. A trend was found towards lower summer minimum flows for 1962–2004 in small catchments in southern and eastern Europe were found, but there was no clear trend in northern or western Europe (Stahl *et al*., 2010). Models can reproduce observed patterns of drought occurrence (e.g. Prudhomme *et al*., 2011), but as with climate models their outputs can be very divergent. In simulations of drought at the global scale in 1963–2000 with an ensemble of hydrological models, strong correlations were noted between ENSO (El Niño-Southern Oscillation) events and hydrological droughts, and – particularly in dry regions – low correlations between meteorological and hydrological droughts, which suggests that hydrological droughts cannot necessarily be inferred from rainfall deficits (van Huijgevoort *et al*., 2013).

3.3. Drivers of Change for Freshwater Resources

3.3.1. Climatic Drivers

Precipitation and potential evaporation are the main climatic drivers controlling freshwater resources. Precipitation is strongly related to atmospheric water-vapor content, because saturation specific humidity depends on temperature: warmer air can hold much more water vapor. Temperature has increased in recent decades while surface and tropospheric relative humidity have changed little (WGI Chapter 2). Among other climatic drivers are atmospheric carbon dioxide, which affects plant transpiration (Box CC-VW), and deposited black carbon and dust, both of which, even in very small concentrations, enhance melting of snow and ice by reducing the surface albedo.

Uncertainty in the climatic drivers is due mainly to internal variability of the atmospheric system, inaccurate modelling of the atmospheric response to external forcing, and the external forcing itself as described by the Representative Concentration Pathways (RCPs; Section 1.1.3 in Chapter 1). Internal variability and variation between models account for all of the uncertainty in precipitation in the first few decades of the 21st century in CMIP (Coupled Model Intercomparison Project) Phase 3 projections (Hawkins and Sutton, 2011). The contribution of internal variability diminishes progressively. By no later than mid-century, most of the uncertainty in precipitation is due to discrepancies between models, and divergent scenarios never contribute more than one third of the uncertainty. In contrast, the uncertainty in temperature (WGI Chapter 11) is due mostly to divergent scenarios.

CMIP5 simulations of the water cycle during the 21st century (WGI Chapter 12), with further constraints added here from 20th-century observations, can be summarized as follows:

- Surface temperature, which affects the vapor-carrying capacity of the atmosphere and the ratio of snowfall to precipitation, increases non-uniformly, but by about 1.5 times more over land than over ocean (*very high confidence*).
- Warming is greatest over the Arctic (*very high confidence*), implying latitudinally variable changes in snowmelt and glacier mass budgets.
- Less precipitation falls as snow and snow cover decreases in extent and duration (*high confidence*). In the coldest regions, however, increased winter snowfall outweighs increased summer snowmelt.
- Wet regions and seasons become wetter and dry regions and seasons become drier (*high confidence*), although one observational analysis (Sun *et al.*, 2012) is discordant; moreover the models tend to underestimate observed trends in precipitation (Noake *et al.*, 2012) and its observed sensitivity to temperature (Liu *et al.*, 2012).
- Global mean precipitation increases in a warmer world (*virtually certain*), but with substantial variations, including some decreases, from region to region. Precipitation tends to decrease in subtropical latitudes, particularly in the Mediterranean, Mexico and central America and parts of Australia, and to increase elsewhere, notably at high northern latitudes and in India and parts of central Asia (*likely* to *very likely*; WGI Chapter 12, Figure 12-41). However, precipitation changes generally become statistically significant only when temperature rises by at least 1.4°C, and in many regions projected 21st-century changes lie within the range of late-20th-century natural variability (Mahlstein *et al.*, 2012).
- Changes in evaporation have patterns similar to those of changes in precipitation, with moderate increases almost everywhere, especially at higher northern latitudes (Figure 12-25 in WGI Chapter 12). Scenario-dependent decreases of soil moisture are widespread, particularly in central and southern Europe, southwestern North America, Amazonia and southern Africa (*medium to high confidence*; Figure 12-23 and Section 12.4.5.3 in WGI Chapter 12).

More intense extreme precipitation events are expected (IPCC, 2012). One proposed reason is the projected increase in specific humidity: intense convective precipitation in short periods (less than 1 hour) tends to “empty” the water vapor from the atmospheric column (Berg *et al.*, 2013; Utsumi *et al.*, 2011). Annual maxima of daily precipitation that are observed to have 20-year return periods in 1986-2005 are projected to have shorter return periods in 2081-2100: about 14 years for RCP2.6, 11 years for RCP4.5 and 6 years for RCP8.5 (Kharin *et al.*, 2013). Unlike annual mean precipitation, for which the simulated sensitivity to warming is typically 1.5-2.5% K^{-1}, the 20-year return amount of daily precipitation typically increases at 4-10% K^{-1}. Agreement between model-simulated extremes and reanalysis extremes is good in the extra-tropics but poor in the tropics, where there is *robust evidence* of greater sensitivity (10±4% K^{-1}, O'Gorman, 2012). In spite of the intrinsic uncertainty of sampling infrequent events, variation between models is the dominant contributor to uncertainty. Model-simulated changes in the incidence of meteorological (rainfall) droughts vary widely, so that there is at best *medium confidence* in projections (Seneviratne *et al.*, 2012). Regions where droughts are projected to become longer and more frequent include the Mediterranean, central Europe, central North America and southern Africa.

3.3.2. Non-Climatic Drivers

In addition to impacts of climate change, the future of freshwater systems will be impacted strongly by demographic, socio-economic and technological changes, including lifestyle changes. These change both exposure to hazard and requirements for water resources. A wide range of socio-economic futures can produce similar climate changes (van Vuuren *et al*., 2012), meaning that certain projected hydrological changes (Section 3.4) can occur under a wide range of future demographic, social, economic and ecological conditions. Similarly the same future socio-economic conditions can be associated with a range of different climate futures.

Changing land use is expected to affect freshwater systems strongly in the future. For example, increasing urbanization may increase flood hazards and decrease groundwater recharge. Of particular importance for freshwater systems is future agricultural land use, especially irrigation, which accounts for about 90% of global water consumption and severely impacts freshwater availability for humans and ecosystems (Döll, 2009). Due mainly to population and economic growth but also to climate change, irrigation may significantly increase in the future. The share of irrigation from groundwater is expected to increase due to increased variability of surface water supply caused by climate change (Taylor R. *et al*., 2013a).

3.4. Projected Hydrological Changes

3.4.1. Methodological Developments in Hydrological Impact Assessment

Most recent studies of the potential impact of climate change on hydrological characteristics have used a small number of climate scenarios. An increasing number has used larger ensembles of regional or global models (e.g. Arnell, 2011; Arnell and Gosling, 2013; Bae *et al*., 2011; Chiew *et al*., 2009; Gosling *et al*., 2010; Jackson *et al*., 2011; Kling *et al*., 2012; Olsson *et al*., 2011). Some studies have developed "probability distributions" of future impacts by combining results from multiple climate projections and, sometimes, different emissions scenarios, making different assumptions about the relative weight to give to each scenario (Brekke *et al*., 2009b; Christierson *et al*., 2012; Liu *et al*., 2013; Manning *et al*., 2009). These studies conclude that the relative weightings given are typically less important in determining the distribution of future impacts than the initial selection of climate models considered. Very few impact studies (Dankers *et al*., 2013; Hanasaki *et al*., 2013; Portmann *et al.*, 2013; Schewe *et al*., 2013) have so far used scenarios based on CMIP5 climate models, and these have only used a small subset.

Most assessments have used a hydrological model with the "delta method" to create scenarios, which applies projected changes in climate derived from a climate model either to an observed baseline or with a stochastic weather generator. Several approaches to the construction of scenarios at the catchment scale have been developed (Fowler *et al*., 2007), including dynamical downscaling using regional climate models and a variety of statistical approaches (e.g. Fu *et al*., 2013). Systematic evaluations of different methods have demonstrated that estimated impacts can be very dependent on the approach used to downscale climate model data, and the range in projected change between downscaling approaches can be as large as the range between different climate models (Chen J. *et al*., 2011; Quintana Segui *et al*., 2010). An increasing number of studies (e.g. Fowler and Kilsby, 2007; Hagemann *et al*., 2011; Kling *et al*., 2012; Teutschbein and Seibert, 2012; Veijalainen *et al*., 2012; Weiland *et al*., 2012a) have run hydrological models with bias-corrected input from regional or global climate model output (Piani *et al*., 2010; van Pelt *et al*., 2009; Yang *et al*., 2010), rather than by applying changes to an observed baseline. The range between different bias correction methods can be as large as the range between climate models (Hagemann *et al*., 2011), although this is not always the case (Chen C. *et al*., 2011; Muerth *et al*., 2013). Some studies (e.g. Falloon and Betts, 2006; 2010; Hirabayashi *et al*., 2008; Nakaegawa *et al*., 2013) have examined changes in global-scale river runoff as simulated directly by a high-resolution climate model, rather than by an "off-line" hydrological model. Assessments of the ability of climate models directly to simulate current river flow regimes (Falloon *et al*., 2011; Weiland *et al*., 2012b) show that performance largely depends on simulated precipitation and is better for large basins, but the limited evidence suggests that direct estimates of change are smaller than off-line estimates (Hagemann *et al*., 2013).

The effects of hydrological model parameter uncertainty on simulated runoff changes are typically small when compared with the range from a large number of climate scenarios (Arnell, 2011; Cloke *et al*., 2010; Lawrence and Haddeland, 2011; Steele-Dunne *et al*., 2008; Vaze *et al*., 2010). However, the effects of hydrological model structural uncertainty on projected changes can be substantial (Dankers *et al*., 2013; Hagemann *et al*., 2013; Schewe *et al*., 2013), due to differences in the representation of evaporation and snowmelt processes. In some regions (e.g. high latitudes; Hagemann et al., 2013) with reductions in precipitation (Schewe *et al*., 2013)), hydrological model uncertainty can be greater than climate model uncertainty – although this is based on small numbers of climate models. Much of the difference in projected changes in evaporation is due to the use of different empirical formulations (Milly and Dunne, 2011). In a study in southeast Australia, the effects of hydrological model uncertainty were small compared with climate model uncertainty, but all the hydrological models used the same potential evaporation data (Teng *et al.*, 2012).

Among other approaches to impact assessment, an inverse technique (Cunderlik and Simonovic, 2007) starts by identifying the hydrological changes which would be critical for a system and then uses a hydrological model to determine the meteorological conditions which trigger those changes; the future likelihood of these conditions is estimated by inspecting climate model output, as in a catchment study in Turkey (Fujihara *et al*., 2008a; 2008b). Another approach constructs response surfaces relating sensitivity of a hydrological indicator to changes in climate. Several studies have used a water-energy balance framework (based on Budyko's hypothesis and formula) to characterise the sensitivity of average annual runoff to changes in precipitation and evaporation (Donohue *et al*., 2011; Renner and Bernhofer, 2012; Renner *et al*., 2012). A response surface showing change in flood magnitudes was constructed by running a hydrological model with systematically-varying changes in climate (Prudhomme *et al*., 2010). This approach show the sensitivity of a system to change, and also allows rapid assessment of impacts under specific climate scenarios which can be plotted on the response surface.

3.4.2. Evapotranspiration, Soil Moisture and Permafrost

Based on global and regional climate models as well as physical principles, potential evapotranspiration over most land areas is *very likely* to increase in a warmer climate, thereby accelerating the hydrologic cycle (WGI Chapter 12). Long-term projections of actual evapotranspiration are uncertain in both magnitude and sign. They are affected not only by rising temperatures but also by changing net radiation and soil moisture, decreases in bulk canopy conductance associated with rising CO_2 concentrations, and vegetation changes related to climate change (Box CC-VW; Katul and Novick, 2009). Projections of the response of potential evapotranspiration to a warming climate are also uncertain. Based on six different methodologies, an increase in potential evapotranspiration was associated with global warming (Kingston *et al*., 2009). Regionally, increases are projected in southern Europe, Central America, southern Africa and Siberia (Seneviratne *et al.*, 2010). The accompanying decrease in soil moisture increases the risk of extreme hot days (Hirschi *et al.*, 2011; Seneviratne *et al.*, 2006) and heat waves. For a range of scenarios, soil-moisture droughts lasting 4–6 months double in extent and frequency, and droughts longer than 12 months become three times more common, between the mid-20th century and the end of the 21st century (Sheffield and Wood, 2008). Because of strong natural variability, the generally monotonic projected increases are statistically indistinguishable from current climate.

Changes consistent with warming are also evident in the freshwater systems and permafrost of northern regions. The area of permafrost is projected to continue to decline over the first half of the 21st century in all emissions scenarios (Figure 4-18 in WGI Chapter 4). Under RCP2.6, permafrost area is projected to stabilize at near 20% less than the 20th century area, and then begin to increase slightly.

3.4.3. Glaciers

All projections for the 21st century (WGI Chapter 13) show continued mass loss from glaciers. In glacierized catchments, runoff reaches an annual maximum in summer. As the glaciers shrink, their relative contribution decreases and the annual runoff peak shifts towards spring (e.g. Huss, 2011). This shift is expected with *very high confidence* in most regions, although not, for example, in the eastern Himalaya where the monsoon and the melt season coincide. The relative importance of high-summer glacier meltwater can be substantial, for example contributing 25% of August discharge in basins draining the European Alps, with area ~10^5 km^2 and only 1% glacier cover (Huss, 2011). Glacier meltwater also increases in importance during droughts and heat waves (Koboltschnig *et al*., 2007).

If the warming rate is constant, and if, as expected, ice melting per unit area increases and total ice-covered area decreases, the total annual yield passes through a broad maximum: "peak meltwater". Peak-meltwater dates have been projected between 2010 and 2050 (parts of China, Xie *et al.*, 2006); 2010–2040 (European Alps, Huss, 2011); and mid- to late-century (glaciers in Norway and Iceland, Jóhannesson *et al.*, 2012). Note that the peak can only be dated relative to a specified reference date. Declining yields relative to various dates in the past have been detected in some observational studies (Table 3-1); that is, a peak has been passed already. There is *medium confidence* that the peak response to 20th- and 21st-century warming will fall within the 21st century in many inhabited glacierized basins, where at present society is benefitting from a transitory "meltwater dividend". Variable forcing leads to complex variations of both the melting rate and the extent of ice, which depend on each other.

If they are in equilibrium, glaciers reduce the interannual variability of water resources by storing water during cold or wet years and releasing it during warm years (Viviroli *et al.*, 2011). As glaciers shrink, however, their diminishing influence may make the water supply less dependable.

_____ START BOX 3-1 HERE _____

Box 3-1. Case Study: Himalayan Glaciers

The total freshwater resource in the Himalayan glaciers of Bhutan, China, India, Nepal and Pakistan is known only roughly; estimates range from 2100 to 5800 Gt (Bolch *et al*., 2012). Their mass budgets have been negative on average for the past five decades. The loss rate may have become greater after about 1995, but it has not been greater in the Himalaya than elsewhere. A recent large-scale measurement, highlighted in Figure 3-3, is the first well-resolved, region-wide measurement of any component of the Himalayan water balance. It suggests strongly that the conventional measurements, mostly on small, accessible glaciers, are not regionally representative.

[INSERT FIGURE 3-3 HERE
Figure 3-3: All published glacier mass balance measurements from the Himalaya (based on Bolch *et al*., 2012). To emphasize the variability of the raw information, each measurement is shown as a box of height ±1 standard deviation centred on the average balance (±1 standard error for multi-annual measurements). Region-wide measurement (Kääb *et al*., 2012) was by satellite laser altimetry. Global average (WGI Chapter 4) is shown as a 1-sigma confidence region.]

Glacier mass changes for 2006-2100 were projected by simulating the response of a glacier model to CMIP5 projections from 14 general circulation models (GCMs) (Radić *et al*., 2013). Results for the Himalaya range between 2% gain and 29% loss to 2035; to 2100, the range of losses is 15-78% under RCP4.5. The model-mean loss to 2100 is 45% under RCP4.5 and 68% under RCP8.5 (*medium confidence*). It is *virtually certain* that these projections are more reliable than an earlier erroneous assessment (Cruz *et al*., 2007) of complete disappearance by 2035.

At the catchment scale, projections do not yet present a detailed region-wide picture. However the GCM-forced simulations of Immerzeel *et al.* (2013) in Kashmir and eastern Nepal show runoff increasing throughout the century. Peak ice meltwater is reached in mid- to late-century, but increased precipitation over-compensates for the loss of ice.

The growing atmospheric burden of anthropogenic black carbon implies reduced glacier albedo, and measurements in eastern Nepal by Yasunari *et al*. (2010) suggest that this could yield 70-200 mm/year of additional meltwater. Deposited soot may outweigh the greenhouse effect as a radiative forcing agent for snowmelt (Qian *et al*., 2011).

The hazard due to moraine-dammed ice-marginal lakes continues to increase. In the western Himalaya, they are small and stable in size, while in Nepal and Bhutan they are more numerous and larger, and most are growing (Gardelle *et al*., 2011). There has been little progress on the predictability of dam failure but, of five dams that have failed since 1980, all had frontal slopes steeper than 10° before failure and much gentler slopes afterwards (Fujita *et al*., 2013). This is a promising tool for evaluating the hazard in detail.

The relative importance of Himalayan glacier meltwater decreases downstream, being greatest where the runoff enters dry regions in the west and becoming negligible in the monsoon-dominated east (Kaser *et al*., 2010). In the mountains, however, dependence on and vulnerability to glacier meltwater are of serious concern when measured per head of population.

_____ END BOX 3-1 HERE _____

3.4.4. Runoff and Streamflow

Many of the spatial gaps identified in AR4 have been filled to a very large extent by catchment-scale studies of the potential impacts of climate change on streamflow. The projected impacts in a catchment depend on the sensitivity of the catchment to change in climatic characteristics and on the projected change in the magnitude and seasonal distribution of precipitation, temperature and evaporation. Catchment sensitivity is largely a function of the ratio of runoff to precipitation: the smaller the ratio, the greater the sensitivity. Proportional changes in average annual runoff are typically between one and three times as large as proportional changes in average annual precipitation (Tang and Lettenmaier, 2012).

Projected scenario-dependent changes in runoff at the global scale, mostly from CMIP3 simulations, exhibit a number of consistent patterns (e.g. Arnell and Gosling, 2013; Döll and Zhang, 2010; Fung *et al*., 2011; Hirabayashi *et al*., 2008; Murray *et al*., 2012; Nakaegawa *et al*., 2013; Okazaki *et al*., 2012; Schewe *et al*., 2013; Tang and Lettenmaier, 2012; Weiland *et al*., 2012a). Average annual runoff is projected to increase at high latitudes and in the wet tropics, and to decrease in most dry tropical regions. However, for some regions there is very considerable uncertainty in the magnitude and direction of change, specifically in China, south Asia and large parts of South America. Both the patterns of change and the uncertainty are largely driven by projected changes in precipitation, particularly across south Asia. Figure 3-4 shows the average percentage change in average annual runoff for an increase in global average temperature of 2°C above the 1980-2010 mean, averaged across five CMIP5 climate models and 11 hydrological models. The pattern of change in Figure 3-4 is different in some regions from the pattern shown in WGI Chapter 12 (Figure 12-24), largely because it is based on fewer climate models.

[INSERT FIGURE 3-4 HERE
Figure 3-4: Percentage change of mean annual streamflow for a global mean temperature rise of 2°C above 1980–2010 (2.7°C above pre-industrial). Color hues show the multi-model mean change across 4 GCMs and 11 global hydrological models (GHMs), and saturation shows the agreement on the sign of change across all 55 GHM-GCM combinations (percentage of model runs agreeing on the sign of change) (Schewe *et al*., 2013).]

The seasonal distribution of change in streamflow varies primarily with the seasonal distribution of change in precipitation, which in turn varies between scenarios. Figure 3-5 illustrates this variability, showing the percentage change in monthly average runoff in a set of catchments from different regions using scenarios from seven climate models, all scaled to represent a 2°C increase in global mean temperature above the 1961-1990 mean. One of the climate models is separately highlighted, and for that model the figure also shows changes with a 4°C rise in temperature. In the Mitano catchment in Uganda, for example, there is a non-linear relationship between amount of climate change and hydrological response. Incorporating uncertainty in hydrological model structure (Section 3.4.1) would increase further the range in projected impacts at the catchment scale.

[INSERT FIGURE 3-5 HERE
Figure 3-5: Change in mean monthly runoff across seven climate models in seven catchments, with a 2ºC increase in global mean temperature above 1961-1990 (Arnell, 2011; Hughes *et al*., 2011; Kingston and Taylor, 2010; Kingston *et al*., 2011; Nobrega *et al*., 2011; Thorne, 2011; Xu *et al*., 2011). One of the seven climate models (HadCM3) is highlighted separately, showing changes with both a 2ºC increase (dotted line) and a 4ºC increase (solid line).]

There is a much more consistent pattern of future seasonal change in areas currently influenced by snowfall and snowmelt. A global analysis (Adam *et al*., 2009) with multiple climate scenarios shows a consistent shift to earlier peak flows, except in some regions areas where increases in precipitation are sufficient to result in increased, rather than decreased snow accumulation during winter. The greatest changes are found near the boundaries of regions which currently experience considerable snowfall, where the marginal effect on snowfall and snowmelt of higher temperatures is greatest.

3.4.5. Groundwater

While the relation between groundwater and climate change was rarely investigated before 2007, the number of studies and review papers (Green *et al*., 2011; Taylor R. *et al*., 2013a) has increased significantly since then. Ensemble studies, relying on between four and twenty climate models, of the impact of climate change on groundwater recharge and partially also on groundwater levels were done for the globe (Portmann *et al*., 2013), all of Australia (Crosbie *et al*., 2013a), the German Danube basin (Barthel *et al*., 2010), aquifers in Belgium and England (Goderniaux *et al*., 2011; Jackson *et al*., 2011), the Pacific coast of the USA and Canada (Allen *et al*., 2010) and the semi-arid High Plains aquifer of the USA (Crosbie *et al*., 2013b; Ng *et al*., 2010). With three exceptions, simulations were run under only one GHG emissions scenario. The range over the climate models of projected groundwater changes was large, from significant decreases to significant increases for the individual study areas, and the range of percentage changes of projected groundwater recharge mostly exceeded the range of projected precipitation changes. The uncertainties in projected groundwater recharge that originate in the hydrological models have not yet been explored. There are only a few studies of the impacts on groundwater of vegetation changes in response to climate change and CO_2 increase (Box CC-VW). Nor are there any studies on the impact of climate-driven changes of land use on groundwater recharge, even though projected increases in precipitation and streamflow variability due to climate change are expected to lead to increased groundwater abstraction (Taylor R. *et al*., 2013a), lowering groundwater levels and storage.

Under any particular climate scenario, the areas where total runoff (sum of surface runoff and groundwater recharge) is projected to increase (or decrease) roughly coincide with the areas where groundwater recharge and thus renewable groundwater resources are projected to increase (or decrease) (Kundzewicz and Döll, 2009). Changes in precipitation intensity affect the fraction of total runoff that recharges groundwater. Increased precipitation intensity may decrease groundwater recharge due to exceedance of the infiltration capacity (typically in humid areas), or may increase it due to faster percolation through the root zone and thus reduced evapotranspiration (typically in semi-arid areas) (Liu, 2011; Taylor R. *et al*., 2013b). The sensitivity of groundwater recharge and levels to climate change is diminished by perennial vegetation, fine-grained soils and aquitards, and is enhanced by annual cropping, sandy soils and unconfined (water-table) aquifers (Crosbie *et al*., 2013b; van Roosmalen *et al*., 2007). The sensitivity of groundwater recharge change to precipitation change was found to be highest for low groundwater recharge and lowest for high groundwater recharge, the ratio of recharge change to precipitation change ranging from 1.5 to 6.0 in the semi-arid High Plains aquifer (Crosbie *et al*., 2013b). Decreasing snowfall may lead to lower groundwater recharge even if precipitation remains constant; at sites in the southwestern USA, snowmelt provides at least 40-70% of groundwater recharge, although only 25-50% of average annual precipitation falls as snow (Earman *et al*., 2006).

Climate change affects coastal groundwater not only through changes in groundwater recharge but also through sea-level rise which, together with the rate of groundwater pumping, determines the location of the saltwater/freshwater interface. While most confined aquifers are expected to be unaffected by sea-level rise, unconfined aquifers are expected to suffer from saltwater intrusion (Werner *et al*., 2012). The volume available for freshwater storage is reduced if the water table cannot rise freely as the sea level rises (Masterson and Garabedian, 2007; Werner *et al*., 2012). This happens where land surfaces are low-lying, for example on many coral islands and in deltas, but also where groundwater discharges to streams. If the difference between the groundwater table and sea level is decreased by 1 meter, the thickness of the unconfined freshwater layer decreases by roughly 40 meter (Ghyben-Herzberg relation). Deltas are also affected by storm surges that drive salt water into stream channels, contaminating the underlying fresh groundwater from above (Masterson and Garabedian, 2007). In three modeling studies, the impact of sea-level rise on groundwater levels was found to be restricted to areas within 10 km from the coast (Carneiro *et al*., 2010; Oude Essink *et al*., 2010; Yechieli *et al*., 2010). Salt water intrusion due to sea-level rise is mostly a very slow process that may take several centuries to reach equilibrium (Webb and Howard, 2011). Even small rates of groundwater pumping from coastal aquifers are expected to lead to stronger salinization of the groundwater than sea-level rise during the 21st century (Ferguson and Gleeson, 2012; Loaiciga *et al*., 2012).

Changes in groundwater recharge also affect streamflow. In the Mitano basin in Uganda, mean global temperature increases of 4°C or more with respect to 1961-1990 are projected to decrease groundwater outflow to the river so much that the spring discharge peak disappears and the river flow regime changes from bimodal to unimodal (one seasonal peak only) (Kingston and Taylor, 2010; Figure 3-5). Changing groundwater tables affect land-surface energy fluxes, including evaporation, and thus feed back on the climate system, in particular in semi-arid areas where the groundwater table is within 2-10 meter of the surface (Ferguson and Maxwell, 2010; Jiang *et al*., 2009).

3.4.6. Water Quality

Climate change affects the quality of water through a complex set of natural and anthropogenic mechanisms working concurrently in parallel and in series. Projections under climate-change scenarios are difficult, both to perform and interpret, because they require not only integration of the climate models with those used to analyze the transportation and transformation of pollutants in water, soil, and air but also the establishment of a proper baseline (Andersen *et al*., 2006; Arheimer *et al*., 2005; Bonte and Zwolsman, 2010; Ducharne, 2008; Marshall and Randhir, 2008; Rehana and Mujumdar, 2012; Towler *et al*., 2010; Trolle *et al*., 2011; Wilby *et al*., 2006). The models have different spatial scales and have to be adapted and calibrated to local conditions for which adequate and appropriate information is needed. In consequence, there are few projections of the impacts of climate change on water quality; where available, their uncertainty is high. It is evident, however, that water-quality projections depend strongly on (a) local conditions; (b) climatic and environmental assumptions; and (c) the current or reference pollution state (Bonte and Zwolsman, 2010; Chang, 2004; Kundzewicz and Krysanova, 2010; Sahoo *et al*., 2010; Trolle *et al*., 2011; Whitehead *et al*., 2009a; 2009b). Most projections suggest that future negative impacts will be similar in kind to those already observed in response to change and variability in air and water temperature, precipitation and storm runoff, and to many confounding anthropogenic factors (Chang, 2004; Whitehead *et al*., 2009a). This holds for natural and artificial reservoirs (Bonte and Zwolsman, 2010; Brikowski, 2008; Ducharne, 2008; Loos *et al*., 2009; Marshall and Randhir, 2008; Qin *et al*., 2010; Sahoo *et al*., 2010; Trolle *et al*., 2011), rivers (Andersen *et al*., 2006; Bowes *et al*., 2012; Whitehead *et al*., 2009a; 2009b) and groundwater (Butscher and Huggenberger, 2009; Rozemeijer *et al*., 2009).

3.4.7. Soil Erosion and Sediment Load

Heavy rainfalls are *likely* to become more intense and frequent during the 21st century in many parts of the world (Seneviratne *et al*., 2012; WGI Chapter 11), which may lead to more intense soil erosion even if the total rainfall does not increase. At the global scale, soil erosion simulated assuming doubled CO_2 is projected to increase about 14% by the 2090s, compared to the 1980s (9% attributed to climate change and 5% to land use change), with increases by as much as 40-50% in Australia and Africa (Yang *et al*., 2003). The largest increases are expected in semiarid areas, where a single event may contribute 40% of total annual erosion (Bussi *et al*., 2013). In agricultural lands in temperate regions, soil erosion may respond to more intense erosion in complex non-linear ways; for instance in the UK a 10% increase in winter rainfall (i.e. during early growing season) could increase annual erosion of arable land by up to 150% (Favis-Mortlock and Boardman, 1995), while in Austria a simulation for 2010–2099 projected a decrease of rainfall by 10-14% in erosion-sensitive months and thus a decline in soil erosion by 11-24% (Scholz *et al*., 2008). Land management practices are critical for mitigating soil erosion under projected climate change. In China's Loess Plateau, four GCMs coupled to an erosion model show soil erosion increasing by 5-195% during 2010-2039 under conventional tillage, for three emission scenarios (A2, B2 and GGa), whereas under conservation tillage they show decreases of 26-77% (Li *et al*., 2011).

Climate change will also affect the sediment load in rivers by altering water discharge and land cover. For example, an increase in water discharge of 11-14% in two Danish rivers under the SRES A2 emission scenario was projected to increase the annual suspended sediment load by 9–16% during 2071-2100 (Thodsen *et al*., 2008). Increases in total precipitation, increased runoff from glaciers, permafrost degradation, and the shift of precipitation from snow to rain will further increase soil erosion and sediment loads in colder regions (Lu *et al*., 2010). In a major headwater basin of the Ganges River, increased precipitation and glacier runoff are projected to increase sediment yield by 26% by 2050 (Neupane and White, 2010). In the tropics, the intensity of cyclones is projected to increase 2-11% by 2100, which may increase soil erosion and landslides (Knutson *et al*., 2010).

In summary, projected increases in heavy rainfall and temperature will lead to changes in soil erosion and sediment load, but due to the non-linear dependence of soil erosion on rainfall rate and its strong dependence on land cover there is *low confidence* in projected changes in erosion rates. At the end of the 21st century, the impact of climate change on soil erosion is expected to be twice the impact of land-use change (Yang *et al*., 2003), although management practices may mitigate the problem at catchment scale.

3.4.8. Extreme Hydrological Events (Floods and Droughts)

The SREX report (Seneviratne *et al*., 2012) recognized that projected increases in temperature and heavy precipitation imply regional-scale changes in flood frequency and intensity, but with *low confidence* because these projections were obtained from a single GCM. Global flood projections based on multiple CMIP5 GCM simulations coupled with global hydrology and land surface models (Dankers *et al*., 2013; Hirabayashi *et al*., 2013) show flood hazards increasing over about half of the globe, but with great variability at the catchment scale. Projections of increased flood hazard are consistent for parts of south and southeast Asia, tropical Africa, northeast Eurasia, and South America (Figure 3-6), while decreases are projected in parts of northern and eastern Europe, Anatolia, central Asia, central North America, and southern South America. This spatial pattern resembles closely that described by Seneviratne *et al.* (2012), but the latest projections justify *medium confidence* despite new appreciation of the large uncertainty due to variation between climate models and their coupling to hydrological models.

[INSERT FIGURE 3-6 HERE
Figure 3-6: a) Multi-model median return period (years) in the 2080s for the 20th-century 100-year flood (Hirabayashi *et al*., 2013), based on one hydrological model driven by 11 CMIP5 GCMs under RCP8.5. At each location the magnitude of the 100-year flood was estimated by fitting a Gumbel distribution function to time series of simulated annual maximum daily discharge in 1971–2000, and the return period of that flood in 2071–2100 was estimated by fitting the same distribution to discharges simulated for that period. b) Global exposure to the 20th-century 100-year flood (or greater) in millions of people (Hirabayashi *et al*., 2013). Left: ensemble means of historical (black thick line) and future simulations (coloured thick lines) for each scenario. Shading denotes ±1 standard deviation. Right: maximum and minimum (whiskers), mean (horizontal thick lines within each bar), ±1 standarddeviation (box) and projections of each GCM (coloured symbols) averaged over the 21st century. The impact of 21st-century climate change is emphasized by fixing the population to that of 2005. Annual global flood exposure increases over the century by 4-14 times as compared to the 20th century [4±3 (RCP2.6), 7±5 (RCP4.5), 7±6 (RCP6.0) and 14±10 (RCP8.5) times, or 0.1% to 0.4-1.2% of the global population in 2005)]. Under a scenario of moderate population growth (UN, 2011), the global number of exposed people is projected to increase by a factor of 7-25, depending on the RCP, with strong increases in Asia and Africa due to high population growth.]

There have been several assessments of the potential effect of climate change on meteorological droughts (less rainfall) and agricultural droughts (drier soil) (e.g. WGI Chapter 12; Orlowsky and Seneviratne, 2013; Vidal *et al*., 2012), but few on hydrological droughts, either in terms of river runoff or groundwater levels. Many catchment-scale studies (Section 3.4.4) consider changes in indicators of low river flow (such as the flow exceeded 95% of the time), but these indicators do not necessarily characterise 'drought' as they define neither duration nor spatial extent, and are not necessarily particularly extreme or rare. In an ensemble comparison under SRES A1B of the proportion of the land surface exhibiting significant projected changes in hydrological drought frequency to the proportions exhibiting significant changes in meteorological and agricultural drought frequency, 18-30% of the land surface (excluding cold areas) experienced a significant increase in the frequency of 3-month hydrological droughts, whilst approximately 15-45% saw a decrease (Taylor I. *et al*., 2013). This is a smaller area with increased frequency, and a larger area with decreased frequency, than for meteorological and agricultural droughts, and is understandable because river flows reflect the accumulation of rainfall over time. Flows during dry periods may be sustained by earlier rainfall. For example at the catchment scale in the Pacific Northwest (Jung and Chang, 2012), short hydrological droughts are projected to increase in frequency whilst longer droughts remain unchanged because, although dry spells last longer, winter rainfall increases.

The impacts of floods and droughts are projected to increase even when the hazard remains constant, due to increased exposure and vulnerability (Kundzewicz *et al*., 2013). Projected flood damages vary greatly between models and from region to region, with the largest losses in Asia. Projections from 21 GCMs under SRES A1B of the population exposed by 2050 to a doubling of flood frequency range from 31 to 449 million people, and the change in risk varies between -9 and +376% (Arnell and Gosling, 2013). Studies of projected flood damages are mainly focussed in Europe, the USA and Australia (Bouwer, 2013; Handmer *et al*., 2012). In Europe, the annual damage (€6.4 billion) and number of people exposed (200,000) in 1961-1990 are expected to increase about twofold by the 2080s under scenario B2 and about three times under scenario A2 (Feyen *et al*., 2012). Drought impacts at continental and smaller scales are difficult to assess because they will vary greatly with the local hydrological setting and water-management practices (Handmer *et al*., 2012). More frequent droughts due to climate change may challenge existing water management systems (Kim *et al*., 2009); together with an increase of population, this may place at risk even the domestic supply in parts of Africa (MacDonald *et al*., 2009).

3.5. Projected Impacts, Vulnerabilities, and Risks

In general, projections of freshwater-related impacts, vulnerabilities and risks caused by climate change are evaluated by comparison to historical conditions. Such projections are helpful for understanding human impact on nature and for supporting adaptation to climate change. However, for supporting decisions on climate mitigation, it is more helpful to compare the different hydrological changes that are projected under different future GHG emissions scenarios, or different amounts of global mean temperature rise. One objective of such projections is to quantify what may happen under current water-resources management practice, and another is to indicate what actions may be needed to avoid undesirable outcomes (Oki and Kanae, 2006). The studies compiled in Table 3-2 illustrate the benefits of reducing GHG emissions for the Earth's freshwater systems. Emissions scenarios are rather similar until the 2050s. Their impacts, and thus the benefits of mitigation, tend to become more clearly marked by the end of the 21st century. For example, the fraction of the world population exposed to a 20th century 100-year flood is projected to be, at the end of the 21st century, three times higher per year for RCP8.5 than for RCP2.6 (Hirabayashi *et al*., 2013). Each degree of global warming (up to 2.7°C above pre-industrial levels; Schewe *et al.*, 2013) is projected to decrease renewable water resources by at least 20% for an additional 7% of the world population. The number of people with significantly decreased access to renewable groundwater resources is projected to be roughly 50% higher under RCP8.5 than under RCP2.6 (Portmann *et al*., 2013). The percentage of global population living in river basins with new or aggravated water scarcity is projected to increase with global warming, from 8% at 2°C to 13% at 5°C (Gerten *et al.*, 2013).

[INSERT TABLE 3-2 HERE
Table 3-2: Effects of different GHG emissions scenarios on hydrological changes and freshwater-related impacts of climate change on humans and ecosystems. Among the SRES scenarios, GHG emissions are highest in A1f and A2, lower in A1 and B2, and lowest in B1. RCP8.5 is similar to A2, while the lower emissions scenarios RCP6.0 and RCP4.5 are similar to B1. RCP2.6 is a very low emissions scenario (Figure 1-4 and Section 1.1.3.1 in Chapter 1). The studies in the table give global warming (GW: global mean temperature rise, quantified as the CMIP5 model

mean) over different reference periods, typically since pre-industrial. GW is projected to be, for RCP8.5, approximately 2°C in the 2040s and 4°C in the 2080s. For RCP6.0, GW is 2°C in the 2060s and 2.5°C in the 2080s, while in RCP2.6, GW stays below 1.8°C throughout the 21st century (Figure 1-4 in Chapter 1). Population scenario SSP2 assumes a medium population increase.]

3.5.1. Availability of Water Resources

Approximately 80% of the world's population already suffers serious threats to its water security, as measured by indicators including water availability, water demand and pollution (Vörösmarty *et al*., 2010). Climate change can alter the availability of water and therefore threaten water security.

Global-scale analyses so far have concentrated on measures of resource availability rather than the multi-dimensional indices used in Vörösmarty *et al*. (2010). All have simulated future river flows or groundwater recharge using global-scale hydrological models. Some have assessed future availability based on runoff per capita (Arnell *et al*., 2011; Arnell *et al*., 2013; Fung *et al*., 2011; Gerten *et al*., 2013; Gosling and Arnell, 2013; Hayashi *et al*., 2010; Murray *et al*., 2012; Schewe *et al*., 2013), whilst others have projected future human withdrawals and characterized availability by the ratio of withdrawals to availability from runoff or recharge (Arnell *et al*., 2011; Gosling and Arnell, 2013; Hanasaki *et al*., 2013). A groundwater vulnerability index was constructed which combined future reductions of renewable groundwater resources with water scarcity, dependence on groundwater and the Human Development Index (Figure 3-7) (Döll, 2009). There are several key conclusions from this set of studies. First, the spatial distribution of the impacts of climate change on resource availability varies considerably between climate models, and strongly with the pattern of projected rainfall change. There is strong consistency in projections of reduced availability around the Mediterranean and parts of southern Africa, but much greater variation in projections for south and east Asia. Second, some water-stressed areas see increased runoff in the future (Section 3.4.4), and therefore less exposure to water-resources stress. Third, over the next few decades and for increases in global mean temperature of less than around 2^{o}C above pre-industrial, changes in population will generally have a greater effect on changes in resource availability than will climate change. Climate change would, however, regionally exacerbate or offset the effects of population pressures. Fourth, estimates of future water availability are sensitive not only to climate and population projections and population assumptions, but also to the choice of hydrological impact model (Schewe *et al*., 2013) and to the adopted measure of stress or scarcity. As an indication of the potential magnitude of the impact of climate change, Schewe *et al*. (2013) estimated that approximately 8% of the global population would see a severe reduction in water resources (a reduction in runoff either greater than 20% or more than the standard deviation of current annual runoff) with a 1^{o}C rise in global mean temperature (compared to the 1990s), rising to 14% at 2^{o}C and 17% at 3^{o}C; the spread across climate and hydrological models was, however, large.

[INSERT FIGURE 3-7 HERE
Figure 3-7: Human vulnerability to climate-change induced decreases of renewable groundwater resources by the 2050s. Lower (B2) and higher (A2) emissions pathways are interpreted by two global climate models. The higher the vulnerability index (computed by multiplying percentage decrease of groundwater recharge by a sensitivity index), the higher the vulnerability. The index is only defined for areas where groundwater recharge is projected to decrease by at least 10% relative to 1961-1990 (Döll, 2009)]

Under climate change, reliable surface water supply is expected to decrease due to increased variability of river flow that is due in turn to increased precipitation variability and decreased snow and ice storage. Under these circumstances, it might be beneficial to take advantage of the storage capacity of groundwater and to increase groundwater withdrawals (Kundzewicz and Döll, 2009). However, this option is only sustainable where, over the long term, withdrawals remain well below recharge, while care must also be taken to avoid excessive reduction of groundwater outflow to rivers. Therefore, groundwater cannot be expected to ease freshwater stress where climate change is projected to decrease groundwater recharge and thus renewable groundwater resources (Kundzewicz and Döll, 2009). The percentage of projected global population (SSP2 population scenario) that will suffer from a decrease of renewable groundwater resources of more than 10% between the 1980s and the 2080s was computed to range from 24% (mean based on five GCMs, range 11-39%) for RCP2.6 to 38% (range 27-50%) for RCP8.5 (Portmann *et al*., 2013; Table 3-2). The land area affected by decreases of groundwater resources increases linearly with global mean temperature rise between 0°C and 3°C. For each degree of global mean temperature rise, an additional 4% of the global land area is projected to suffer a groundwater resources decrease of more than 30%, and an additional 1% to suffer a decrease of more than 70% (Portmann *et al*., 2013).

3.5.2. Water Uses

3.5.2.1. Agriculture

Water demand and use for food and livestock feed production is governed not only by crop management and its efficiency, but also by the balance between atmospheric moisture deficit and soil water supply. Thus, changes in climate (precipitation, temperature, radiation) will affect the water demand of crops grown in both irrigated and rainfed systems. Using projections from 19 CMIP3 GCMs forced by SRES A2 emissions to drive a global vegetation and hydrology model, climate change by the 2080s would hardly alter the global irrigation water demand of major crops in areas currently equipped for irrigation (Konzmann *et al.*, 2013). However, there is *high confidence* that irrigation demand will increase significantly in many areas (by more than 40% across Europe, the USA and parts of Asia). Other regions – including major irrigated areas in India, Pakistan and southeastern China – might experience a slight decrease in irrigation demand, due for example to higher precipitation, but only under some climate change scenarios (also see Biemans *et al.*, 2013). Using seven global hydrological models but a limited set of CMIP5 projections, Wada *et al.* (2013) suggested a global increase in irrigation demand by the 2080s (ensemble average 7–21% depending on emissions scenario), with a pronounced regional pattern, a large inter-model spread, and possible seasonal shifts in crop water demand and consumption. By contrast, based on projections from two GCMs and two emissions scenarios, a slight global decrease in crop water deficits was suggested in both irrigated and rainfed areas by the 2080s, which can partly be explained by a smaller difference between daily maximum and minimum temperatures (Zhang and Cai, 2013). As in other studies, region-to-region variations were very heterogeneous.

Where poor soil is not a limiting factor, physiological and structural crop responses to elevated atmospheric CO_2 concentration (CO_2 fertilization) might partly cancel out the adverse effects of climate change, potentially reducing global irrigation water demand (Konzmann *et al.*, 2013; Box CC-VW). However, even in this optimistic case, increases in irrigation water demand by >20% are still projected under most scenarios for some regions, such as southern Europe. In general, future irrigation demand is projected to exceed local water availability in many places (Wada *et al.*, 2013). The water demand to produce a given amount of food on either irrigated or rainfed cropland will increase in many regions due to climate change alone (Gerten *et al.*, 2011, projections from 17 CMIP3 GCMs, SRES A2 emissions), but this increase might be moderated by concurrent increases in crop water productivity due to CO_2 effects, i.e. decreases in per-calorie water demand. The CO_2 effects may thus lessen the global number of people suffering water scarcity; nonetheless, the effect of anticipated population growth is *likely* to exceed those of climate and CO_2 change on agricultural water demand, use, and scarcity (Gerten *et al.*, 2011).

Rainfed agriculture is vulnerable to increasing precipitation variability. Differences in yield and yield variability between rainfed and irrigated land may increase with changes in climate and its variability (e.g. Finger *et al.*, 2011). Less irrigation water might be required for paddy rice cultivation in monsoon regions where rainfall is projected to increase and the crop growth period to become shorter (Yoo *et al*., 2013). Water demand for rainfed crops could be reduced by better management (Brauman *et al.*, 2013), but unmitigated climate change may counteract such efforts, as shown in a global modelling study (Rost *et al.*, 2009). In some regions, expansion of irrigated areas or increases of irrigation efficiencies may overcome climate change impacts on agricultural water demand and use (McDonald and Girvetz, 2013).

3.5.2.2. Energy Production

Hydroelectric and thermal power plants, and the irrigation of bioenergy crops (Box CC-WE), require large amounts of water. This section assesses the impact of hydrological changes (as described in Section 3.4) on hydroelectric and thermal power production. The impacts of changes in energy production due to climate change mitigation efforts are discussed in Section 3.7.2.1, while the economic implications of the impact of climate change on thermal power and hydropower production as well as adaptation options are assessed in Chapter 10.

Climate change affects hydropower generation through changes in the mean annual streamflow, shifts of seasonal flows and increases of streamflow variability (including floods and droughts) as well as by increased evaporation from reservoirs and changes in sediment fluxes. Therefore, the impact of climate change on a specific hydropower plant will depend on the local change of these hydrological characteristics, as well as on the type of hydropower plant and on the (seasonal) energy demand, which will itself be affected by climate change (Golombek *et al*., 2012). Run-of-river power plants are more susceptible to increased flow variability than plants at dams. Projections of future hydropower generation are subject to the uncertainty of projected precipitation and streamflow. For example, projections to the 2080s of hydropower generation in the Pacific Northwest of the USA range from a decrease of 25% to an increase of 10% depending on the climate model (Markoff and Cullen, 2008). Based on an ensemble of 11 GCMs, hydropower generation at the Aswan High Dam (Egypt) was computed to remain constant until the 2050s but to decrease, following the downward trend of mean annual river discharge, to 90% (ensemble mean) of current mean annual production under both SRES B1 and A2 (Beyene *et al*., 2010; Table 3-2). In snow-dominated basins, increased discharge in winter, smaller and earlier spring floods and reduced discharge in summer have already been observed (Section 3.2.5) and there is *high confidence* that these trends will continue. In regions with high electricity demands for heating, this makes the annual hydrograph more similar to seasonal variations in electricity demand, reducing required reservoir capacities and providing opportunities for operating dams and power stations to the benefit of riverine ecosystems (Golombek *et al*., 2012; Renofalt *et al*., 2010). In regions with high electricity demand for summertime cooling, however, this seasonal streamflow shift is detrimental. In general, climate change requires adaptation of operating rules (Minville *et al*., 2009; Raje and Mujumdar, 2010) which may, however, be constrained by reservoir capacity. In California, for example, high-elevation hydropower systems with little storage, which rely on storage in the snowpack, are projected to yield less hydropower due to the increased occurrence of spills, unless precipitation increases significantly (Madani and Lund, 2010). Storage capacity expansion would help increase hydropower generation but might not be cost-effective (Madani and Lund, 2010).

Regarding water availability for cooling of thermal power plants, the number of days with a reduced useable capacity is projected to increase in Europe and the USA, due to increases in stream temperatures and the incidence of low flows (Flörke *et al*., 2012; van Vliet *et al*., 2012; Table 3-2). Warmer cooling water was computed to lower thermal power plant efficiency and thus electricity production by 1.5-3% in European countries by the 2080s under emissions scenario A1b (Golombek *et al*., 2012).

3.5.2.3. Municipal Services

Under climate change, water utilities are confronted by the following (Bates *et al*., 2008; Black and King, 2009; Bonte and Zwolsman, 2010; Brooks *et al*., 2009; Chakraborti *et al*., 2011; Christierson *et al*., 2012; Hall and Murphy, 2010; Jiménez, 2008; Major *et al*., 2011; Mukhopadhyay and Dutta, 2010; Qin *et al*., 2010; Thorne and Fenner, 2011; van Vliet and Zwolsman, 2008; Whitehead *et al*., 2009a):

- Higher ambient temperatures, which reduce snow and ice volumes and increase the evaporation rate from lakes, reservoirs and aquifers. These changes decrease natural storage of water and hence, unless precipitation increases, its availability. Moreover, higher ambient temperatures increase water demand, and with it the competition for the resource (*medium to high agreement, limited evidence*).
- Shifts in timing of river flows and possible more frequent or intense droughts, which increase the need for artificial water storage.
- Higher water temperatures, which encourage algal blooms and increase risks from cyanotoxins and natural organic matter in water sources, requiring additional or new treatment of drinking water (*high agreement, medium evidence*). On the positive side, biological water and wastewater treatment is more efficient when the water is warmer (Tchobanoglous *et al*., 2003).
- Possibly drier conditions, which increase pollutant concentrations. This is a concern especially for groundwater sources that are already of low quality, even when pollution is natural as in India and Bangladesh, North and Latin America and Africa; here arsenic, iron, manganese and fluorides are often a problem (Black and King, 2009).

- Increased storm runoff, which increases loads of pathogens, nutrients and suspended sediment.
- Sea-level rise, which increases the salinity of coastal aquifers, in particular where groundwater recharge is also expected to decrease.

Climate change also impacts water quality indirectly. For instance, at present many cities rely on water from forested catchments that requires very little treatment. More frequent and severe forest wildfires could seriously degrade water quality (Emelko *et al*., 2011; Smith *et al*., 2011).

Many drinking-water treatment plants – especially small ones – are not designed to handle the more extreme influent variations that are to be expected under climate change. These demand additional or even different infrastructure capable of operating for up to several months per year, which renders wastewater treatment very costly, notably in rural areas (Arnell *et al*., 2011; Zwolsman *et al*., 2010).

Sanitation technologies vary in their resilience to climate impacts (Howard *et al*., 2010). For sewage, three climatic conditions are of interest (NACWA, 2009; Zwolsman *et al*., 2010):

- Wet weather: heavier rainstorms mean increased amounts of water and wastewater in combined systems for short periods. Current designs, based on critical “design storms” defined through analysis of historical precipitation data, therefore need to be modified. New strategies to adapt to and mitigate urban floods need to be developed, considering not only climate change but also urban design, land use, the “heat island effect” and topography (Changnon, 1969).
- Dry weather: soil shrinks as it dries, causing water mains and sewers to crack and making them vulnerable to infiltration and exfiltration of water and wastewater. The combined effects of higher temperatures, increased pollutant concentrations, longer retention times, and sedimentation of solids may lead to increasing corrosion of sewers, shorter asset lifetimes, more drinking-water pollution and higher maintenance costs.
- Sea-level rise: intrusion of brackish or salty water into sewers necessitates processes that can handle saltier wastewater.

Increased storm runoff implies the need to treat additional wastewater when combined sewers are used, as storm runoff adds to sewage; in addition, the resulting mixture has a higher content of pathogens and pollutants. Under drier conditions higher concentrations of pollutants in wastewater, of any type, are to be expected and must be dealt with (Whitehead *et al*., 2009a; 2009b; Zwolsman *et al*., 2010). The cost may rule this out in low-income regions (Chakraborti *et al*., 2011; Jiménez, 2011). The disposal of wastewater or faecal sludge is a concern that is just beginning to be addressed in the literature (Seidu *et al*., 2013).

3.5.2.4. Freshwater Ecosystems

Freshwater ecosystems are comprised of biota (animals, plants and other organisms) and their abiotic environment in slow-flowing surface waters such as lakes, man-made reservoirs or wetlands; in fast-flowing surface waters such as rivers and creeks; and in the groundwater. They have suffered more strongly from human activities than have marine and terrestrial ecosystems. Between 1970 and 2000, populations of freshwater species included in the Living Planet Index declined on average by 50%, compared to 30% for marine and also for terrestrial species (Millennium Ecosystem Assessment, 2005). Climate change is an additional stressor of freshwater ecosystems, which it affects not only through increased water temperatures (discussed in Chapter 4.3.3.3) but also by altered streamflow regimes, river water levels, and extent and timing of inundation (Box CC-RF). Wetlands in dry environments are hotspots of biological diversity and productivity, and their biotas are at risk of extinction if runoff decreases and the wetland dries out (as described for Mediterranean-type temporary ponds by Zacharias and Zamparas, 2010). Freshwater ecosystems are also affected by water quality changes induced by climate change (Section 3.2.5), and by human adaptations to climate-change induced increases of streamflow variability and flood risk, such as the construction of dykes and dams (Ficke *et al*., 2007; Section 3.7.2).

3.5.2.5. Other Uses

In addition to direct impacts, vulnerabilities and risks in water-related sectors, indirect impacts of hydrological changes are expected for navigation, transportation, tourism, and urban planning (Badjeck *et al*., 2010; Beniston, 2012; Koetse and Rietveld, 2009; Pinter *et al*., 2006; Rabassa, 2009). Social and political problems can result from hydrological changes. For example, water scarcity and water overexploitation may increase the risks of violent conflicts and nation-state instability (Barnett and Adger, 2007; Buhaug *et al*., 2010; Burke *et al*. 2009; Hsiang *et al*., 2011). Snowline rise and glacier shrinkage are *very likely* to impact environmental, hydrological, geomorphological, heritage, and tourism resources in cold regions (Rabassa, 2009), as already observed for tourism in the European Alps (Beniston, 2012). While most impacts will be adverse, some might be beneficial.

3.6. Adaptation and Managing Risks

In the face of hydrological changes and freshwater-related impacts, vulnerability and risks due to climate change, there is need for adaptation and for increasing resilience. Managing the changing risks due to the impacts of climate change is the key to adaptation in the water sector (IPCC, 2012), and risk management should be part of decision making and the treatment of uncertainty (ISO, 2009). Even to exploit the positive impacts of climate change on freshwater systems, adaptation is generally required.

3.6.1. Options

There is growing agreement that an adaptive approach to water management can successfully address uncertainty due to climate change. Although there is *limited evidence* of the effectiveness of such an approach, the evidence is growing (Section 3.6.2). Many practices identified as adaptive were originally reactions to climate variability. Climate change provides many opportunities for “low-regret” solutions, capable of yielding social and/or economic benefits and adaptive both to variability and to change (Table 3-3). Adaptive techniques include scenario planning, experimental approaches that involve learning from experience, and the development of flexible solutions that are resilient to uncertainty. A programme of adaptation typically mixes “hard” infrastructural and “soft” institutional measures (Bates *et al*., 2008; Cooley, 2008; Mertz *et al*., 2009; Olhoff and Schaer, 2010; Sadoff and Muller, 2009; UNECE, 2009).

(2011); Emelko *et al*. (2011); Godfrey *et al*. (2010); Howard *et al*. (2010); Jiménez and Asano (2008); Jiménez (2011); Keller (2008); Kingsford (2011); Mackay and Last (2010); Major *et al*. (2011); Marsalek *et al*. (2006); McCafferty (2008); McGuckin (2008); Mogaka *et al*. (2006); Mukhopadhyay and Dutta (2010); Munasinghe (2009); NACWA (2009); OECD (2010); OFWAT (2009); Reiter (2009); Renofalt *et al*. (2010); Seah (2008); Sprenger *et al*. (2011); Thöle (2008); UNESCO (2011); UNHABITAT (2008); Vörösmarty *et al*. (2000); Wang X. *et al*. (2011); Whitehead *et al*. (2009b); Zwolsman *et al*. (2010)]

To avoid adaptation that goes wrong – “maladaptation” – scientific research results should be analyzed during planning. Low-regret solutions, such as those for which moderate investment clearly increases the capacity to cope with projected risks or for which the investment is justifiable under all or almost all plausible scenarios, should be considered explicitly. Involving all stakeholders, reshaping planning processes, coordinating the management of land and water resources, recognizing linkages between water quantity and quality, using surface water and groundwater conjunctively, and protecting and restoring natural systems, are examples of principles that can beneficially inform planning for adaptation (World Bank, 2007).

Integrated Water Resource Management continues to be a promising instrument for exploring adaptation to climate change. It can be joined with a Strategic Environmental Assessment to address broader considerations. Attention is currently increasing to "robust measures" (European Communities, 2009), which are measures that perform well under different future conditions and clearly optimize prevailing strategies (Sigel *et al.*, 2010). Barriers to adaptation are discussed in detail in Section 16.5 in Chapter 16. Barriers to adaptation in the freshwater sector include lack of human and institutional capacity, lack of financial resources, lack of awareness, and lack of communication (Browning-Aiken *et al*., 2007; Burton, 2008; Butscher and Huggenberger, 2009; Zwolsman *et al*., 2010). Institutional structures can be major barriers to adaptation (Bergsma *et al*., 2012; Engle and Lemos, 2010; Goulden *et al*., 2009; Huntjens *et al*., 2010; Stuart-Hill and Schulze, 2010; Wilby and Vaughan, 2011; Ziervogel *et al*., 2010); structures that promote participation of and collaboration between stakeholders tend to encourage adaptation. Some adaptation measures may not pass the test of workability in an uncertain future (Campbell *et al.*, 2008), and uncertainty (Section 3.6.2) can be another significant barrier.

Case studies of the potential effectiveness of adaptation measures are abundant. Changes in operating practices and infrastructure improvements could help California's water managers respond to changes in the volume and timing of supply (Connell-Buck *et al*., 2011; Medellin-Azuara *et al*., 2008). Other studies include evaluations of the effectiveness of different adaptation options in Washington state, USA (Miles *et al*., 2010) and the Murray-Darling basin, Australia (Pittock and Finlayson, 2011), and of two dike-heightening strategies in the Netherlands (Hoekstra and de Kok, 2008). Such studies have demonstrated that it is technically feasible in general to adapt to projected climate changes, but not all have considered how adaptation would be implemented.

3.6.2. Dealing with Uncertainty in Future Climate Change

One of the key challenges in factoring climate change into water resources management lies in the uncertainty. Some approaches (e.g. in England and Wales, Arnell, 2011) use a small set of climate scenarios to characterise the potential range of impacts on water resources and flooding. Others (e.g. Brekke *et al*., 2008; Christierson *et al*., 2012; Hall *et al*., 2012; Lopez *et al*., 2009) use very large numbers of scenarios to generate likelihood distributions of indicators of impact for use in risk assessment. However, it has been argued (Dessai *et al*., 2009; Hall, 2007; Stainforth *et al*., 2007) that attempts to construct probability distributions of impacts are misguided because of "deep" uncertainty, which arises because analysts do not know, or cannot agree upon, how the climate system and water-management systems may change, how models represent possible changes, or how to value the desirability of different outcomes. Stainforth *et al*. (2007) therefore argue that it is impossible in practice to construct robust quantitative probability distributions of climate change impacts, and that climate change uncertainty needs to be represented differently, for example by using fewer plausible scenarios and interpreting the outcomes of scenarios less quantitatively.

Some go further, arguing that climate models are not sufficiently robust or reliable to provide the basis for adaptation (Anagnostopoulos *et al*., 2010; Blöschl and Montanari, 2010; Koutsoyiannis *et al*., 2008; Wilby, 2010), because they are frequently biased and do not reproduce the temporal characteristics (specifically the persistence or "memory") often found in hydrological records. It has been argued (Lins and Cohn, 2011; Stakhiv, 2011) that existing water-resources planning methods are sufficiently robust to address the effects of climate change. This view of climate model performance has been challenged and is the subject of some debate (Huard, 2011; Koutsoyiannis *et al*., 2009; 2011); the critique also assumes that adaptation assessment procedures would only use climate scenarios derived directly from climate model simulations.

Addressing uncertainty in practice by quantifying it through some form of risk assessment, however, is only one way of dealing with uncertainty. A large and increasing literature recommends that water managers should move from the traditional "predict and provide" approach towards adaptive water management (Gersonius *et al*., 2013; Huntjens *et al*., 2012; Matthews and Wickel, 2009; Mysiak *et al*., 2009; Pahl-Wostl, 2007; Pahl-Wostl *et al*., 2008; Short *et al*., 2012) and the adoption of resilient or "no-regrets" approaches (Henriques and Spraggs, 2011; WWAP, 2009). Approaches that are resilient to uncertainty are not entirely technical (or supply-side), and participation and collaboration amongst all stakeholders are central to adaptive water management. However, whilst climate change is frequently cited as a key motive, there is very little published guidance on how to implement the adaptive water management approach. Some examples are given in Ludwig *et al*. (2009). The most comprehensive overview of adaptive water management which explicitly incorporates climate change and its uncertainty is the three-step framework of the US Water Utilities Climate Alliance (WUCA, 2010): system vulnerability assessment, utility planning using decision-support methods, and decision-making and implementation. Planning methods for decision support include classic decision analysis, traditional scenario planning and robust decision making (Lempert *et al*., 1996; 2006; Nassopoulos *et al*., 2012). The latter was applied by the Inland Empire Utilities Agency, supplying water to a region in southern California (Lempert and Groves, 2010). This led to the refinement of the company's water resource management plan, making it more robust to three particularly challenging aspects of climate change that were identified by the scenario analysis. Another framework, based on risk assessment, is the threshold-scenario framework of Freas *et al*. (2008).

3.6.3. Costs of Adaptation to Climate Change

Calculating the global cost of adaptation in the water sector is a difficult task and results are highly uncertain. Globally, to maintain water services at non-climate change levels to the year 2030 in more than 200 countries, total adaptation costs for additional infrastructure were estimated as US$531 billion, with US$451 billion (85%) required in developing countries, mainly in Asia and Africa (Kirshen, 2007). Including two further costs, for reservoir construction since the best locations have already been taken, and for unmet irrigation demands, total water-sector adaptation costs were estimated as US$225 billion, or US$11 billion per year (UNFCCC, 2007).

Average annual water-supply and flood-protection costs to 2050 for restoring service to non-climate change levels were estimated to be US$14.0 billion for a dry GCM projection of the SRES A2 scenario and US$19.7 billion for a wet GCM projection (World Bank, 2010; Ward *et al*., 2010). Annual urban infrastructure costs, primarily for wastewater treatment and urban drainage, were US$13.7 billion (dry) and US$27.5 billion (wet). Under both GCM projections for the A2 scenario, the water sector accounted for approximately 50% of total global adaptation cost, which was distributed regionally in the proportions: East Asia/Pacific, 20%; Europe/Central Asia, 10%; Latin America/Caribbean, 20%; Middle East/North Africa, 5%; South Asia, 20%; Sub-Saharan Africa, 20%.

Annual costs for adaptation to climate change in sub-Saharan Africa are estimated as US$1.1–2.7 billion for current urban water infrastructure, plus US$1.0–2.5 billion for new infrastructure to meet the 2015 Millennium Development Goals (Muller, 2007). These estimates assume a 30% reduction in stream flow and an increase of at least 40% in the unit cost of water. Annual estimates of adaptation costs for urban water storage are $0.15-0.5 billion for existing facilities and $0.55-1.5 billion for new developments. For wastewater treatment, the equivalent estimates are $0.1-0.2 billion and $0.075-0.2 billion. For the coterminous United States under "business as usual", over 45% of economic costs are due to water quality and environmental flow impacts, suggesting significant costs for wastewater treatment infrastructure (Henderson *et al.*, 2013).

3.6.4. Adaptation in Practice in the Water Sector

A number of water management agencies are beginning to factor climate change into processes and decisions (Kranz *et al*., 2010; Krysanova *et al*., 2010), with the amount of progress strongly influenced by institutional characteristics. Most of the work has involved developing methodologies to be used by water resources and flood managers (e.g. Rudberg *et al*., 2012), and therefore represents attempts to improve adaptive capacity. In England and Wales, for example, methodologies to gauge the effects of climate change on reliability of water supplies have evolved since the late 1990s (Arnell, 2011) and the strategic plans of water supply companies now generally allow for climate change. Brekke *et al*. (2009a) describe proposed changes to practices in the USA. Several studies report community-level activities to reduce exposure to current hydrological variability, regarded explicitly as a means of adapting to future climate change (e.g. Barrios *et al*., 2009; Gujja *et al*., 2009; Kashaigili *et al*., 2009; Yu *et al*., 2009).

[INSERT TABLE 3-4 HERE
Table 3-4: Key risks from climate change and the potential for reducing risk through mitigation and adaptation. Key risks are identified based on assessment of the literature and expert judgments by chapter authors, with evaluation of evidence and agreement in supporting chapter sections. Each key risk is characterized as very low to very high. Risk levels are presented in three time frames: the present, near-term (here assessed over 2030-2040), and longer term (here assessed over 2080-2100). Sources: Xie et al., 2006; Döll, 2009; Kaser et al., 2010; Arnell et al., 2011; Huss, 2011; Jóhannesson et al., 2012; Seneviratne et al., 2012; Arnell and Gosling, 2013; Dankers et al., 2013; Gosling and Arnell, 2013; Hanasaki et al., 2013; Hirabayashi et al., 2013; Kundzewicz et al., 2013; Portmann et al., 2013; Radić et al., 2013; Schewe et al., 2013; WGI AR5 Chapter 13.]

3.7. Linkages with Other Sectors and Services

3.7.1. Impacts of Adaptation in Other Sectors on Freshwater Systems

Adaptation in other sectors such as agriculture, forestry and industry might have impacts on the freshwater system, and therefore needs to be considered while planning adaptation in the water sector (Jiang *et al.*, 2013). For example, better agricultural land management practices can also reduce erosion and sedimentation in river channels (Lu *et al.*, 2010), while controlled flooding of agricultural land can alleviate the impacts of urban flooding. Increased irrigation upstream may limit water availability downstream (World Bank, 2007). A project designed for other purposes may also deliver increased resilience to climate change as a co-benefit, even without a specifically identified adaptive component (World Bank, 2007; Falloon and Betts, 2010).

3.7.2. Climate Change Mitigation and Freshwater Systems

3.7.2.1. Impact of Climate Change Mitigation on Freshwater Systems

Many measures for climate change mitigation affect freshwater systems. Afforestation generally increases evapotranspiration and decreases total runoff (van Dijk and Keenan, 2007). Afforestation of areas deemed suitable according to the Clean Development Mechanism–Afforestation/Reforestation provisions of the Kyoto Protocol (7.5 million km^2) would lead to large and spatially-extensive decreases of long-term average runoff (Trabucco *et al*., 2008). On 80% of the area, runoff is computed to decline by more than 40%, while on 27% runoff decreases of 80-100% were computed, mostly in semi-arid areas (Trabucco *et al*., 2008). For example, economic incentives for carbon sequestration may encourage the expansion of *Pinus radiata* timber plantations in the Fynbos biome of South Africa, with negative consequences for water supply and biodiversity; afforestation is viable to the forestry industry only because it pays less than 1% of the actual cost of streamflow reduction caused by replacing Fynbos by the plantations (Chisholm, 2010). In general, afforestation has beneficial impacts on soil erosion, local flood risk, water quality (nitrogen, phosphorus, suspended sediments) and stream habitat quality (Trabucco *et al*., 2008; van Dijk and Keenan, 2007; Wilcock *et al*., 2008).

Irrigated bioenergy crops and hydropower can have negative impacts on freshwater systems (Jacobson, 2009). In the USA, water use for irrigating biofuel crops could increase from 2% of total water consumption in 2005 to 9% in 2030 (King *et al*., 2010). Irrigating some bioenergy crops may cost more than the energy thus gained. In dry parts of India, pumping from a depth of 60 meter for irrigating jatropha is estimated to consume more energy than that gained from the resulting higher crop yields (Gupta *et al*., 2010). For a biofuel scenario of the International Energy Agency, global consumptive irrigation water use for biofuel production is projected to increase from 0.5% of global renewable water resources in 2005 to 5.5% in 2030; biofuel production is projected to increase water consumption significantly in some countries (e.g. Germany, Italy and South Africa), and to exacerbate the already serious water scarcity in others (e.g. Spain and China) (Gerbens-Leenes *et al*., 2012). Conversion of native Caatinga forest into rainfed fields for biofuels in semi-arid northwestern Brazil may lead to a significant increase of groundwater recharge (Montenegro and Ragab, 2010), but there is a risk of soil salinization due to rising groundwater tables.

Hydropower generation leads to alteration of river flow regimes that negatively affect freshwater ecosystems, in particular biodiversity and abundance of riverine organisms (Döll and Zhang, 2010; Poff and Zimmerman, 2010), and to fragmentation of river channels by dams, with negative impacts on migratory species (Bourne *et al*., 2011). Hydropower operations often lead to discharge changes on hourly timescales that are detrimental to the downstream river ecosystem (Bruno *et al*., 2009; Zimmerman *et al*., 2010). However, release management and structural measures like fish ladders can mitigate these negative impacts somewhat (Williams, 2008). In tropical regions, the global warming potential of hydropower, due to methane emissions from man-made reservoirs, may exceed that of thermal power; based on observed emissions of a tropical reservoir, this might be the case where the ratio of hydropower generated to the surface area of the reservoir is less than 1 MW/km^2 (Gunkel, 2009).

CO_2 leakage to freshwater aquifers from saline aquifers used for carbon capture and storage (CCS) can lower pH by 1-2 units and increase concentrations of metals, uranium and barium (Little and Jackson, 2010). Pressure exerted by gas injection can push brines or brackish water into freshwater parts of the aquifer (Nicot, 2008). Displacement of brine into potable water was not considered in a screening methodology for CCS sites in the Netherlands (Ramírez *et al*., 2010). Another emergent freshwater-related risk of climate mitigation is increased natural gas extraction from low-permeability rocks. The required hydraulic fracturing process ("fracking") uses large amounts of water (a total of approximately 9,000-30,000 m^3 per well, mixed with a number of chemicals), of which a part returns to the surface (Rozell and Reaven, 2012). Fracking is suspected to lead to pollution of the overlying freshwater aquifer or surface waters, but appropriate observations and peer-reviewed studies are still lacking (Jackson *et al*., 2013). Densification of urban areas to reduce traffic emissions is in conflict with providing additional open space for inundation in case of floods (Hamin and Gurran, 2009).

3.7.2.2. Impact of Water Management on Climate Change Mitigation

A number of water management decisions affect GHG emissions. Water demand management has a significant impact on energy consumption because energy is required to pump and treat water, to heat it, and to treat wastewater. For example, water supply and water treatment were responsible for 1.4 % of total electricity consumption in Japan in 2008 (MLIT, 2011). In the USA, total water-related energy consumption was equivalent to 13% of total electricity production in 2005, with 70% for water heating, 14% for wastewater treatment and only 5% for pumping of irrigation water (Griffiths-Sattenspiel and Wilson, 2009). In China, where agriculture accounts for 62% of water withdrawals, groundwater pumping for irrigation accounted for only 0.6% of China's GHG emissions in 2006, a small fraction of the 17-20% share of agriculture as a whole (Wang *et al*., 2012). Where climate change reduces water resources in dry regions, desalination of seawater as an adaptation option is expected to increase GHG emissions if carbon-based fuels are used as energy source (McEvoy and Wilder, 2012).

In southeast Asia, emissions due to peatland drainage contribute 1.3-3.1% of current global CO_2 emissions from the combustion of fossil fuels (Hooijer *et al*., 2010), and peatland rewetting could substantially reduce net GHG emissions (Couwenberg *et al*., 2010). Climate change mitigation by conservation of wetlands will also benefit water quality and biodiversity (House *et al*., 2010). Irrigation can increase CO_2 storage in soils by reducing water stress and so enhancing biomass production. Irrigation in semi-arid California did not significantly increase soil organic carbon (Wu *et al*., 2008). Water management in rice paddies can reduce CH_4 emissions. If rice paddies are drained at least once during the growing season, with resulting increased water withdrawals, global CH_4 emissions from rice fields could be decreased by 4.1 Tg/year (16% around the year 2000), and N_2O emissions would not increase significantly (Yan *et al*., 2009).

3.8. Research and Data Gaps

Precipitation and river discharge are systematically observed, but data records are unevenly available and unevenly distributed geographically. Information on many other relevant variables, such as soil moisture, snow depth, groundwater depth and water quality, is particularly limited in developing countries. Relevant socio-economic data, such as rates of surface water and groundwater withdrawal by each sector, and information on already-implemented adaptations for stabilizing water supply, such as long-range diversions, are limited even in developed countries. In consequence, assessment capability is limited in general, and especially so in developing countries.

Modeling studies have shown that the adaptation of vegetation to changing climate may have large impacts on the partitioning of precipitation into evapotranspiration and runoff. This feedback should be investigated more thoroughly.

Relatively little is known about the economic aspects of climate-change impacts and adaptation options related to water resources. For example, regional damage curves need to be developed, relating the magnitudes of major water-related disasters (such as intense precipitation and surface soil dryness) to the expected costs.

There is a continuing, although narrowing, mismatch between the large scales resolved by climate models and the catchment scale at which water is managed and adaptations must be implemented. Improving the spatial resolution of regional and global climate models, and the accuracy of methods for downscaling their outputs, can produce information more relevant to water management, although the robustness of regional climate projections is still constrained by the realism of GCM simulations of large-scale drivers. More computing capacity is needed to address these problems with more ensemble simulations at high spatial resolution. More research is also needed into novel ways of combining different approaches to projection of plausible changes in relevant climate variables so as to provide robust information to water managers. Robust attribution to anthropogenic climate change of hydrological changes, particularly changes in the frequency of extreme events, is similarly demanding, and further study is required to develop rigorous attribution tools that require less computation. In addition, there is a difficulty to model and interpret results obtained from applying models at different scales and with different logics to follow the future changes on water quality. Morover, the establishment of a proper baseline to isolate the effects derived from climate change from those antropogenic caused is a major challenge.

Interactions among socio-ecological systems are not yet well considered in most impact assessments. Particularly, there are few studies on the impacts of mitigation and adaptation in other sectors on the water sector, and conversely. A valuable advance would be to couple hydrological models, or even the land-surface components of climate models, to data on water-management activities such as reservoir operations, irrigation and urban withdrawals from surface water or groundwater.

To support adaptation by increasing reliance on groundwater and on the coordinated and combined use of groundwater and surface water, ground-based data are needed in the form of a long-term program to monitor groundwater dynamics and stored groundwater volumes. Understanding of groundwater recharge and groundwater-surface water interactions, particularly by the assessment of experiences of conjunctive use of groundwater and surface water, needs to be better developed.

More studies are needed, especially in developing countries, on the impacts of climate change on water quality, and of vulnerability to and ways of adapting to those impacts.

Frequently Asked Questions

FAQ 3.1: How will climate change affect the frequency and severity of floods and droughts?
[to be placed in Section 3.4.9]
Climate change is projected to alter the frequency and magnitude of both floods and droughts. The impact is expected to vary from region to region. The few available studies suggest that flood hazards will increase over more than half of the globe, in particular in central and eastern Siberia, parts of south-east Asia including India, tropical Africa, and northern South America, but decreases are projected in parts of northern and eastern Europe, Anatolia, central and east Asia, central North America, and southern South America (*limited evidence, high agreement*).The frequency of floods in small river basins is *very likely* to increase, but that may not be true of larger watersheds because intense rain is usually confined to more limited areas. Spring snowmelt floods are *likely* to become smaller, both because less winter precipitation will fall as snow and because more snow will melt during thaws over the

course of the entire winter. Worldwide, the damage from floods will increase because more people and more assets will be in harm's way.

By the end of the 21st century meteorological droughts (less rainfall) and agricultural droughts (drier soil) are projected to become longer, or more frequent, or both, in some regions and some seasons, because of reduced rainfall or increased evaporation or both. But it is still uncertain what these rainfall and soil moisture deficits might mean for prolonged reductions of streamflow and lake and groundwater levels. Droughts are projected to intensify in southern Europe and the Mediterranean region, central Europe, central and southern North America, Central America, northeast Brazil and southern Africa. In dry regions, more intense droughts will stress water-supply systems. In wetter regions, more intense seasonal droughts can be managed by current water-supply systems and by adaptation; for example, demand can be reduced by using water more efficiently, or supply can be increased by increasing the storage capacity in reservoirs.

FAQ 3.2: How will the availability of water resources be affected by climate change?
[to be placed in Section 3.5.1]
Climate models project decreases of renewable water resources in some regions and increases in others, albeit with large uncertainty in many places. Broadly, water resources are projected to decrease in many mid-latitude and dry subtropical regions, and to increase at high latitudes and in many humid mid-latitude regions (*high agreement, robust evidence)*. Even where increases are projected, there can be short-term shortages due to more variable streamflow (because of greater variability of precipitation), and seasonal reductions of water supply due to reduced snow and ice storage. Availability of clean water can also be reduced by negative impacts of climate change on water quality; for instance the quality of lakes used for water supply could be impaired by the presence of algae-producing toxins.

FAQ 3.3: How should water management be modified in the face of climate change?
[to be placed in Section 3.6.1]
Managers of water utilities and water resources have considerable experience in adapting their policies and practices to the weather. But in the face of climate change, long-term planning (over several decades) is needed for a future that is highly uncertain. A flexible portfolio of solutions that produces benefits regardless of the impacts of climate change ("low-regret" solutions) and that can be implemented adaptively, step by step, is valuable because it allows policies to evolve progressively, thus building on – rather than losing the value of – previous investments. Adaptive measures that may prove particularly effective include rainwater harvesting, conservation tillage, maintaining vegetation cover, planting trees in steeply-sloping fields, mini-terracing for soil and moisture conservation, improved pasture management, water re-use, desalination, and more efficient soil and irrigation-water management. Restoring and protecting freshwater habitats, and managing natural floodplains, are additional adaptive measures that are not usually part of conventional management practice.

FAQ 3.4: Does climate change imply only bad news about water resources?
[to be placed after Section 3.6]
There is good news as well as bad about water resources, but the good news is very often ambiguous. Water may become less scarce in regions that get more precipitation, but more precipitation will probably also increase flood risk; it may also raise the groundwater table, which could lead to damage to buildings and other infrastructure or to reduced agricultural productivity due to wet soils or soil salinization. More frequent storms reduce the risk of eutrophication and algal blooms in lakes and estuaries by flushing away nutrients, but increased storm runoff will carry more of those nutrients to the sea, exacerbating eutrophication in marine ecosystems, with possible adverse impacts as discussed in Chapter 30. Water and wastewater treatment yields better results under warmer conditions, as chemical and biological reactions needed for treatment perform in general better at higher temperatures. In many rivers fed by glaciers, there will be a "meltwater dividend" during some part of the 21st century, due to increasing rates of loss of glacier ice, but the continued shrinkage of the glaciers means that after several decades the total amount of meltwater that they yield will begin to decrease (*medium confidence*). An important point is that often impacts do not become "good news" unless investments are made to exploit them. For instance, where additional water is expected to become available, the infrastructure to capture that resource would need to be developed if it is not already in place.

Box CC-RF. Impact of Climate Change on Freshwater Ecosystems due to Altered River Flow Regimes

[Petra Döll (Germany), Stuart E. Bunn (Australia)]

It is widely acknowledged that the flow regime is a primary determinant of the structure and function of rivers and their associated floodplain wetlands, and flow alteration is considered to be a serious and continuing threat to freshwater ecosystems (Bunn and Arthington, 2002; Poff and Zimmerman, 2010; Poff *et al*., 2010). Most species distribution models do not consider the effect of changing flow regimes (i.e. changes to the frequency, magnitude, duration and/or timing of key flow parameters) or they use precipitation as proxy for river flow (Heino *et al.*, 2009).

There is growing evidence that climate change will significantly alter ecologically important attributes of hydrologic regimes in rivers and wetlands, and exacerbate impacts from human water use in developed river basins (*medium confidence*) (Aldous *et al.*, 2011; Xenopoulos *et al.*, 2005). By the 2050s, climate change is projected to impact river flow characteristics like long-term average discharge, seasonality and statistical high flows (but not statistical low flows) more strongly than dam construction and water withdrawals have done up to around the year 2000 (Figure RF-1; Döll and Zhang, 2010). For one climate scenario (SRES A2 emissions, HadCM3 climate model), 15% of the global land area may be negatively affected, by the 2050s, by a decrease of fish species in the upstream basin of more than 10%, as compared to only 10% of the land area that has already suffered from such decreases due to water withdrawals and dams (Döll and Zhang, 2010). Climate change may exacerbate the negative impacts of dams for freshwater ecosystems but may also provide opportunities for operating dams and power stations to the benefit of riverine ecosystems. This is the case if total runoff increases and, as occurs in Sweden, the annual hydrograph becomes more similar to variation in electricity demand, i.e. with a lower spring flood and increased runoff during winter months (Renofalt *et al.*, 2010).

Because biota are often adapted to a certain level of river flow variability, the projected larger variability of river flows that is due to increased climate variability is *likely* to select for generalist or invasive species (Ficke *et al.*, 2007). The relatively stable habitats of groundwater-fed streams in snow-dominated or glacierized basins may be altered by reduced recharge by meltwater and as a result experience more variable (possibly intermittent) flows (Hannah *et al.*, 2007). A high-impact change of flow variability is a flow regime shift from intermittent to perennial or vice versa. It is projected that until the 2050s, river flow regime shifts may occur on 5-7% of the global land area, mainly in semi-arid areas (Döll and Müller Schmied, 2012; see Table 3-2 in Chapter 3).

In Africa, one third of fish species and one fifth of the endemic fish species occur in eco-regions that may experience a change in discharge or runoff of more than 40% by the 2050s (Thieme *et al.*, 2010). Eco-regions containing over 80% of Africa's freshwater fish species and several outstanding ecological and evolutionary phenomena are *likely* to experience hydrologic conditions substantially different from the present, with alterations in long-term average annual river discharge or runoff of more than 10% due to climate change and water use (Thieme *et al.*, 2010).

Due to increased winter temperatures, freshwater ecosystems in basins with significant snow storage are affected by higher river flows in winter, earlier spring peak flows and possibly reduced summer low flows (Section 3.2.3 in Chapter 3). Strongly increased winter peak flows may lead to a decline in salmonid populations in the Pacific Northwest of the USA of 20-40% by the 2050s (depending on the climate model) due to scouring of the streambed during egg incubation, the relatively pristine high-elevation areas being affected most (Battin *et al.*, 2007). Reductions in summer low flows will increase the competition for water between ecosystems and irrigation water users (Stewart *et al.*, 2005). Ensuring environmental flows through purchasing or leasing water rights and altering reservoir release patterns will be an important adaptation strategy (Palmer *et al.*, 2009).

[INSERT FIGURE RF-1 HERE
Figure RF-1: Impact of climate change relative to the impact of water withdrawals and dams on natural flows for two ecologically relevant river flow characteristics (mean annual river flow and monthly low flow Q_{90}), computed by a global water model (Döll and Zhang, 2010). Monthly Q_{90} was defined as the flow that is exceeded in 9 out 10 months. Impact of climate change is the percent change of flow between 1961-1990 and 2041-2070 according to the emissions scenario A2 as implemented by the global climate model HadCM3. Impact of water withdrawals and

reservoirs is computed by running the model with and without water withdrawals and dams that existed in 2002. Please note that the figure does not reflect spatial differences in the magnitude of change.]

Observations and models suggest that global warming impacts on glacier and snow-fed streams and rivers will pass through two contrasting phases (Burkett *et al.*, 2005; Vuille *et al.*, 2008; Jacobsen *et al.*, 2012). In the first phase, when river discharge is increased due to intensified melting, the overall diversity and abundance of species may increase. However, changes in water temperature and stream-flow may have negative impacts on narrow range endemics (Jacobsen *et al.*, 2012). In the second phase, when snowfields melt early and glaciers have shrunken to the point that late-summer stream flow is reduced, broad negative impacts are foreseen, with species diversity rapidly declining once a critical threshold of roughly 50% glacial cover is crossed (Figure RF-2).

River discharge also influences the response of river temperatures to increases of air temperature. Globally averaged, air temperature increases of 2°C, 4°C and 6°C are estimated to lead to increases of annual mean river temperatures of 1.3°C, 2.6°C and 3.8°C, respectively (van Vliet *et al.*, 2011). Discharge decreases of 20% and 40% are computed to result in additional increases of river water temperature of 0.3° C and 0.8°C on average (van Vliet *et al.*, 2011). Therefore, where rivers will experience drought more frequently in the future, freshwater-dependent biota will suffer not only directly by changed flow conditions but also by drought-induced river temperature increases, as well as by related decreased oxygen and increased pollutant concentrations.

[INSERT FIGURE RF-2 HERE
Figure RF-2: Accumulated loss of regional species richness (gamma diversity) of macroinvertebrates as a function of glacial cover in catchment. Obligate glacial river macroinvertebrates begin to disappear from assemblages when glacial cover in the catchment drops below approximately 50%, and 9-14 species are predicted to be lost with the complete disappearance of glaciers in each region, corresponding to 11, 16 and 38% of the total species richness in the three study regions in Ecuador, Europe and Alaska. Data are derived from multiple river sites from the Ecuadorian Andes and Swiss and Italian Alps, and a temporal study of a river in the Coastal Range Mountains of southeast Alaska over nearly three decades of glacial shrinkage. Each data point represents a river site or date (Alaska), and lines are Lowess fits. Adapted by permission from Macmillan Publishers Ltd: *Nature Climate Change*, Jacobsen *et al.*, 2012, © 2012.]

Box CC-VW. Active Role of Vegetation in Altering Water Flows under Climate Change

[Dieter Gerten (Germany), Richard Betts (UK), Petra Döll (Germany)]

Climate, vegetation and carbon and water cycles are intimately coupled, in particular via the simultaneous transpiration and CO_2 uptake through plant stomata in the process of photosynthesis. Hence, water flows such as runoff and evapotranspiration are affected not only directly by anthropogenic climate change as such (i.e. by changes in climate variables such as temperature and precipitation), but also indirectly by plant responses to increased atmospheric CO_2 concentrations. In addition, effects of climate change (e.g. higher temperature or altered precipitation) on vegetation structure, biomass production and plant distribution have an indirect influence on water flows. Rising CO_2 concentration affects vegetation and associated water flows in two contrasting ways, as suggested by ample evidence from Free Air CO_2 Enrichment (FACE), laboratory and modelling experiments (e.g. Leakey *et al.*, 2009; de Boer *et al.*, 2011; Reddy *et al.*, 2010). On the one hand, a *physiological* effect leads to reduced opening of stomatal apertures, which is associated with lower water flow through the stomata, i.e. lower leaf-level transpiration. On the other hand, a *structural* effect ("fertilization effect") stimulates photosynthesis and biomass production of C3 plants including all tree species, which eventually leads to higher transpiration at regional scales. A key question is to what extent the climate- and CO_2-induced changes in vegetation and transpiration translate into changes in regional and global runoff.

The physiological effect of CO_2 is associated with an increased intrinsic water use efficiency (WUE) of plants, which means that less water is transpired per unit of carbon assimilated. Records of stable carbon isotopes in woody plants (Peñuelas *et al.*, 2011) verify this finding, suggesting an increase in WUE of mature trees by 20.5% between the early 1960s and the early 2000s. Increases since pre-industrial times have also been found for several forest sites (Andreu-Hayles *et al.*, 2011; Gagen *et al.*, 2011; Loader *et al.*, 2011; Nock *et al.*, 2011) and in a temperate semi-natural grassland (Koehler *et al.*, 2010), although in one boreal tree species WUE ceased to increase after 1970 (Gagen *et al.*, 2011). Analysis of long-term whole-ecosystem carbon and water flux measurements from 21 sites in North American temperate and boreal forests corroborates a notable increase in WUE over the two past decades (Keenan *et al.*, 2013). An increase in global WUE over the past century is supported by ecosystem model results (Ito and Inatomi, 2012).

A key influence on the significance of increased WUE for large-scale transpiration is whether vegetation structure and production has remained approximately constant (as assumed in the global modelling study by Gedney *et al.*, 2006) or has increased in some regions due to the structural CO_2 effect (as assumed in models by Piao *et al.*, 2007;

Gerten *et al.*, 2008). While field-based results vary considerably among sites, tree ring studies suggest that tree growth did not increase globally since the 1970s in response to climate and CO_2 change (Peñuelas *et al.*, 2011; Andreu-Hayles *et al.*, 2011). However, basal area measurements at over 150 plots across the tropics suggest that biomass and growth rates in intact tropical forests have increased in recent decades (Lewis *et al.*, 2009). This is also confirmed for 55 temperate forest plots, with a suspected contribution of CO_2 effects (McMahon *et al.*, 2010). Satellite observations analysed in Donohue *et al.* (2013) suggest that an increase in vegetation cover by 11% in warm drylands (1982–2010 period) is attributable to CO_2 fertilization. Owing to the interplay of physiological and structural effects, the net impact of CO_2 increase on global-scale transpiration and runoff remains rather poorly constrained. This is also true because nutrient limitation, often omitted in modelling studies, can suppress the CO_2 fertilization effect (see Rosenthal and Tomeo, 2013).

Therefore, there are conflicting views on whether the direct CO_2 effects on plants already have a significant influence on evapotranspiration and runoff at global scale. AR4 reported work by Gedney *et al.* (2006) which suggested that the physiological CO_2 effect (lower transpiration) contributed to a supposed increase in global runoff seen in reconstructions by Labat *et al.* (2004). However, a more recent analysis based on a more complete dataset (Dai *et al.*, 2009) suggested that river basins with decreasing runoff outnumber basins with increasing runoff, such that a small decline in global runoff is *likely* for the period 1948–2004. Hence, detection of vegetation contributions to changes in water flows critically depends on the availability and quality of hydrometeorological observations (Haddeland *et al.*, 2011; Lorenz and Kunstmann, 2012). Overall, the evidence since AR4 suggests that climatic variations and trends have been the main driver of global runoff change in the past decades; both CO_2 increase and land use change have contributed less (Piao *et al*., 2007; Gerten *et al*., 2008; Alkama *et al.*, 2011; Sterling *et al.*, 2013). Oliveira *et al.* (2011) furthermore pointed to the importance of changes in incident solar radiation and the mediating role of vegetation; according to their global simulations, a higher diffuse radiation fraction during 1960–1990 may have increased evapotranspiration in the tropics by 3% due to higher photosynthesis from shaded leaves.

It is uncertain how vegetation responses to future increases in CO_2 and to climate change will modulate the impacts of climate change on freshwater flows. 21st century continental- and basin-scale runoff is projected by some models to either increase more or decrease less when the physiological CO_2 effect is included in addition to climate change effects (Betts *et al.*, 2007; Murray *et al.*, 2012). This could somewhat ease the increase in water scarcity anticipated in response to future climate change and population growth (Gerten *et al.*, 2011; Wiltshire *et al.*, in press). In absolute terms, the isolated effect of CO_2 has been modelled to increase future global runoff by 4–5% (Gerten *et al.*, 2008) up to 13% (Nugent and Matthews, 2012) compared to the present, depending on the assumed CO_2 trajectory and whether feedbacks of changes in vegetation structure and distribution to the atmosphere are accounted for (they were not in Nugent and Matthews, 2012). In a global model intercomparison study (Davie *et al.*, in press), two out of four models projected stronger increases and, respectively, weaker decreases in runoff when considering CO_2 effects compared to simulations with constant CO_2 concentration (consistent with above findings, though magnitudes differed between the models), but two other models showed the reverse. Thus, the choice of models and the way they represent the coupling between CO_2, stomatal closure and plant growth is a source of uncertainty, as also suggested by Cao *et al.* (2009). Lower transpiration due to rising CO_2 concentration may also affect future regional climate change itself (Boucher *et al.*, 2009) and enhance the contrast between land and ocean surface warming (Joshi *et al.*, 2008). Overall, although physiological and structural effects will influence water flows in many regions, precipitation and temperature effects are *likely* to remain the prime influence on global runoff (Alkama *et al.*, 2010).

An application of a soil-vegetation-atmosphere-transfer model indicates complex responses of groundwater recharge to vegetation-mediated changes in climate, with computed groundwater recharge being always larger than would be expected from just accounting for changes in rainfall (McCallum *et al.*, 2010). Another study found that even if precipitation slightly decreased, groundwater recharge might increase as a net effect of vegetation responses to climate change and CO_2 rise, i.e. increasing WUE and either increasing or decreasing leaf area (Crosbie *et al.*, 2010). Depending on the type of grass in Australia, the same change in climate is suggested to lead to either increasing or decreasing groundwater recharge in this location (Green *et al.*, 2007). For a site in the Netherlands, a biomass decrease was computed for each of eight climate scenarios indicating drier summers and wetter winters (A2 emissions scenario), using a fully coupled vegetation and variably saturated hydrological model. The resulting increase in groundwater recharge up-slope was simulated to lead to higher water tables and an extended habitat for down-slope moisture-adapted vegetation (Brolsma *et al.*, 2010).

Using a large ensemble of climate change projections, Konzmann *et al.* (2013) put hydrological changes into an agricultural perspective and suggested that the net result of physiological and structural CO_2 effects on crop irrigation requirements would be a global reduction (Figure VW-1). Thus, adverse climate change impacts on irrigation requirements and crop yields might be partly buffered as WUE and crop production improve (Fader *et al.*, 2010). However, substantial CO_2-driven improvements will only be realized if proper management abates limitation of plant growth by nutrient availability or other factors.

[INSERT FIGURE VW-1 HERE
Figure VW-1: Percentage change in net irrigation requirements of 11 major crops from 1971–2000 to 2070–2099 on areas currently equipped for irrigation, assuming current management practices. Top: impact of climate change including physiological and structural crop responses to increased atmospheric CO_2 concentration (maximum effect in the absence of co-limitation by nutrients). Bottom: impact of climate change only. Shown is the median change derived from climate change projections by 19 GCMs (based on the SRES A2 emissions scenario) used to force a vegetation and hydrology model. Modified after Konzmann *et al.* (2013).]

Changes in vegetation coverage and structure due to long-term climate change or shorter-term extreme events such as droughts (Anderegg *et al.*, 2013) also affect the partitioning of precipitation into evapotranspiration and runoff, sometimes involving complex feedbacks with the atmosphere such as in the Amazon region (Port *et al.*, 2012; Saatchi *et al.*, 2013). One model in the study by Davie *et al.* (in press) showed regionally diverse climate change effects on vegetation distribution and structure, which had a much weaker effect on global runoff than the structural and physiological CO_2 effects. As water, carbon and vegetation dynamics evolve synchronously and interactively under climate change (Heyder *et al.*, 2011; Gerten *et al.*, in press), it remains a challenge to disentangle the individual effects of climate, CO_2 and land cover change on the water cycle.

Box CC-WE: The Water-Energy-Food/Feed/Fiber Nexus as Linked to Climate Change

[Douglas J. Arent (USA), Petra Döll (Germany), Kenneth M. Strzepek (UNU / USA), Blanca Elena Jimenez Cisneros (Mexico), Andy Reisinger (New Zealand), FerencToth (IAEA / Hungary), Taikan Oki (Japan)]

Water, energy, and food/feed/fiber are linked through numerous interactive pathways and subject to a changing climate, as depicted in Figure WE-1. The depth and intensity of those linkages vary enormously between countries, regions and production systems. Energy technologies (e.g. biofuels, hydropower, thermal power plants), transportation fuels and modes, and food products (from irrigated crops, in particular animal protein produced by feeding irrigated crops and forages) may require significant amounts of water (Sections 3.7.2, 7.3.2, 10.2, 10.3.4, 22.3.3, 25.7.2; Allan, 2003; King and Weber 2008; McMahon and Price, 2011; Macknick *et al*., 2012a). In irrigated agriculture, climate, irrigating procedure, crop choice and yields determine water requirements per unit of produced crop. In areas where water (and wastewater) must be pumped and/or treated, energy must be provided (Asano et al., 2006; Khan and Hanjra, 2009; USEPA, 2010; Gerten et al., 2011). While food production, refrigeration, transport and processing require large amounts of energy (Pelletier et al., 2011), a major link between food and energy as related to climate change is the competition of bioenergy and food production for land and water (Section 7.3.2, Box 25-10; Diffenbaugh et al., 2012; Skaggs et al., 2012) *(robust evidence, high agreement)*. Food and crop wastes, and wastewater, may be used as sources of energy, saving not only the consumption of conventional non-renewable fuels used in their traditional processes, but also the consumption of the water and energy employed for processing or treatment and disposal (Schievano et al., 2009; Sung et al., 2010; Olson, 2012). Examples of this can be found in several countries across all income ranges. For example, sugar cane by-products are increasingly used to produce electricity or for cogeneration (McKendry, 2002; Kim and Dale 2004) for economic benefits, and increasingly as an option for greenhouse gas mitigation.

[INSERT FIGURE WE-1 HERE
Figure WE-1: The water-energy-food nexus as related to climate change. The interlinkages of supply/demand, quality and quantity of water, energy and food/feed/fiber with changing climatic conditions have implications for both adaptation and mitigation strategies.]

Most energy production methods require significant amounts of water, either directly (e.g., crop-based energy sources and hydropower) or indirectly (e.g., cooling for thermal energy sources or other operations) (Sections 10.2.2 10.3.4, 25.7.4; van Vliet et al., 2012; Davies et al., 2013) *(robust evidence, high agreement)*. Water for biofuels, for example, under the IEA Alternative Policy Scenario, which has biofuels production increasing to 71 EJ in 2030, has been reported by Gerbens-Leenes et al. (2012) to drive global consumptive irrigation water use from 0.5% of global renewable water resources in 2005 to 5.5% in 2030, resulting in increased pressure on freshwater resources, with potential negative impacts on freshwater ecosystems. Water is also required for mining (Section 25.7.3), processing, and residue disposal of fossil and nuclear fuels or their byproducts. Water for energy currently ranges from a few percent in most developing countries to more than 50% of freshwater withdrawals in some developed countries, depending on the country (Kenny et al., 2009; WEC, 2010). Future water requirements will depend on electricity demand growth, the portfolio of generation technologies and water management options employed (WEC, 2010; Sattler et al., 2012) *(medium evidence, high agreement)*. Future water availability for energy production will change due to climate change (Sections 3.4, 3.5.1, 3.5.2.2) *(robust evidence, high agreement).*

Water may require significant amounts of energy for lifting, transport and distribution and for its treatment either to use it or to depollute it. Wastewater and even excess rainfall in cities requires energy to be treated or disposed. Some non-conventional water sources (wastewater or seawater) are often highly energy intensive. Energy intensities per m^3 of water vary by about a factor of 10 between different sources, e.g. locally produced potable water from ground/surface water sources vs. desalinated seawater (Box 25-2, Tables 25-6 and 25-7; Macknick et al., 2012b; Plappally and Lienhard, 2012). Groundwater (35% of total global water withdrawals, with irrigated food production being the largest user; Döll et al., 2012) is generally more energy intensive than surface water. In India, for example, 19% of total electricity use in 2012 was for agricultural purposes (Central Statistics Office, 2013), with a large share for groundwater pumping. Pumping from greater depth increases energy demand significantly– electricity use ($kWhr/m^3$ of water) increases by a factor of 3 when going from 35 to 120 m depth (Plappally and Lienhard, 2012). The reuse of appropriate wastewater for irrigation (reclaiming both water and energy-intense nutrients) may increase agricultural yields, save energy, and prevent soil erosion (Smit and Nasr, 1992; Jimenez, 1996; Wichelns et al., 2007; Raschid-Sally and Jayakody, 2008) *(medium confidence)*. More energy efficient treatment methods enable poor quality (“black”) wastewater to be treated to quality levels suitable for discharge into water courses, avoiding additional fresh water and associated energy demands (Keraita et al, 2008). If properly treated to retain nutrients, such treated water may increase soil productivity, contributing to increased crop yields/food security in regions unable to afford high power bills or expensive fertilizer (Oron, 1996; Lazarova and Bahri, 2005; Redwood and Huibers, 2008; Jimenez, 2009) *(high confidence)*.

Linkages among water, energy, food/feed/fiber and climate are also strongly related to land use and management (Section 4.4.4, Box 25-10) *(robust evidence, high agreement)*. Land degradation often reduces efficiency of water and energy use (e.g. resulting in higher fertilizer demand and surface runoff), and compromises food security (Sections 3.7.2, 4.4.4). On the other hand, afforestation activities to sequester carbon have important co-benefits of reducing soil erosion and providing additional (even if only temporary) habitat (see Box 25-10) but may reduce renewable water resources. Water abstraction for energy, food or biofuel production or carbon sequestration can also compete with minimal environmental flows needed to maintain riverine habitats and wetlands, implying a potential conflict between economic and other valuations and uses of water (Sections 25.4.3 and 25.6.2, Box 25-10) *(medium evidence, high agreement)*. Only a few reports have begun to evaluate the multiple interactions among energy, food, land, and water and climate (McCornick et al., 2008; Bazilian et al., 2011; Bierbaum and Matson, 2013), addressing the issues from a security standpoint and describing early integrated modeling approaches. The interaction among each of these factors is influenced by the changing climate, which in turn impacts energy and water demand, bioproductivity and other factors (see Figure WE-1 and Wise et al., 2009), and has implications for security of supplies of energy, food and water, adaptation and mitigation pathways, air pollution reduction as well as the implications for health and economic impacts as described throughout this report.

The interconnectivity of food/fiber, water, land use, energy and climate change, including the perhaps not yet well understood cross-sector impacts, are increasingly important in assessing the implications for adaptation/mitigation policy decisions. Fuel-food-land use-water-GHG mitigation strategy interactions, particularly related to bioresources for food/feed, power, or fuel, suggest that combined assessment of water, land type and use requirements, energy requirements and potential uses and GHG impacts often epitomize the interlinkages. For example, mitigation scenarios described in the IPCC Special Report on Renewable Energy Sources and Climate Change Mitigation (IPCC, 2011) indicate up to 300EJ of biomass primary energy by 2050 under increasingly stringent mitigation scenarios. Such high levels of biomass production, in the absence of technology and process/management/operations change, would have significant implications for land use, water and energy, as well as food production and pricing. Consideration of the interlinkages of energy, food/feed/fiber, water, land use and climate change is increasingly recognized as critical to effective climate resilient pathway decision making *(medium evidence, high agreement)*, although tools to support local- and regional-scale assessments and decision-support remain very limited.

Table 3-1: Selected examples, mainly from Section 3.2, of the observation, detection and attribution of impacts of climate change on freshwater resources. Observed hydrological changes are attributed here to their climatic drivers, not all of which are necessarily anthropogenic; in the diagram, symbols with borders represent end-to-end attribution of the impact on resources to anthropogenic climate change.

Observed change	*Attributed to*	*Ref*
Changed runoff (global, 1960-1994)	Mainly climatic change, and to a lesser degree CO_2 increase and land-use change	1
Reduced runoff (Yellow River, China)	Increased temperature; only 35% of reduction attributable to human withdrawals	2
Earlier annual peak discharge (Russian Arctic, 1960-2001)	Increased temperature and earlier spring thaw	3
Earlier annual peak discharge (Columbia River, western USA, 1950-1999)	Anthropogenic warming	4
Glacier meltwater yield greater in 1910-1940 than in 1980-2000 (European Alps)	Glacier shrinkage forced by comparable warming rates in the two periods	5
Decreased dry-season discharge (Peru, 1950s-1990s)	Decreased glacier extent in the absence of a clear trend in precipitation	6
Disappearance of Chacaltaya Glacier, Bolivia (2009)	Ascent of freezing isotherm at 50 meters per decade, 1980s to 2000s	7
More intense extremes of precipitation (northern tropics and mid-latitudes, 1951-1999)	Anthropogenic greenhouse-gas emissions	8
Fraction of risk of flooding (England and Wales, autumn 2000)	Extreme precipitation attributable to anthropogenic greenhouse radiation	9
Decreased recharge of karst aquifers (Spain, 20th century)	Decreased precipitation, and possibly increased temperature; multiple confounding factors	10
Decreased groundwater recharge (Kashmir, 1985-2005)	Decreased winter precipitation	11
Increased dissolved organic carbon in upland lakes (UK, 1988-2004)	Increased temperature and precipitation; multiple confounding factors	12
Increased anoxia in a reservoir, moderated during ENSO (El Niño-Southern Oscillation) episodes (Spain, 1954-2007)	Decreased runoff due to decreased precipitation and increased evaporative demand	13
Variable faecal pollution in a saltwater wetland (California, 1969-2000)	Variable storm runoff; 70% of coliform variability attributable to variable precipitation	14
Nutrient flushing from swamps, reservoirs (North Carolina, 1970s-2002)	Hurricanes	15
Increased lake nutrient content (Victoria, Australia, 1984-2000)	Increased air and water temperature	16

Table 3-2: Effects of different GHG emissions scenarios on hydrological changes and freshwater-related impacts of climate change on humans and ecosystems. Among the SRES scenarios, GHG emissions are highest in A1f and A2, lower in A1 and B2, and lowest in B1. RCP8.5 is similar to A2, while the lower emissions scenarios RCP6.0 and RCP4.5 are similar to B1. RCP2.6 is a very low emissions scenario (Figure 1-4 and Section 1.1.3.1 in Chapter 1). The studies in the table give global warming (GW: global mean temperature rise, quantified as the CMIP5 model mean) over different reference periods, typically since pre-industrial. GW is projected to be, for RCP8.5, approximately 2°C in the 2040s and 4°C in the 2080s. For RCP6.0, GW is 2°C in the 2060s and 2.5°C in the 2080s, while in RCP2.6, GW stays below 1.8°C throughout the 21st century (Figure 1-4 in Chapter 1). Population scenario SSP2 assumes a medium population increase.

Type of hydrological change or impact	Description of indicator	Hydrological change or impact in different emissions scenarios or for different degrees of global warming (GW)	Reference
Decrease of renewable water resources, global scale	Percent of global population affected by a water resource decrease of more than 20% as compared to the 1990s (mean of 5 GCMs and 11 global hydrological models, population scenario SSP2)	Up to 2°C above the 1990s (GW 2.7°C) each degree of GW affects an additional 7%	Schewe *et al.* (2013)
Decrease of renewable groundwater resources, global scale	Percent of global population affected by a groundwater resource decrease of more than 10% by the 2080s as compared to the 1980s (mean and range of 5 GCMs, population scenario SSP2)	RCP2.6: 24% (11-39%) RCP4.5: 26% (23-32%) RCP6.0: 32% (18-45%) RCP8.5: 38% (27-50%)	Portmann *et al.* (2013)
Exposure to floods, global scale	Percent of global population annually exposed, in the 2080s, to a flood corresponding to the 100-year flood discharge for the 1980s (mean and range of 5-11 GCMs, population constant at 2005 values)	RCP2.6: 0.4% (0.2-0.5%) RCP4.5: 0.6% (0.4-1.0%) RCP6.0: 0.7% (0.3-1.1%) RCP8.5: 1.2% (0.6-1.7%) GW 2°C: 0.5% (0.3-0.6%) GW 4°C: 1.2% (0.8-2.2%) 1980s: 0.1% (0.04-0.16%)	Hirabayashi *et al.* (2013)
Change in irrigation water demand, global scale	Change of required irrigation water withdrawals by the 2080s (on area irrigated around 2000) as compared to the 1980s (range of 3 GCMs)	RCP2.6: -0.2-1.6% RCP4.5: 1.9-2.8% RCP8.5: 6.7-10.0%	Hanasaki *et al.* (2013)
River flow regime shifts from perennial to intermittent and vice versa, global scale	Percent of global land area (except Greenland and Antarctica) affected by regime shifts between the 1970s and the 2050s (range of 2 GCMs)	SRES B2: 5.4-6.7% SRES A2: 6.3-7.0%	Döll and Müller Schmied (2012)
Water scarcity	Percent of global population living in countries with less than 1300 m^3/year of per-capita in the 2080s (mean of 17 GCMs, population constant at 2000 values)	No significant differences between SRES B1 and A2	Gerten *et al.* (2011)
New or aggravated water scarcity	Percent of global population living in river basins with new or aggravated water scarcity around 2100 as compared to 2000 (less than 1000 m^3/year of per-capita blue water resources) (median of 19 GCMs, population constant at 2000 values)	GW 2°C: 8% GW 3.5°C: 11% GW 5°C: 13%	Gerten *et al.* (2013)
Exposure to water scarcity	Population in water-stressed watersheds (less than 1000 m^3/year of	For emissions scenarios with 2°C target, compared to SRES	Arnell *et al.* (2013)

	per-capita blue water resources) exposed to an increase in stress (1 GCM)	A1: 5-8% impact reduction in 2050 10-20% reduction in 2100	
Change of groundwater recharge in the whole of Australia	Probability that groundwater recharge decreases to less than 50% of the 1990s value by 2050 (16 GCMs)	GW 1.4°C: close to 0 almost everywhere GW 2.8°C: in western Australia 0.2-0.6, in central Australia 0.2-0.3, elsewhere close to 1	Crosbie *et al.* (2013a)
Change in groundwater recharge in East Anglia, UK	Percent change between baseline and future groundwater recharge, in %, by the 2050s (1 GCM)	SRES B1: -22% SRES A1f: -26%	Holman *et al.* (2009)
Change of river discharge, groundwater recharge and hydraulic head in groundwater in two regions of Denmark	Changes between the 1970s and the 2080s (1 regional climate model)	Differences between SRES B2 and A2 are very small compared to the changes between the 1970s and the 2080s in each scenario	van Roosmalen *et al.* (2007)
River flow regime shift for river in Uganda	Shift from bimodal to unimodal (1 GCM)	Occurs in scenarios with GW of at least 4.3°C but not for smaller GW	Kingston and Taylor (2010)
Agricultural (soil moisture) droughts in France	Mean duration, affected area and magnitude of short and long drought events throughout the 21st century (1 GCM)	Smaller increases over time for SRES B1 than for A2 and A1B	Vidal *et al.* (2012)
Salinization of artificial coastal freshwater lake IJsselmeer in the Netherlands (a drinking water source) due to seawater intrusion	(1) Daily probability of exceedance of maximum allowable concentration (MAC) of chloride (150 mg/liter), (2) Maximum duration of MAC exceedance (2050, 1 GCM)	Reference period 1997-2007 (GW 0.8°C): (1) 2.5%, (2) 103 days GW 1.8°C, no change in atmospheric circulation: (1) 3.1%, (2) 124 days GW 2.8°C and change in atmospheric circulation: (1) 14.3%, (2) 178 days	Bonte and Zwolsman (2010)
Decrease of hydropower production at Lake Nasser, Egypt	Reduction of mean annual hydropower production by the 2080s compared to hydropower production 1950-99 (11 GCMs)	SRES B1: 8% SRES A2: 7%	Beyene *et al.* (2010)
Reduction of usable capacity of thermal power plants in Europe and USA due to low river flow and excessive water temperature	Number of days per year with a capacity reduction of more than 50% (for existing power plants) (2031-2060, 3 GCMs)	Without climate change: 16 SRES B1: 22 SRES A2: 24	van Vliet *et al.* (2012)
Flood damages in Europe (EU27)	(1) Expected annual damages, in 2006- €, (2) Expected annual population exposed (2080s, 2 GCMs)	SRES B2: (1) 14-15 billion €/year, (2) 440,000-470,000 people SRES A2: (1) 18-21 billion €/year, (2) 510,000-590,000 people Reference period: (1) 6.4 billion €/year, (2) 200,000 people	Feyen *et al.* (2012)

Table 3-3: Categories of climate change adaptation options for the management of freshwater resources.

OPTION	A+M
Institutional	
Support integrated water resources management, including the integrated management of land considering specifically negative and positive impacts of climate change	X
Promote synergy of water and energy savings and efficient use	X
Identify "low-regret policies" and build a portfolio of relevant solutions for adaptation	X
Increase resilience by forming water utility network working teams	
Build adaptive capacity	
Improve and share information	X
Adapt the legal framework to make it instrumental for addressing climate change impacts	X
Develop financial tools (credit, subsidies and public investment) for the sustainable management of water, and for considering poverty eradication and equity	
Design and operation	
Design and apply decision-making tools that consider uncertainty and fulfill multiple objectives	
Revise design criteria of water infrastructure to optimize flexibility, redundancy and robustness	
Ensure plans and services are robust, adaptable or modular, give good value, are maintainable, and have long-term benefits, especially in low-income countries	X
Operate water infrastructure so as to increase resilience to climate change for all users and sectors	
When and where water resources increase, alter dam operations to allow freshwater ecosystems to benefit	
Take advantage of hard and soft adaptation measures	X
Carry out programs to protect water resources in quantity and quality	
Increase resilience to climate change by diversifying water sources(1) and improving reservoir management	X
Reduce demand by controlling leaks, implementing water-saving programs, cascading and reusing water	X
Improve design and operation of sewers, sanitation and wastewater treatment infrastructure to cope with variations in influent quantity and quality	
Provide universal sanitation with technology locally adapted, and provide for proper disposal and reintegration of used water into the environment or for its reuse	
Reduce impact of natural disasters	
Implement monitoring and early warning systems	
Develop contingency plans	
Improve defenses and site selection for key infrastructure that is at risk of floods	
Design cities and rural settlements to be resilient to floods	
Seek and secure water from a diversity (spatially and source-type) of sources to reduce impacts of droughts and variability in water availability	
Promote both the reduction of water demand and the efficient use of water by all users	
Improve irrigation efficiency and reduce demand for irrigation water	X
Promote switching to more appropriate crops (drought-resistant, salt-resistant; low water demand)	X
Plant flood- or drought-resistant crop varieties	
Agricultural irrigation	
Reuse wastewater to irrigate crops and use soil for carbon sequestration	X
Industrial use	
When selecting alternative sources of energy, assess the need for water	X
Relocate water-thirsty industries and crops to water-rich areas	
Implement industrial water efficiency certifications	X

A+M: may assist both adaptation and mitigation
(1) This includes water reuse, rain water harvesting, and desalination, among others.

Table 3-4: Key risks from climate change and the potential for reducing risk through mitigation and adaptation. Key risks are identified based on assessment of the literature and expert judgments by chapter authors, with evaluation of evidence and agreement in supporting chapter sections. Each key risk is characterized as very low to very high. Risk levels are presented in three time frames: the present, near-term (here assessed over 2030-2040), and longer term (here assessed over 2080-2100). Sources: Xie et al., 2006; Döll, 2009; Kaser et al., 2010; Arnell et al., 2011; Huss, 2011; Jóhannesson et al., 2012; Seneviratne et al., 2012; Arnell and Gosling, 2013; Dankers et al., 2013; Gosling and Arnell, 2013; Hanasaki et al., 2013; Hirabayashi et al., 2013; Kundzewicz et al., 2013; Portmann et al., 2013; Radić et al., 2013; Schewe et al., 2013; WGI AR5 Chapter 13.

Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
Flood risks associated with climate change increase with increasing greenhouse gas emissions (*high agreement, medium confidence*)	By 2100, the number of people exposed annually to a 20th-century 100-year flood is projected to be three times greater for very high emissions (RCP8.5) than for very low emissions (RCP2.6).		3.4.8	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high
Climate change is projected to reduce renewable water resources significantly in most dry subtropical regions (*high agreement, robust confidence*)	This will exacerbate competition for water among agriculture, ecosystems, settlements, industry and energy production, affecting regional water, energy and food security.		3.5.1	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high
Because nearly all glaciers are too large for equilibrium with the present climate, there is a committed water-resources change during much of the 21st century, and changes beyond the committed change are expected due to continued warming; in glacier-fed rivers, total meltwater yields from stored glacier ice will increase in many regions during the next decades but decrease thereafter (*high agreement, robust confidence*)	Continued loss of glacier ice implies a shift of peak discharge from summer to spring, except in monsoonal catchments, and possibly a reduction of summer flows in the downstream parts of glacierized catchments.		3.4.3	Present Near-term (2030-2040) Long-term (2080-2100) 2°C / 4°C	Very low – Medium – Very high

Climatic drivers of impacts			Risk & potential for adaptation
Warming trend	Drying trend	Extreme precipitation	Potential for adaptation to reduce risk; Risk level with **high** adaptation; Risk level with **current** adaptation

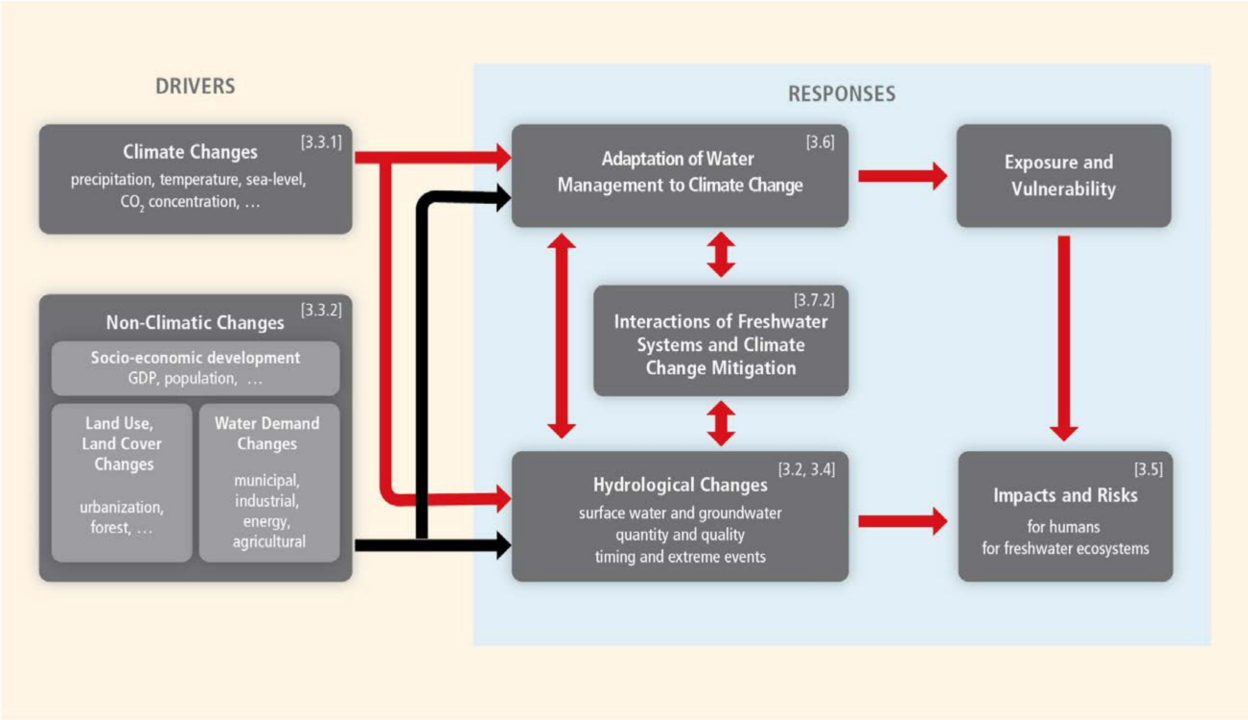

Figure 3-1: Framework (boxes) and linkages (arrows) for considering impacts of climatic and social changes on freshwater systems, and consequent impacts on and risks for humans and freshwater ecosystems. Both climatic (Section 3.3.1) and non-climatic (Section 3.3.2) drivers have changed natural freshwater systems (Section 3.2) and are expected to continue to do so (Section 3.4). They also stimulate adaptive measures (Section 3.6). Hydrological and water-management changes interact with each other and with measures to mitigate climate change (Section 3.7.2). Adaptive measures influence the exposure and vulnerability of human beings and ecosystems to water-related risks (Section 3.5).

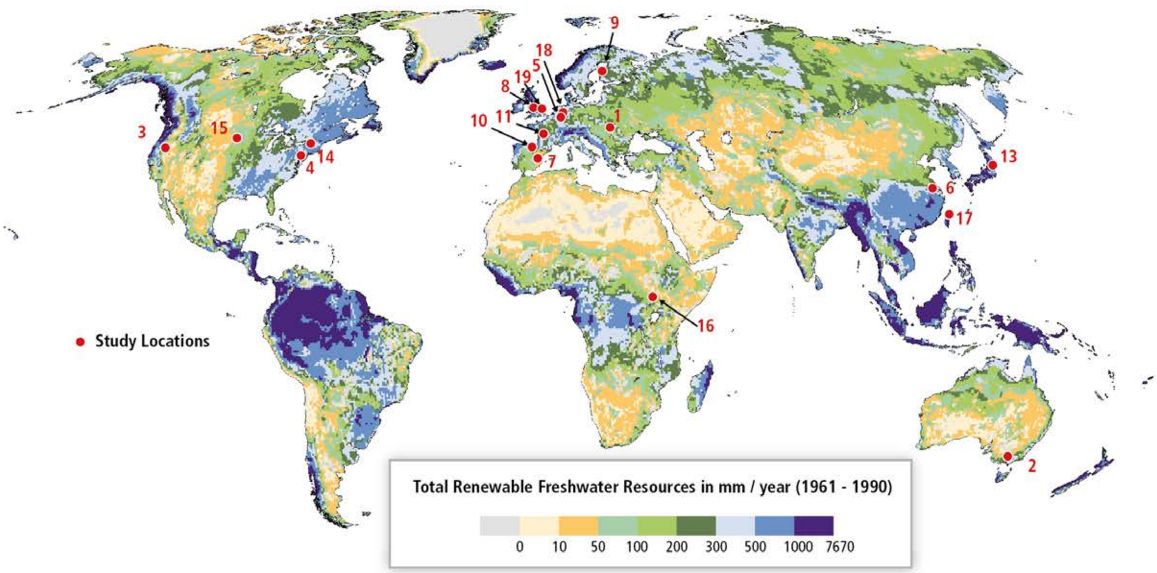

#	Location	Study Period	Observation on water quality	Reference
1	Danube River, Bratislava, Slovakia	1926-2005	The water temperature is rising but the trend of the weighted long term average temperature values resulted close to zero because of the inter-annual distribution of the mean monthly discharge.	Pekarova et al., 2008
2	Purrumbete, Colac & Bullen Merri Lakes, Victoria, Australia	1984-2000	The increases in salinity and nutrient content were associated with the air temperature increase; salinity in addition was associated with variations in the effective precipitation.	Tibby and Tiller, 2007
3	Lake Tahoe, California and Nevada States, US	1970-2007	Thermal stability resulting from a higher ambient temperature decreased the dissolved oxygen content.	Sahoo et al., 2010
4	Neuse River Estuary, North Carolina, US	1979-2003	Intense storms and hurricanes flushed nutrients from the estuary reducing eutrophic conditions and the risk of algal blooms.	Paerl et al., 2006; Paerl and Huisman, 2008
5	River Meuse, western Europe	1976-2003	Increase of water temperature and the content of major elements and some heavy metals were associated with droughts. Algal blooms resulted from a higher nutrient content due to higher water temperature and longer residence time.	van Vliet and Zwolsman, 2008
6	Lake Taihu, Wuxi, Jiangsu, China	2007	The lake already suffering from periodic cyanobacterial blooms, was affected by a very intensive bloom in May 2007 attributed to an unusually warm spring and leading to the presence of Microcystis toxins in the water. This forced two million people to drink bottled water for at least one week.	Qin et al., 2010
7	Sau Reservoir, Spain	1964-2007	Stream flow variations were of greater significance than temperature increases in the depletion of dissolved oxygen.	Marcé et al., 2010
8	22 upland waters in UK	1988-2002	Dissolved organic matter increased due to temperature increase but also to rainfall variations, acid deposition, land-use, and CO_2 enrichment.	Evans et al., 2005
9	Coastal rivers from western Finland	1913-2007	Low pH values associated with higher rainfall and river discharge in an acid sulphate soil basin.	Saarinen et al., 2010
		1961-2007	Critical values of dissolved organic carbon associated with higher rainfall and river discharge.	
10	15 pristine mountain rivers, Northern Spain	1973-2005	For a semiarid area, a clear relationship between increases in air temperature and a higher nutrient and dissolved organic carbon content.	Benítez-Gilabert et al., 2010
11	30 coastal rivers and groundwater of Western France	1973-2007 (2-6 years)	Inter-annual variations in the nutrient content associated with air temperature, rainfall and management practices changes. These effects were not observed in groundwater because of the delay in response time and the depuration of soil on water.	Gascuel-Odoux et al., 2010
12	Girnock, Scotland	14 months	Higher risks of faecal pollution clearly related to rainfall during the wet period	Tetzlaff et al., 2010
13	27 rivers in Japan	1987-1995	Increases in organic matter and sediment and decreases in the dissolved oxygen content associated with increases in ambient temperature. Precipitation increases and variations associated with increase in the organic matter, sediments and chemical oxygen demand content in water.	Ozaki et al., 2003
14	Conestoga River Basin, Pennsylvania, US	1977-1997	Close association between annual loads of total nitrogen and annual precipitation increases.	Chang 2004
15	US	1948-1994	Increased rainfall and runoff associated with site-specific outbreaks of waterborne disease.	Curriero et al., 2001
16	Northern and Eastern Uganda	1999-2001, 2004, 2007	Elevated concentrations of faecal coliforms observed in groundwater-fed water supplies during the rainy season.	Tumwine et al. 2002, 2003; Taylor et al., 2009
17	Taiwan, China	1998	The probability of detecting cases of enterovirus infection was greater than 50% with rainfall rates >31 mm/h. The higher the rainfall rate, the higher the probability of an enterovirus epidemic.	Jean et al., 2006
18	Rhine Basin	1980-2001	Nutrient content in rivers followed seasonal variations in precipitation which were also linked to erosion within the basin.	Loos et al., 2009
19	River Thames, England	1868-2008	Higher nutrient contents were associated to changes in river runoff and land use.	Howden et al., 2010

Figure 3-2: Observations of the impacts of climate on water quality.

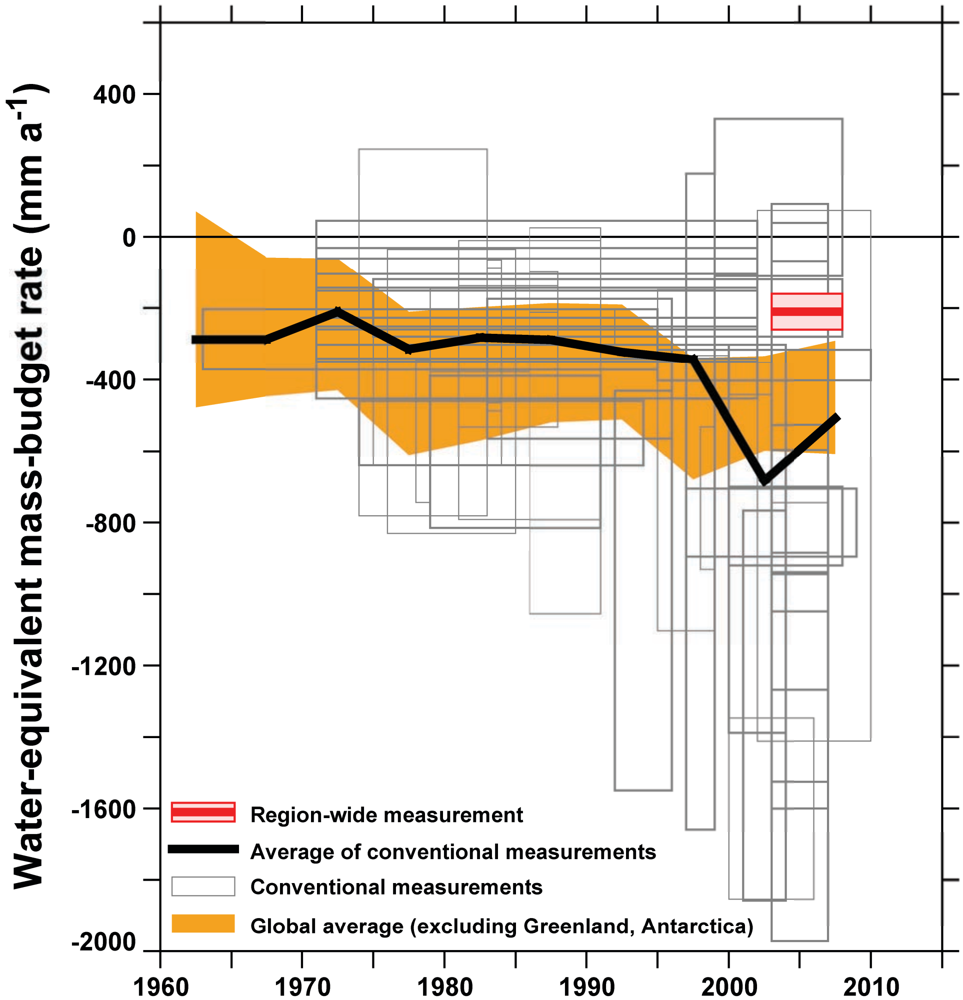

Figure 3-3: All published glacier mass balance measurements from the Himalaya (based on Bolch *et al*., 2012). To emphasize the variability of the raw information, each measurement is shown as a box of height ±1 standard deviation centred on the average balance (±1 standard error for multi-annual measurements). Region-wide measurement (Kääb *et al*., 2012) was by satellite laser altimetry. Global average (WGI Chapter 4) is shown as a 1-sigma confidence region.

[Illustration to be redrawn to conform to IPCC publication specifications.]

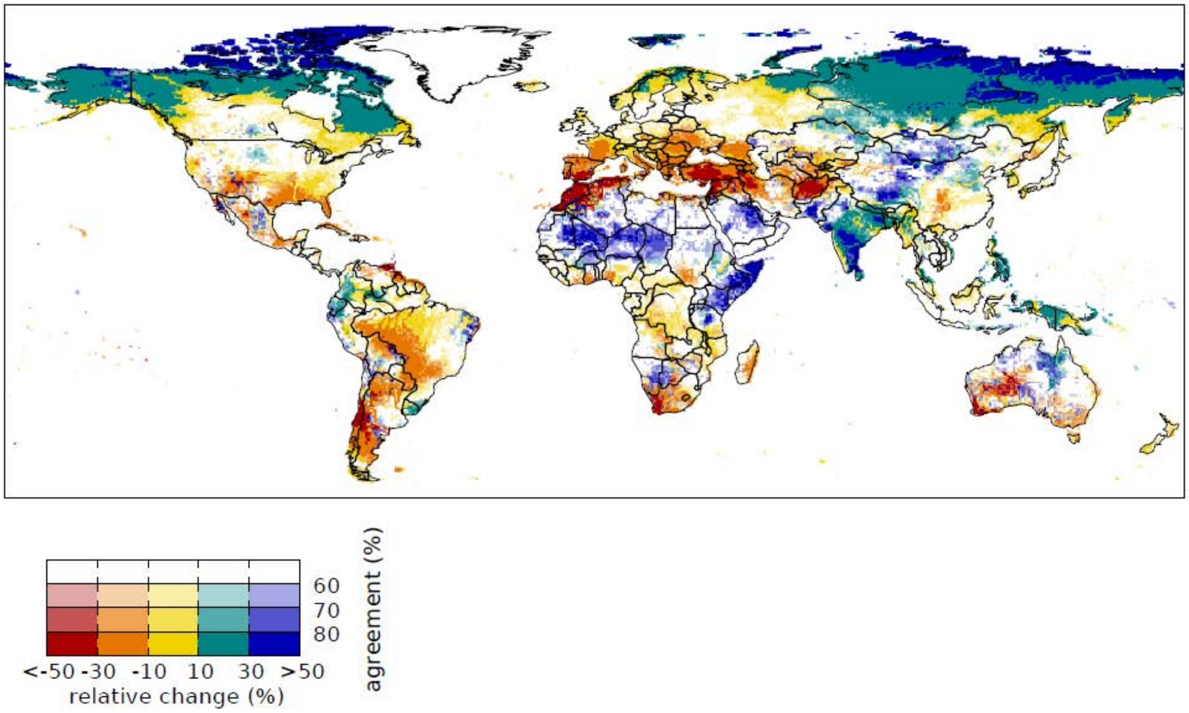

Figure 3-4: Percentage change of mean annual streamflow for a global mean temperature rise of 2°C above 1980–2010 (2.7°C above pre-industrial). Color hues show the multi-model mean change across 4 GCMs and 11 global hydrological models (GHMs), and saturation shows the agreement on the sign of change across all 55 GHM-GCM combinations (percentage of model runs agreeing on the sign of change) (Schewe *et al*., 2013).
[Illustration to be redrawn to conform to IPCC publication specifications.]

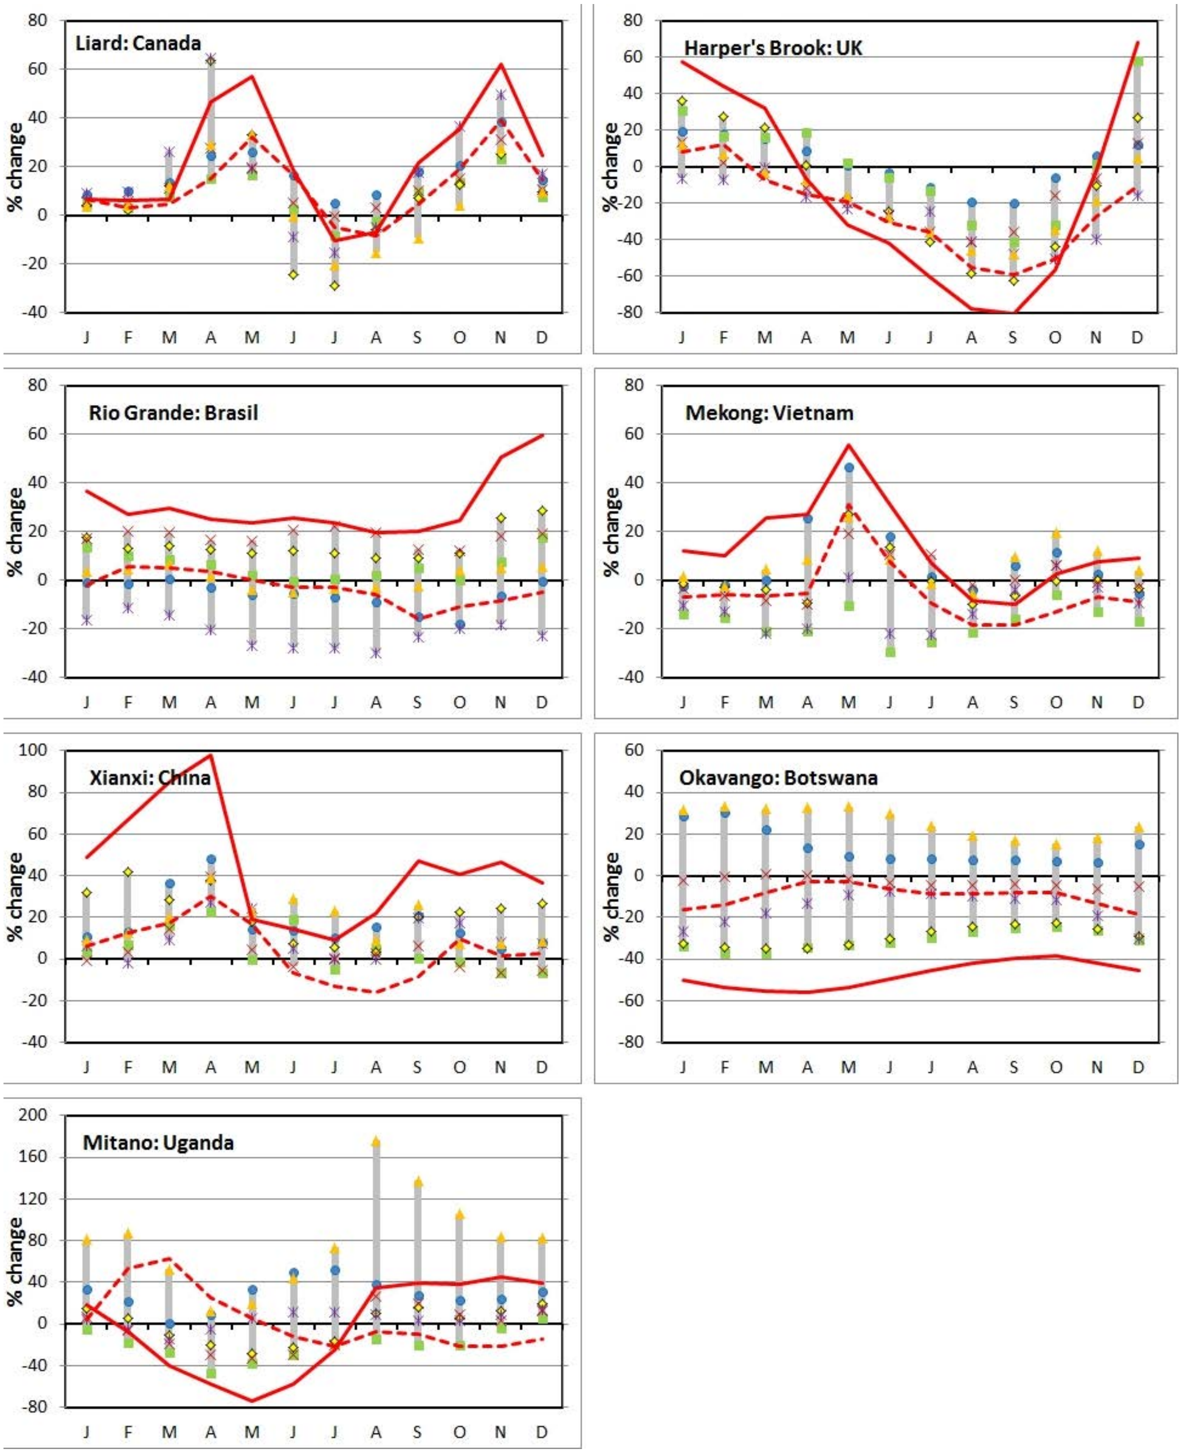

Figure 3-5: Change in mean monthly runoff across seven climate models in seven catchments, with a 2ºC increase in global mean temperature above 1961-1990 (Arnell, 2011; Hughes *et al*., 2011; Kingston and Taylor, 2010; Kingston *et al*., 2011; Nobrega *et al*., 2011; Thorne, 2011; Xu *et al*., 2011). One of the seven climate models (HadCM3) is highlighted separately, showing changes with both a 2ºC increase (dotted line) and a 4ºC increase (solid line). **[Illustration to be redrawn to conform to IPCC publication specifications.]**

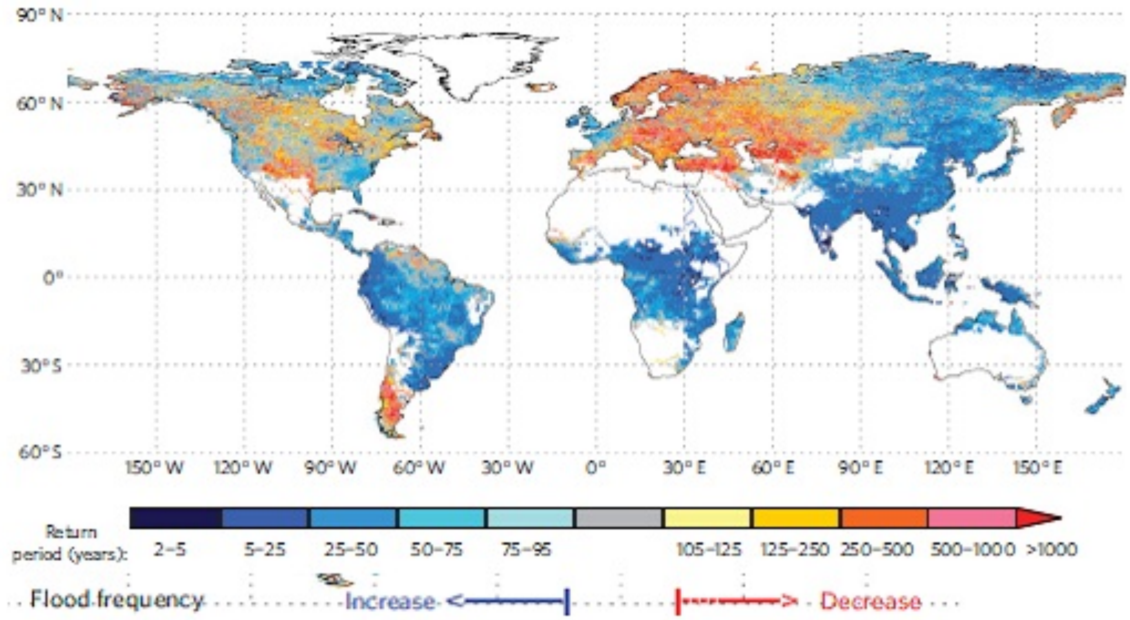
a)



b)

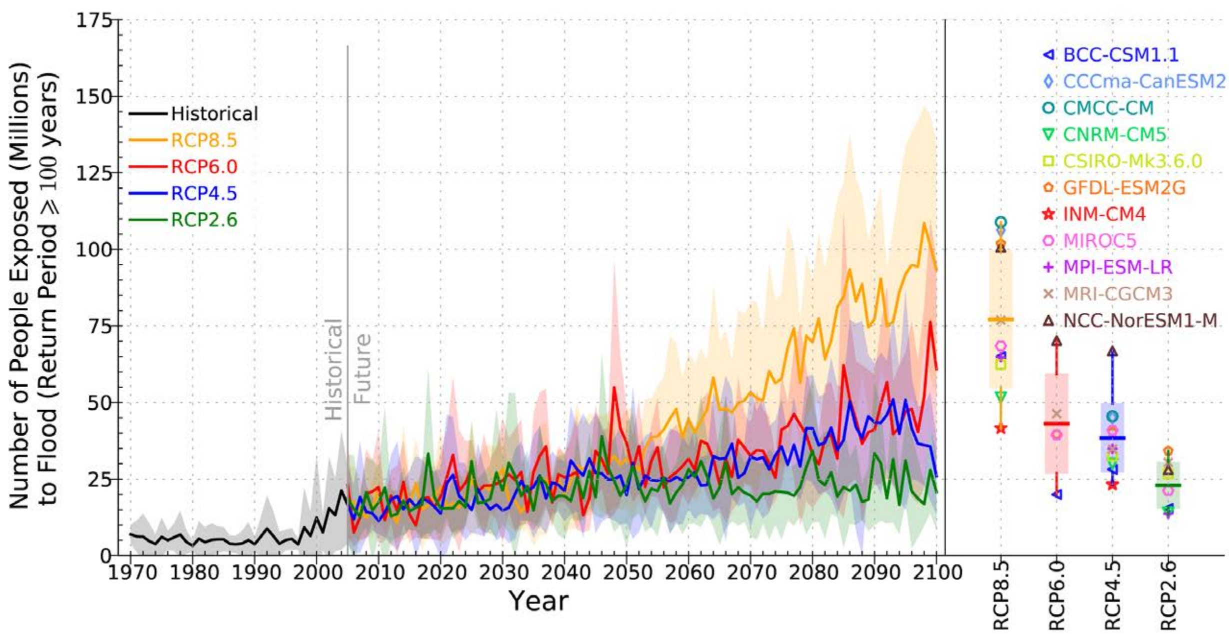


Figure 3-6: a) Multi-model median return period (years) in the 2080s for the 20th-century 100-year flood (Hirabayashi *et al*., 2013), based on one hydrological model driven by 11 CMIP5 GCMs under RCP8.5. At each location the magnitude of the 100-year flood was estimated by fitting a Gumbel distribution function to time series of simulated annual maximum daily discharge in 1971–2000, and the return period of that flood in 2071–2100 was estimated by fitting the same distribution to discharges simulated for that period. b) Global exposure to the 20th-century 100-year flood (or greater) in millions of people (Hirabayashi *et al*., 2013). Left: ensemble means of historical (black thick line) and future simulations (colored thick lines) for each scenario. Shading denotes ±1 standard deviation. Right: maximum and minimum (whiskers), mean (horizontal thick lines within each bar), ±1 standard deviation (box) and projections of each GCM (colored symbols) averaged over the 21st century. The

impact of 21st-century climate change is emphasized by fixing the population to that of 2005. Annual global flood exposure increases over the century by 4-14 times as compared to the 20th century [4±3 (RCP2.6), 7±5 (RCP4.5), 7±6 (RCP6.0) and 14±10 (RCP8.5) times, or 0.1% to 0.4-1.2% of the global population in 2005)]. Under a scenario of moderate population growth (UN, 2011), the global number of exposed people is projected to increase by a factor of 7-25, depending on the RCP, with strong increases in Asia and Africa due to high population growth.
[Illustration to be redrawn to conform to IPCC publication specifications.]

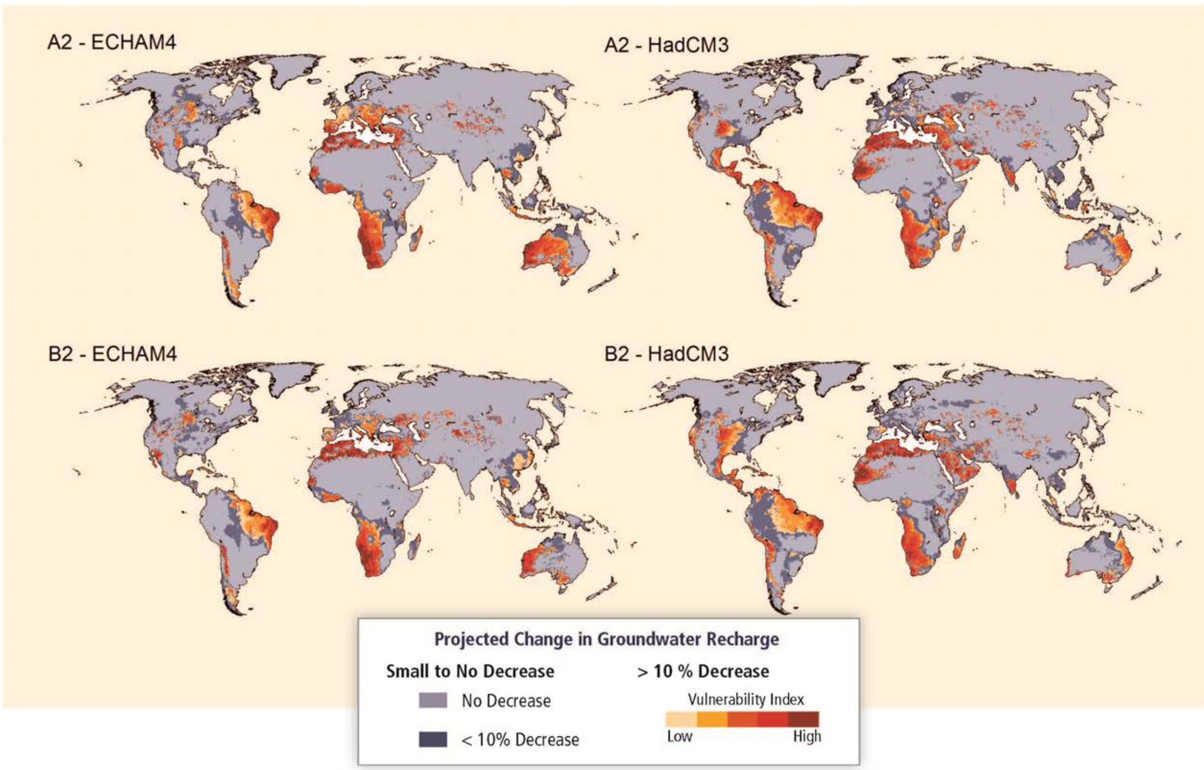

Figure 3-7: Human vulnerability to climate-change induced decreases of renewable groundwater resources by the 2050s. Lower (B2) and higher (A2) emissions pathways are interpreted by two global climate models. The higher the vulnerability index (computed by multiplying percentage decrease of groundwater recharge by a sensitivity index), the higher the vulnerability. The index is only defined for areas where groundwater recharge is projected to decrease by at least 10% relative to 1961-1990 (Döll, 2009).

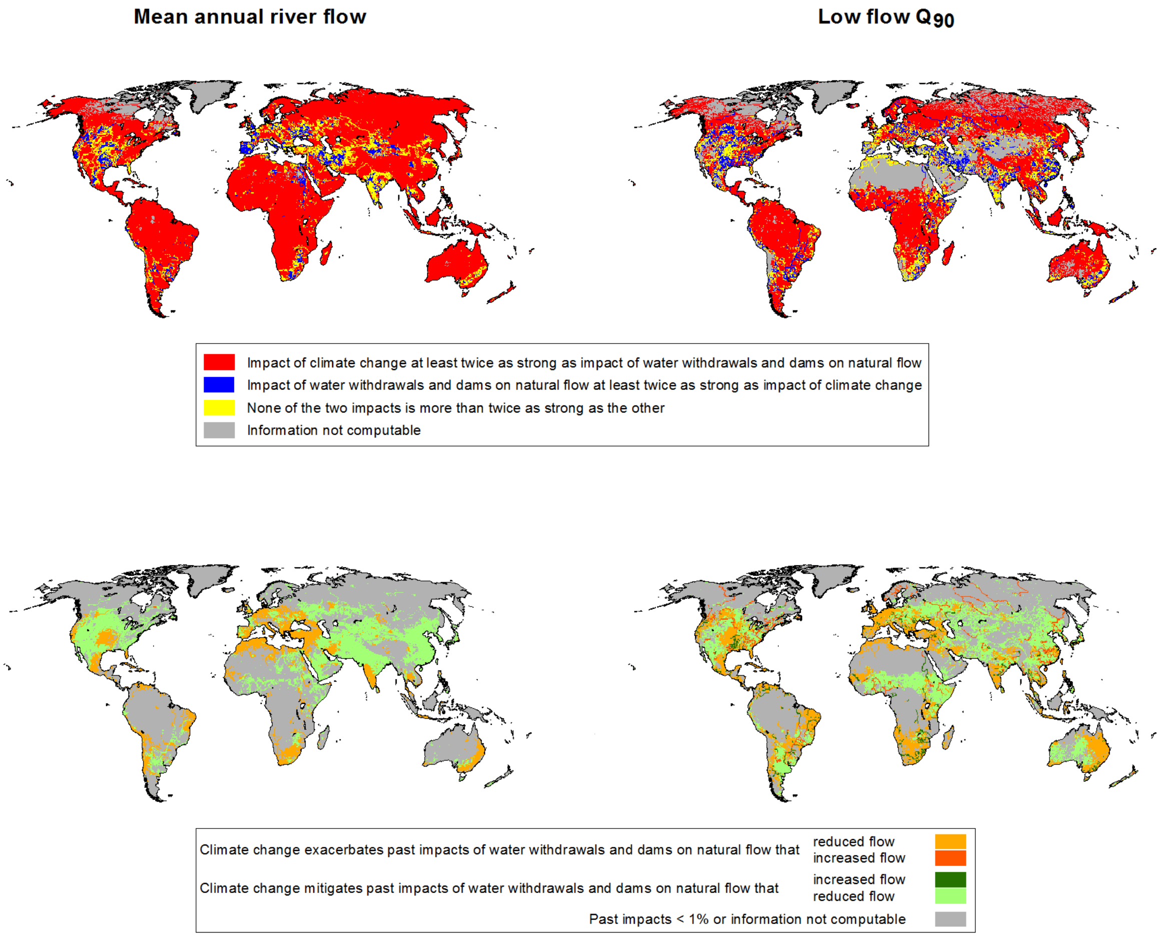

Figure RF-1: Impact of climate change relative to the impact of water withdrawals and dams on natural flows for two ecologically relevant river flow characteristics (mean annual river flow and monthly low flow Q_{90}), computed by a global water model (Döll and Zhang, 2010). Monthly Q_{90} was defined as the flow that is exceeded in 9 out 10 months. Impact of climate change is the percent change of flow between 1961-1990 and 2041-2070 according to the emissions scenario A2 as implemented by the global climate model HadCM3. Impact of water withdrawals and reservoirs is computed by running the model with and without water withdrawals and dams that existed in 2002. Please note that the figure does not reflect spatial differences in the magnitude of change.
[Illustration to be redrawn to conform to IPCC publication specifications.]

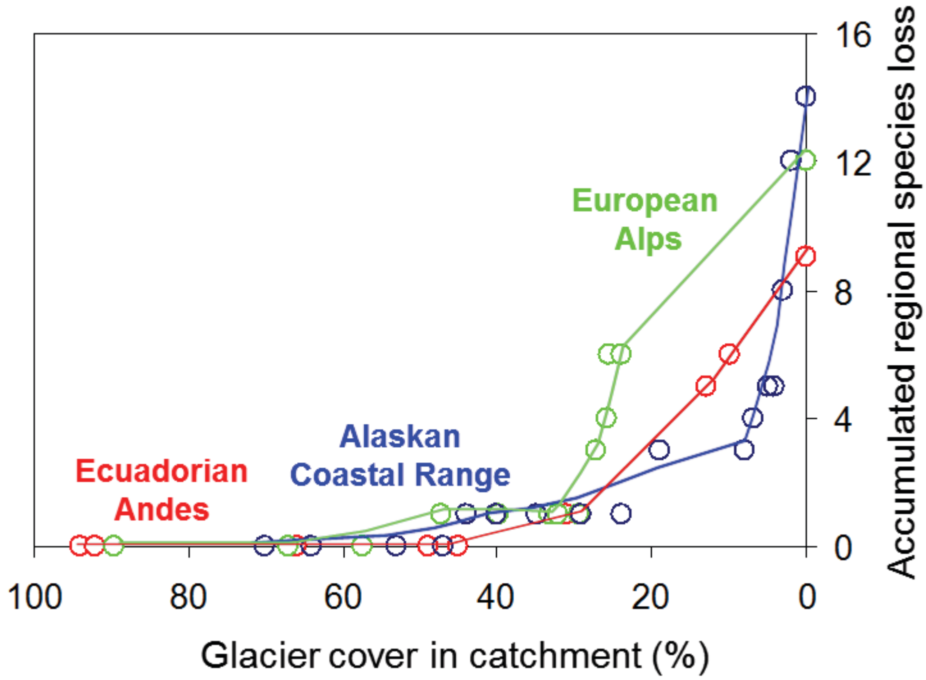

Figure RF-2: Accumulated loss of regional species richness (gamma diversity) of macroinvertebrates as a function of glacial cover in catchment. Obligate glacial river macroinvertebrates begin to disappear from assemblages when glacial cover in the catchment drops below approximately 50%, and 9-14 species are predicted to be lost with the complete disappearance of glaciers in each region, corresponding to 11, 16 and 38% of the total species richness in the three study regions in Ecuador, Europe and Alaska. Data are derived from multiple river sites from the Ecuadorian Andes and Swiss and Italian Alps, and a temporal study of a river in the Coastal Range Mountains of southeast Alaska over nearly three decades of glacial shrinkage. Each data point represents a river site or date (Alaska), and lines are Lowess fits. Adapted by permission from Macmillan Publishers Ltd: *Nature Climate Change*, Jacobsen *et al.*, 2012, © 2012.

[Illustration to be redrawn to conform to IPCC publication specifications.]

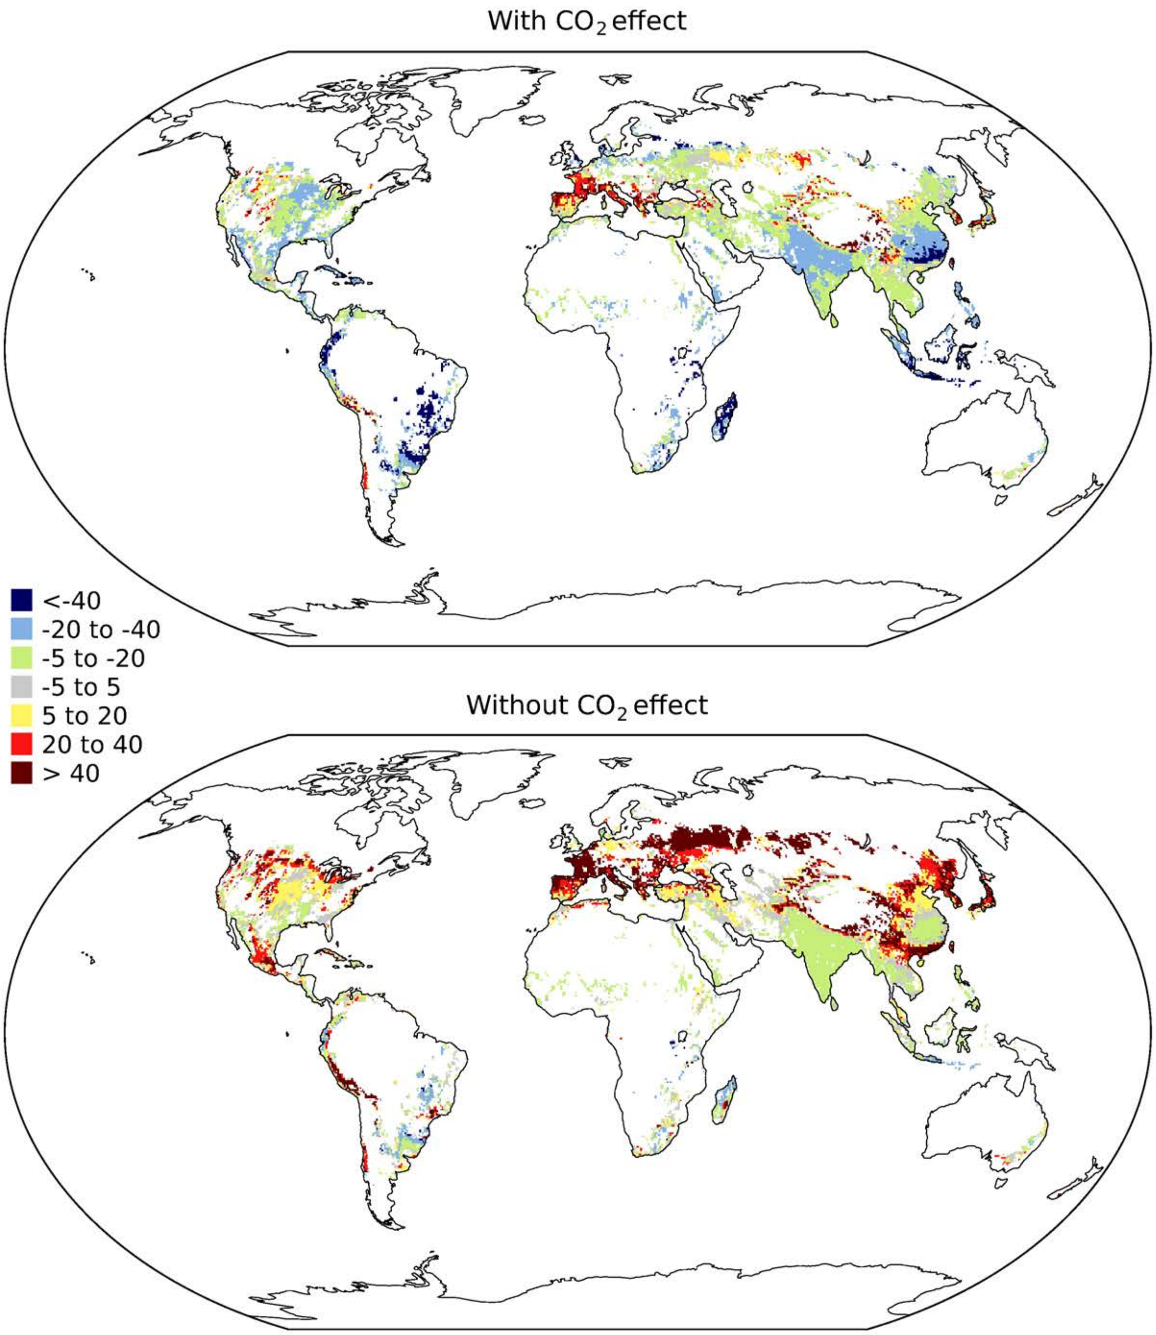

Figure VW-1: Percentage change in net irrigation requirements of 11 major crops from 1971–2000 to 2070–2099 on areas currently equipped for irrigation, assuming current management practices. Top: impact of climate change including physiological and structural crop responses to increased atmospheric CO_2 concentration (maximum effect in the absence of co-limitation by nutrients). Bottom: impact of climate change only. Shown is the median change derived from climate change projections by 19 GCMs (based on the SRES A2 emissions scenario) used to force a vegetation and hydrology model. Modified after Konzmann *et al.* (2013).
[Illustration to be redrawn to conform to IPCC publication specifications.]

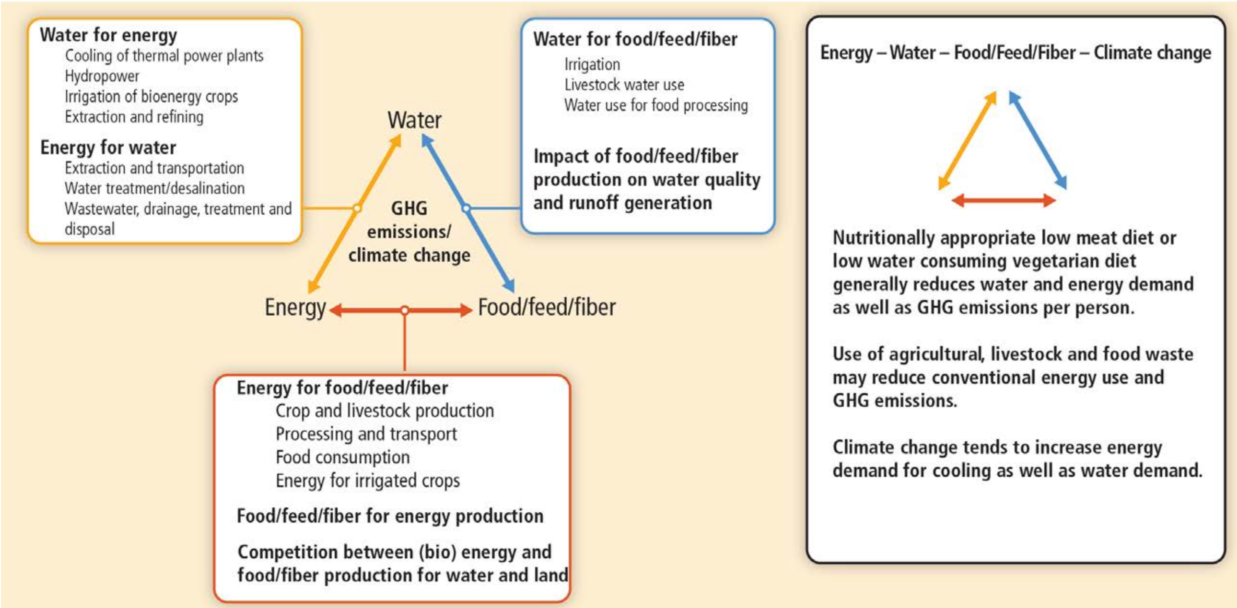

Figure WE-1: The water-energy-food nexus as related to climate change. The interlinkages of supply/demand, quality and quantity of water, energy and food/feed/fiber with changing climatic conditions have implications for both adaptation and mitigation strategies.

Executive Summary

The planet's biota and ecosystem processes were strongly affected by past climate changes at rates of climate change lower than those projected during the 21st century under high warming scenarios (e.g., RCP8.5) (*high confidence*). Most ecosystems are vulnerable to climate change even at rates of climate change projected under low- to medium-range warming scenarios (e.g., RCP2.6 to RCP6.0). The paleoecological record shows that global climate changes comparable in magnitudes to those projected for the 21st century under all scenarios resulted in large-scale biome shifts and changes in community composition; and that for rates projected under RCP6 and 8.5, was associated with species extinctions in some groups (*high confidence*). [4.2.3]

Climate change is projected to be a powerful stressor on terrestrial and freshwater ecosystems in the second half of the 21st century, especially under high-warming scenarios such as RCP6.0 and RCP8.5 (*high confidence*). Direct human impacts such as land-use and land use change, pollution and water resource development will continue to dominate the threats to most freshwater (*high confidence*) and terrestrial (*medium confidence*) ecosystems globally over the next three decades. **Changing climate exacerbates other impacts on biodiversity (*high confidence*).** Ecosystem changes resulting from climate change may not be fully apparent for several decades, due to long response times in ecological systems (*medium confidence*). Model-based projections imply that under low to moderate warming scenarios (e.g., RCP2.6 to RCP6.0), direct land cover change will continue to dominate over (and conceal) climate-induced change as a driver of ecosystem change at the global scale; for higher climate change scenarios, some model projections imply climate-driven ecosystem changes sufficiently extensive to equal or exceed direct human impacts at the global scale (*medium confidence*). In high altitude and high latitude freshwater and terrestrial ecosystems, climate changes exceeding those projected under RCP2.6 will lead to major changes in species distributions and ecosystem function, especially in the second half of the 21st century (*high confidence*). [4.2.4, 4.3.2.5, 4.3.3, 4.3.3.1, 4.3.3.3, 4.4.1.1]

When terrestrial ecosystems are substantially altered (in terms of plant cover, biomass, phenology or plant group dominance), either through the effects of climate change or through other mechanisms such as conversion to agriculture or human settlement, the local, regional and global climates are also affected (*high confidence*). The feedbacks between terrestrial ecosystems and climate include, among other mechanisms, changes in surface albedo, evapotranspiration and greenhouse gas emissions and uptake. The physical effects on the climate can be opposite in direction to the greenhouse gas effects, and can materially alter the net outcome of the ecosystem change on the global climate (*high confidence*). The regions where the climate is affected may extend beyond the location of the ecosystem that has changed. [4.2.4.1, 4.3.3.4]

Rising water temperatures, due to global warming, will lead to shifts in freshwater species distributions and worsen water quality problems, especially in those systems experiencing high anthropogenic loading of nutrients (*high confidence*). Climate change-induced changes in precipitation will substantially alter ecologically important attributes of flow regimes in many rivers and wetlands and exacerbate impacts from human water use in developed river basins (*medium confidence*). [4.3.3.3, Box CC-RF]

Many plant and animal species have moved their ranges, altered their abundance and shifted their seasonal activities in response to observed climate change over recent decades (*high confidence*). They are doing so now in many regions and will continue to do so in response to projected future climate change (*high confidence*). The broad patterns of species and biome shifts towards the poles and higher in altitude in response to a warming climate are well established for periods thousands of years in the past (*very high confidence*). These general patterns of range shifts have also been observed over the last few decades in some well-studied species groups such as insects and birds and can be attributed to observed climatic changes (*high confidence*). Interactions between changing temperature, precipitation and land use can sometimes result in range shifts that are downhill or away from the poles. Certainty regarding past species movements in response to changing climate, coupled with projections from a variety of models and studies, provide *high confidence* that such species movements will be the norm with continued warming. Under all RCP climate change scenarios for the second half of the 21st century, with *high confidence*: a) community composition will change as a result of decreases in the abundances of some species and increases in others; b) the seasonal activity of many species will change differentially disrupting life cycles and interactions between species. Composition and seasonal change will both alter ecosystem function. **[**4.2.1, 4.2.3, 4.3.2, 4.3.2.1, 4.3.2.5, 4.3.3, 4.4.1.1]

Many species will be unable to move fast enough during the 21st century to track suitable climates under mid- and high-range rates of climate change (i.e., RCP 4.5, RCP 6.0 and RCP 8.5 scenarios) (*medium confidence*). The climate velocity (the rate of movement of the climate across the landscape) will exceed the maximum velocity at which many groups of organisms, in many situations, can disperse or migrate, except after mid-century in the RCP 2.6 scenario. Populations of species that cannot keep up with their climate niche will find themselves in unfavourable climates, unable to reach areas of potentially suitable climate. Species occupying extensive flat landscapes are particularly vulnerable because they must disperse over longer distances to keep pace with shifting climates than species in mountainous regions. Species with low dispersal capacity will also be especially vulnerable:

examples include many plants (especially trees), many amphibians and some small mammals. For example, the maximum observed and modelled dispersal and establishment rates for mid- and late-successional tree species are insufficient to track climate change except in mountainous areas, even at moderate projected rates of climate change. Barriers to dispersal, such as habitat fragmentation, prior occupation of habitat by competing species and human-made impediments such dams on rivers and urbanized areas on land, reduce the ability of species to migrate to more suitable climates (*high confidence*). Intentional and accidental anthropogenic transport can speed dispersal. [4.3.2.5, 4.3.3.3]

Large magnitudes of climate change will reduce the populations, vigour and viability of species with spatially-restricted populations, such as those confined to small and isolated habitats, mountaintops or mountain streams, even if the species has the biological capacity to move fast enough to track suitable climates (*high confidence*). The adverse effects on restricted populations are modest for low magnitudes of climate change (e.g., RCP 2.6) but very severe for the highest magnitudes of projected climate change (e.g., RCP 8.5). [4.3.2.5, 4.3.3.4, 4.3.4.1]

The capacity of many species to respond to climate change will be constrained by non-climate factors (*high confidence*), including but not limited to the simultaneous presence of inhospitable land-uses, habitat fragmentation and loss, competition with alien species, exposure to new pests and pathogens, nitrogen loading and tropospheric ozone. [4.2.4.6, 4.3.3.5, Figure 4-1]

The establishment, growth, spread and survival of populations of invasive alien species has increased (*high confidence*), but the ability to attribute alien species invasion to climate change is low in most cases. Some invasive alien species have traits that favour their survival and reproduction under changing climates. Future movement of species into areas where they were not present historically will continue to be mainly driven by increased dispersal opportunities associated with human activities and by increased disturbances from natural and anthropogenic events, in some cases facilitated and promoted by climate change. [4.2.4.6, Figure 4-4]

A large fraction of terrestrial and freshwater species face increased extinction risk under projected climate change during and beyond the 21st century, especially as climate change interacts with other pressures, such as habitat modification, over-exploitation, pollution and invasive species (*high confidence*). The extinction risk is increased under all RCP scenarios, and the risk increases with both the magnitude and rate of climate change. While there is *medium confidence* that recent warming contributed to the extinction of many species of Central American amphibians, there is generally *very low confidence* that observed species extinctions can be attributed to recent climate change. Models project that the risk of species extinctions will increase in the future due to climate change, but there is *low agreement* concerning the fraction of species at increased risk, the regional and taxonomic focus for such extinctions and the timeframe over which extinctions could occur. Modelling studies and syntheses since the AR4 report broadly confirm that a large proportion of species are projected to be at increased risk of extinction at all but the lowest levels of climate warming (RCP2.6). Some aspects leading to uncertainty in the quantitative projections of extinction risks were not taken into account in previous models; as more realistic details are included, it has been shown that the extinction risks may be either under- or overestimated when based on simpler models. [4.3.2.5]

Terrestrial and freshwater ecosystems have sequestered about a quarter of the carbon dioxide emitted to the atmosphere by human activities in the past three decades (*high confidence*). The net fluxes out of the atmosphere and into plant biomass and soils show large year-to-year variability; as a result there is *low confidence* in the ability to determine whether the net rate at which carbon has been taken up by terrestrial ecosystems at the global scale has changed between the decades 1991-2000 and 2001-2010. There is *high confidence* that the factors causing the current increase in land carbon include the positive effects of rising CO_2 on plant productivity, a warming climate, nitrogen deposition and recovery from past disturbances, but *low confidence* regarding the relative contribution by each of these and other factors. [4.2.4.1, 4.2.4.2, 4.2.4.4, 4.3.2.2, 4.3.2.3, WGI AR5 Sections 6.3.1 and 6.3.2.6]

The natural carbon sink provided by terrestrial ecosystems is partially offset at the decadal timescale by carbon released through the conversion of natural ecosystems (principally forests) to farm and grazing land

and through ecosystem degradation (*high confidence*). Carbon stored in the terrestrial biosphere is vulnerable to loss back to the atmosphere as a result of the direct and indirect effects of climate change, deforestation and degradation (*high confidence*). The net transfer of carbon dioxide from the atmosphere to the land is projected to weaken during the 21st century (*medium confidence*). The direct effects of climate change on stored terrestrial carbon include high temperatures, drought and windstorms, indirect effects include increased risk of fires, pest and disease outbreaks. Experiments and modelling studies provide *medium confidence* that increases in CO_2 up to about 600 ppm will continue to enhance photosynthesis and plant water-use efficiency, but at a diminishing rate; and *high confidence* that low availability of nutrients, particularly nitrogen, will limit the response of many natural ecosystems to rising CO_2. There is *medium confidence* that other factors associated with global change, including high temperatures, rising ozone concentrations and in some places drought, decrease plant productivity by amounts comparable in magnitude to the enhancement by rising CO_2. There are few field-scale experiments on ecosystems at the highest CO_2 concentrations projected by RCP 8.5 for late in the century, and none of these include the effects of other potential confounding factors. [4.2.4, 4.2.4.1, 4.2.4.2, 4.2.4.3, 4.2.4.4, 4.3.2.2, 4.3.3.1, Box 4-3, Box CC-VW, WGI AR5 6.4.3.3]

Increases in the frequency or intensity of ecosystem disturbances such as droughts, wind-storms, fires and pest outbreaks have been detected in many parts of the world and in some cases are attributed to climate change (*medium confidence*). Changes in the ecosystem disturbance regime beyond the range of natural variability will alter the structure, composition and functioning of ecosystems (*high confidence*). Ecological theory and experimentation predicts that ecological change resulting from altered disturbance regimes will be manifested as relatively abrupt and spatially-patchy transitions in ecosystem structure, composition and function, rather than gradual and spatially-uniform shifts in location or abundance of species (*medium confidence*). [4.2.4.6, 4.3.3, 4.3.2.5, Box 4-3, Box 4-4, Figure 4-10]

Increased tree death has been observed in many places worldwide, and in some regions has been attributed to climate change (high confidence). In some places it is sufficiently intense and widespread as to result in forest dieback (*low confidence*). Forest dieback is a major environmental risk with potentially large impacts on climate, biodiversity, wood production, water quality, amenity and economic activity. In detailed regional studies in western and boreal North America, the tree mortality observed over the past few decades has been attributed to the effects of high temperatures and drought, or to changes in the distribution and abundance of insect pests and pathogens related, in part, to warming *(high confidence)***.** Tree mortality and associated forest dieback will become apparent in many regions sooner than previously anticipated (*medium confidence*). Earlier projections of increased tree growth and enhanced forest C sequestration due to increased growing season duration, rising CO_2 concentration and atmospheric N deposition, must be balanced by observations and projections of increasing tree mortality and forest loss due to fires and pest attacks. The consequences for the provision of timber and other wood products are projected to be highly variable between regions and products, depending on the balance of the positive *versus* negative effects of global change. [4.3.2, 4.3.3.1, 4.3.3.4, 4.3.3.5, 4.3.4, 4.3.4.2, Box 4-2, Box 4-3]

There is a high risk that the large magnitudes and high rates of climate change associated with low-mitigation climate scenarios (RCP4.5 and higher) will result within this century in abrupt and irreversible regional-scale change in the composition, structure and function of terrestrial and freshwater ecosystems, especially in the Amazon and Arctic, leading to substantial additional climate change (*medium confidence*). There are plausible mechanisms, supported by experimental evidence, observations, and model results, for the existence of ecosystem tipping points in both boreal-tundra Arctic systems and the rainforests of the Amazon basin. Continued climate change will transform the species composition, land cover, drainage and permafrost extent of the boreal-tundra system, leading to decreased albedo and the release of greenhouse gases (*medium confidence*). Adaptation measures will be unable to prevent substantial change in the boreal-arctic system (*high confidence*). Climate change alone is not projected to lead to abrupt widespread loss of forest cover in the Amazon during this century a (*medium confidence*), but a projected increase in severe drought episodes, together with land-use change and forest fire, would cause much of the Amazon forest to transform to less dense, drought- and fire-adapted ecosystems, and in doing so, put a large stock of biodiversity at elevated risk, while decreasing net carbon uptake from the atmosphere (*medium confidence*)**.** Large reductions in deforestation, as well as wider application of effective wildfire management, lower the risk of abrupt change in the Amazon, as well as the impacts of that change (*medium confidence*). [4.2.4.1, 4.3.3.1.1, 4.3.3.1.3, 4.3.3.4, Figure 4-8, Box 4-3, Box 4-4]

Management actions can reduce, but not eliminate, the risk of impacts to terrestrial and freshwater ecosystems due to climate change, as well as increase the inherent capacity of ecosystems and their species to adapt to a changing climate (*high confidence*). The capacity for natural adaptation by ecosystems and their constituent organisms is substantial, but for many ecosystems and species it will be insufficient to cope with projected rates and magnitudes of climate change in the 21st century without substantial loss of species and ecosystem services, under medium-range warming (e.g., RCP6.0) or high–range warming scenarios (e.g., RCP8.5) (*medium confidence*). The capacity for ecosystems to adapt to climate change can be increased by reducing the other stresses operating on them; reducing the rate and magnitude of climate change; reducing habitat fragmentation and increasing connectivity; maintaining a large pool of genetic diversity and functional evolutionary processes; assisted translocation of slow moving organisms or those whose migration is impeded, along with the species on which they depend; and manipulation of disturbance regimes to keep them within the ranges necessary for species persistence and sustained ecosystem functioning. [4.4, 4.4.1, 4.4.2]

Adaptation responses to climate change in the urban and agricultural sectors can have unintended negative outcomes for terrestrial and freshwater ecosystems (*medium confidence*). For example, adaptation responses to counter increased variability of water supply, such as building more and larger impoundments and increased water extraction, will in many cases worsen the direct effects of climate change in freshwater ecosystems**.** [4.3.3.3, 4.3.4.6]

Widespread transformation of terrestrial ecosystems in order to mitigate climate change, such as carbon sequestration through planting fast-growing tree species into ecosystems where they did not previously occur, or the conversion of previously uncultivated or non-degraded land to bioenergy plantations, will lead to negative impacts on ecosystems and biodiversity (*high confidence*). For example, the land use scenario accompanying the mitigation scenario RCP2.6 features a large expansion of biofuel production, displacing natural forest cover. [4.2.4.1, 4.4.4]

4.1. Past Assessments

The topics assessed in this chapter were last assessed by the IPCC in 2007, principally in the Working Group II report Chapters 3 (Freshwater resources and their management; Kundzewicz *et al.*, 2007) and 4 (Ecosystems, their properties, goods and services; Fischlin *et al.*, 2007), but also Chapter 1 (Assessment of observed changes and responses in natural and managed systems, Sections 1.3.4 and 1.3.5; Rosenzweig *et al.*, 2007). The WGII SPM said "Observational evidence from all continents and most oceans shows that many natural systems are being affected by regional climate changes, particularly temperature increases", though they noted that documentation of observed changes in tropical regions and the Southern Hemisphere was sparse (Rosenzweig *et al.*, 2007). Fischlin *et al.* (2007) found that 20-30% of the plant and animal species that had been assessed to that time were considered to be at increased risk of extinction if the global average temperature increase exceeds 2-3°C above the pre-industrial level *with medium confidence*, and that substantial changes in structure and functioning of terrestrial, marine and other aquatic ecosystems are *very likely* under that degree of warming and associated atmospheric CO_2 concentration. No timescale was associated with these findings. The carbon stocks in terrestrial ecosystems were considered to be at high risk from climate change and land use change. The report warned that the capacity of ecosystems to adapt naturally to the combined effect of climate change and other stressors is likely to be exceeded if greenhouse emission continued at or above the then-current rate.

4.2. A Dynamic and Inclusive View of Ecosystems

There are three aspects of the contemporary scientific view of ecosystems that are important to know for policy purposes. Firstly, ecosystems usually have imprecise and variable boundaries. They span a wide range of spatial scales, nested within one another, from the whole biosphere, down through its major ecosystem types (biomes) to local and possibly short-lived associations of organisms. Secondly, the human influence on ecosystems is globally pervasive. Humans are regarded as an integral, rather than separate, part of social-ecological systems (Gunderson and Holling, 2001; Berkes *et al.*, 2003). Ecosystems are connected across boundaries through the movement of energy, materials and organisms, and subsidies between terrestrial and freshwater systems are known to be particularly important (Polis *et al.*, 1997; Loreau *et al.*, 2003). As a consequence, human activities in terrestrial systems can significantly impact freshwater ecosystems and their biota (Allan, 2004). The dynamics of social-ecological systems are governed not only by biophysical processes such as energy flows, material cycles, competition and predation, but also by social processes such as economics, politics, culture and individual preferences (Walker and Salt, 2006). Thirdly, ecologists do not view ecosystems as necessarily inherently static and at equilibrium in the absence of a human disturbance (Hastings, 2004). Ecosystems vary over time and space in the relative magnitude of their components and fluxes, even under a constant environment, due to internal dynamics (Scheffer, 2009). Furthermore, attempts to restrict this intrinsic variation - or that resulting from externally-generated disturbances - are frequently futile, and may damage the capacity of the ecosystem to adapt to a changing environment (Folke *et al.*, 2004). This contrasts with the popular view that ecosystems exhibit a 'balance of Nature' and benefit from being completely protected from disturbance.

4.2.1. Ecosystems, Adaptation, Thresholds, and Tipping Points

The term "adaptation" has different meanings in climate policy, ecology and evolutionary biology. In climate policy (see glossary) it implies human actions intended to reduce negative outcomes. In ecology, ecosystems are said to be adaptive because their composition or function can change in response to a changing environment, without necessarily involving deliberate human actions (see Section 4.4.1). In evolutionary biology, adaptation means a change in the genetic properties of a population of individuals as a result of natural selection (Section 4.4.1.2); a possibility seen since the Fourth Assessment Report as increasingly relevant to climate change.

The notion of thresholds has become a prominent ecological and political concern (Lenton *et al.*, 2008; Knapp *et al.*, 2008a; Leadley *et al.*, 2010). To avoid policy confusion, three types of threshold need to be distinguished. The first reflects a human preference that the ecosystem stays within certain bounds, such as above a certain forest cover. These can be, by definition, negotiated. The second type reflects fundamental biological or physical properties, for instance the temperature at which frozen soils thaw (see Box 4-4) or the physiological tolerance limits of species. The third type is caused by system dynamics: the point at which the net effect of all the positive and negative feedback loops regulating the system is sufficiently large and positive that a small transgression becomes sufficiently amplified to lead to a change in ecosystem state called a regime shift (Lenton *et al.*, 2008). The new state exhibits different dynamics, mean composition, sensitivity to environmental drivers and flows of ecosystem services relative to the prior state. This type of threshold is called a "tipping point" (defined in the glossary as a level of change in system properties beyond which a system reorganizes, often abruptly, and persists in its new state even if the drivers of the change are abated) and is important in the context of climate change because its onset may be abrupt, hard to predict precisely and effectively irreversible (Scheffer *et al.*, 2009; Leadley *et al.*, 2010; Barnosky *et al.*, 2012; Brook *et al.*, 2013; Hughes *et al.*, 2013). Many examples of tipping points have now been identified (Scheffer, 2009). Regional-scale ecosystem tipping points have not occurred in the recent past, but there is good evidence for tipping points in the distant past (Section 4.2.3) and there is concern that they could occur in the near future (see Boxes 4-3 and 4-4).

The early detection and prediction of ecosystem thresholds, particularly tipping points, is an area of active research. There are indications (Scheffer, 2009) that an increase in ecosystem variability signals the impending approach of a threshold. In practice, such signals may not be detectable against background noise and uncertainty until the threshold is crossed (Biggs *et al.*, 2009). The dynamics of ecosystems are complex and our present level of knowledge is inadequate to predict all ecosystem outcomes with confidence, even if the future climate was precisely known.

Field observations over the past century in numerous locations in boreal, temperate and tropical ecosystems have detected biome shifts, the replacement at a location of one suite of species by another (*high confidence*). The effect is usually of biomes moving upwards in elevation and to higher latitudes (Gonzalez *et al.*, 2010). These shifts have often been attributed to anthropogenic climate change, since biome distribution is known to broadly reflect climate zones, and the shifts have been observed in area without major human disturbance (*medium confidence*) (Table 4-1). Projections of future vegetation distribution under climate change indicate that many biomes could shift substantially, including in areas where ecosystems are largely undisturbed by direct human land use (Figure 4-2). The extent of the shift increases with increasing global mean warming, without a sudden threshold (Scholze *et al.*, 2006; Pereira *et al.*, 2010; Rehfeldt *et al.*, 2012).

[INSERT TABLE 4-1 HERE
Table 4-1: Biome shifts of the 20th century from published field research that examined trends over periods > 30 y for biomes in areas where climate (rather than land-use change or other factors) predominantly influenced vegetation, derived from a systematic analysis of published studies (Gonzalez *et al.*, 2010). Pre-AR4 publications are included to provide a comprehensive review. Shift type: elevational (E), latitudinal (L), examined but not detected (N). The biome abbreviations match those in Figure 4-1. Rate of change in temperature (Temp.) and fractional rate of change in precipitation (Precip.) are derived from linear least squares regression of 1901-2002 data (Mitchell and Jones, 2005; Gonzalez *et al.*, 2010). The table provides general regional climate trends at 50 km spatial resolution because the references do not give uniform site-specific climate data to compare across locations. The regional trends are consistent with local trends reported in each reference. * rate significant at $P \leq 0.05$.]

[INSERT FIGURE 4-1 HERE
Figure 4-1: Locations of observed biome shifts during the 20th century, listed in Table 4-1, derived from Gonzalez *et al.* (2010). The color of each semi-circle indicates the retracting biome (top for North America, Europe, Asia; bottom for Africa and New Zealand) and the expanding biome (bottom for North America, Europe, Asia; top for Africa and New Zealand), according to published field observations. Biomes, from poles to equator: ice (IC), tundra and alpine (UA), boreal conifer forest (BC), temperate conifer forest (TC), temperate broadleaf forest (TB), temperate mixed forest (TM), temperate shrubland (TS), temperate grassland (TG), desert (DE), tropical grassland (RG), tropical woodland (RW), tropical deciduous broadleaf forest (RD), tropical evergreen broadleaf forest (RE). The background is the potential biome according to the MC1 dynamic global vegetation model under the 1961-1990 climate.]

[INSERT FIGURE 4-2 HERE
Figure 4-2: Implications of climate change and land use change for biome shifts. (a) Fraction of land covered by primary vegetation in 2005 (Hurtt *et al.*, 2011); (b) Fraction of simulations showing climate change-driven biome shift for any level of global warming between 1990 and 2100, with no direct anthropogenic land use change, using the MC1 vegetation model under 9 CMIP3 climate projections (3 GCMs each forced by the SRES A2, A1B and B1 scenarios; Gonzalez *et al.*, 2010); (c) Fraction of land covered by primary vegetation in 2100 under the RCP2.6 land use scenario with the IMAGE model, with no effect of climate change (Hurtt *et al.*, 2011); (d) Fraction of land covered by primary vegetation in 2100 under the RCP8.5 land use scenario with the MESSAGE model, with no effect of climate change (Hurtt *et al.*, 2011). Comparison of coloured areas in (b) with those in (a) shows where climate- driven biome shifts would occur in current areas of primary vegetation. Comparison of (b) and (d) shows where climate-driven biome shifts would occur in areas of primary vegetation projected under a land use scenario associated with RCP6.0. Comparison of (c) and (a) illustrates a scenario of land use change associated with RCP2.6, in which global climate change is projected to be smaller than that driving the biome shifts in (b) as a result of mitigation measures, some of which involve land use. Further details of the RCP land use / cover scenarios are given in Box 4-1, Figure 4-3 and Table 4-2.]

4.2.2. Methods and Models Used

Analysis of the current and past impacts of climate change on terrestrial and freshwater ecosystems and their projection into the future relies on three general approaches: inference from analogous situations in the past or elsewhere in the present; manipulative experimentation, deliberately altering one of a few factors at a time; and models with a mechanistic or statistical basis. Studies of the relatively distant past are discussed in depth in 4.2.3. Inferences from present spatial patterns in relation to climate is at the core of climate envelope niche modelling, a well-established but limited statistical technique for making projections of the future distribution under equilibrium conditions (Elith and Leathwick, 2009). Representing the rate of change during the non-equilibrium conditions which will prevail over the next century requires a more mechanistic approach, of which there are some examples (e.g., Keith *et al.*, 2008; Kearney and Porter, 2009). Changes in ecosystem function are usually determined by experimentation (see examples in Section 4.3.3) and are modelled using mechanistic models, in many cases with relatively high uncertainty (Seppelt *et al.*, 2011).

4.2.3. Paleoecological Evidence

Paleoclimatic observations and modelling indicate that the Earth's climate has always changed on a wide range of time-scales. In many cases, particularly over the last million years, it has changed in ways that are well understood in terms of both patterns and causes (Jansen *et al.*, 2007; see WGI AR5 Chapter 5). Paleoecological records demonstrate with *high confidence* that the planet's biota (both terrestrial and aquatic), carbon cycle and associated feedbacks and services have responded to this climatic change, particularly when the climatic change was as large as that projected during the 21st century under mid- to high-end radiative forcing pathways (e.g., MacDonald *et al.*, 2008; Claussen, 2009; Arneth *et al.*, 2010; Willis and MacDonald, 2011; Dawson *et al.*, 2011). Excellent examples of past large climate change events that drove large ecological change, as well as recovery periods in excess of a million years, include the events that led to the Earth's five mass extinctions in the distant past (i.e., during the Ordovician, ca. 443 Ma, the Devonian, ca. 359 Ma, the Permian, ca. 251 Ma, the Triassic, ca. 200 Ma, and the Cretaceous, ca. 65 Ma; Barnosky *et al.*, 2011). Major ecological change was also driven by climate change during the Paleocene-Eocene Thermal Maximum (PETM, 56 Ma; Wing *et al.*, 2005; Jaramillo *et al.*, 2010; Wing and Currano, 2013), the early Eocene Climatic Optimum (EECO, 53-50 Ma; Woodburne *et al.*, 2009), the Pliocene (5.3 to 2.6 Ma; Haywood and Valdes, 2006; Haywood *et al.*, 2011), and the Last Glacial Maximum (LGM) to Holocene transition between 21 and 6 ka (MacDonald *et al.*, 2008; Clark *et al.*, 2009; Gill *et al.*, 2009; Williams *et al.*, 2010a; Prentice *et al.*, 2011; Daniau *et al.*, 2012). The paleoecological record thus provides *high confidence* that large global climate change, comparable in magnitudes to that projected for the 21st century, can result in large ecological changes, including large scale biome shifts, reshuffling of communities and species extinctions.

Rapid, regional warming before and after the Younger Dryas cooling event (11.7-12.9 ka) provides a relatively recent analogy for climate change at a rate approaching, for many regions, that projected for the 21st century for all RCPs (Alley *et al.*, 2003; Steffensen *et al.*, 2008). Ecosystems and species responded rapidly during the Younger Dryas by shifting distributions and abundances, and there were some notable large animal extinctions, probably exacerbated by humans activities (Gill *et al.*, 2009; Dawson *et al.*, 2011). In some regions, species became locally or regionally extinct (extirpated), but there is no evidence for climate-driven global-scale extinctions during this period (Botkin *et al.*, 2007; Willis *et al.*, 2010a). However, the Younger Dryas climate changes differ from those projected for the future because they were regional rather than global; may have only regionally exceeded rates of warming projected for the future; and started from a baseline substantially colder than present (Alley *et al.*, 2003). The mid-Holocene, around ca. 6 ka, provides a very recent example of the effects of modest climate change. Regional mean warming during this period (mean annual temperature ca. 0.5-1.0°C above pre-industrial in some continental-scale regions; see WGI AR5 5.5.1) was the same order of magnitude as the warming the Earth has experienced over the last century. Ecological effects were small compared to periods with larger climate excursions, but even this small warming was characterized by frequent fires in a drier parts of the Amazon (Mayle and Power, 2008), development of lush vegetation and lakes in a wetter Sahara (Watrin *et al.*, 2009), temperate deciduous forests in Europe expanding further north and up to higher elevations (Adamik and Kral, 2008) and large-scale migration of Boreal Forest into a warmer tundra (Jackson and Overpeck, 2000). Past climate change, even more modest than mid-range projected future change, also clearly impacted inland water systems (e.g., Smol and Douglas, 2007a; Battarbee *et al.*, 2009; Beilman *et al.*, 2009). However, there are no exact analogues for future climate change: none of the well-studied past periods of large climate change involved simultaneously the rates, magnitude and spatial scale of climate and atmospheric CO_2 change projected for the next century and beyond (Jansen *et al.*, 2007; Schulte *et al.*, 2010; Wing and Currano, 2013; see WGI AR5 Chapter 5). Direct analogy with the paleoecological record is also unwarranted because future climate change will interact with other global changes such as land-use change, invasive species, pollution and overexploitation of natural resources (Pereira *et al.*, 2010). There is *high confidence* that these interactions will be important: the paleoecological record provides *medium confidence* (*medium evidence, high agreement*) that exploitation by humans helped drive many large mammal species to extinction during periods of climate change in past (Lorenzen *et al.*, 2011).

It has been demonstrated that state-of-the-art vegetation models are able to simulate much of the biome-level equilibrium response of terrestrial vegetation to large paleoclimate change (Prentice *et al.*, 1996; Salzmann *et al.*, 2008; Prentice *et al.*, 2011). The same types of models predict large changes in species ranges, ecosystem function and carbon storage when forced by 21st century climate change, although the future situation is complicated by land-use and other factors absent in the paleoenvironmental case (Sitch *et al.*, 2008; Cheaib *et al.*, 2012; see WGI AR5 6.4). Thus, the paleoecological record and models that have been tested against it provide a coherent message that biomes will alter their functioning and composition in response to changing and often novel future climates: they will move as species mixtures change (Section 4.3.2.5 has more specific information on projected migration rates), novel plant communities will emerge and significant carbon stock changes take place (Williams and Jackson, 2007; MacDonald, 2010; Prentice *et al.*, 2011; Willis and MacDonald, 2011). The paleoecological record and models provide *high confidence* that it will be difficult or impossible to maintain many ecological systems in their current states if global warming exceeds 2 to 3°C, raising questions about the long-term viability of some current protected areas and conservation schemes, particularly where the objective is to maintain present-day species mixtures (Jackson and Hobbs, 2009; Hickler *et al.*, 2012).

Much of the complex, time-dependent change at regional scales has not yet been simulated by models. The paleoecological record indicates that vegetation in many parts of the world has the potential to respond within years to a few decades to climate change (e.g., Watrin *et al.*, 2009; Williams *et al.*, 2009; Mueller *et al.*, 2009a; Harrison and Goni, 2010). This record provides a critical opportunity for model evaluation that should be more thoroughly exploited to gain confidence in time-dependent simulations of future change, particularly given the complex role that interacting climate change and vegetation disturbance has played in the past (e.g., Marlon *et al.*, 2009; Jackson *et al.*, 2009; Williams *et al.*, 2009; Daniau *et al.*, 2010; Dawson *et al.*, 2011). The paleoecological record also highlights the importance of including the direct effects of changing atmospheric CO_2 levels in efforts to simulate future ecosystem functioning and plant species competition (Prentice *et al.*, 2011; Woillez *et al.*, 2011; Bond and Midgley, 2012; Claussen *et al.*, 2013).

The paleoeclimatic record also reveals that past radiative climate forcing change was slower than that anticipated for the 21st century (see WGI AR5 Chapters 5, 8 and 12), but even these slower changes often drove surprisingly abrupt, non-linear, regional-scale change in terrestrial and inland water systems (e.g., Harrison and Goni, 2010; Williams *et al.*, 2011), as did even slower climate change during the most recent Holocene interglacial (e.g., Booth *et al.*, 2005; Kropelin *et al.*, 2008; Williams *et al.*, 2010a; Williams *et al.*, 2011). In all cases, specific periods of abrupt ecological response were regionally distinct in nature and were less synchronous for small, slow changes in forcing (e.g., during the Holocene) than for the global-scale rapid changes listed at the start of this section. State-of-the-art climate and Earth system models are unable to simulate the full range of abrupt change observed in many of these periods (e.g., Valdes, 2011). Thus there is *high confidence* that these models may not capture some aspects of future abrupt climate change and associated ecosystem impacts (Leadley *et al.*, 2010).

4.2.4. Multiple Stressors Interacting with Climate Change

The climatic and non-climatic drivers of ecosystem change need to be distinguished if the joint and separate attribution of changes to their causes is to be performed (see Chapter 18). In this section we elaborate on factors affecting ecosystems, operating simultaneously with climate change. These factors share underlining drivers with one another and with climate change to varying degrees, together they form a syndrome known as “global change”. The individual effects of climate change, habitat loss and fragmentation, chemical pollution, overharvesting and invasive alien species are increasingly well documented (Millennium Ecosystem Assessment, 2005c; Settele *et al.*, 2010a) but much less is known about their combined consequences. Ecosystem changes may occur in cascades, where a change in one factor precipitates increased vulnerability with respect to other factors (Wookey *et al.*, 2009) or propagates through the ecosystem as a result of species interactions (Gilman *et al.*, 2010). Multiple stressors can act in a non-additive way (Settele *et al.*, 2010b; Shaw *et al.*, 2002; Larsen *et al.*, 2011), potentially invalidating findings and interventions based on single-factor analysis. For instance, Larsen *et al.* (2011) demonstrated that non-additive interactions among the climate factors in a multifactor experiment were frequent and most often antagonistic, leading to smaller effects than predicted from the sum of single factor effects. Leuzinger *et al.* (2011) and Dieleman *et al.* (2012) have synthesized multifactor experiments and demonstrated that in general, the effect size is reduced when more factors are involved, but Leuzinger *et al.* (2011) suggest that multifactor models tend to show the opposite tendency.

4.2.4.1. Land-Use and Cover-Change (LUCC)

LUCC is both a cause (WGI AR5 6.1.2) and consequence of climate change. It is the major driver of current ecosystem and biodiversity change (Millennium Ecosystem Assessment, 2005b) and a key cause of changes in freshwater systems (Section 4.3.3.3). In tropical and subtropical areas of Asia, Africa, Oceania and South America, the dominant contemporary changes are conversion of forests and woodlands to annual and perennial agriculture, grazing pastures, industrial logging and commercial plantations; followed by conversion of savannas, grasslands and pastures to annual agriculture (Hosonuma *et al.*, 2012; Macedo *et al*. 2012). In Europe there is net conversion of agricultural lands to forest (Rounsevell and Reay, 2009; Miyake *et al.*, 2012). Conversion of peatlands to agriculture has been an important source of carbon to the atmosphere in Southeast Asia (Limpens *et al.*, 2008; Hooijer *et al.*, 2010; see Section 4.3.3.3).

Contemporary drivers of LUCC include rising demand for food, fibre and bioenergy and changes in lifestyle and technologies (Hosonuma *et al.*, 2012; Macedo *et al*. 2012). By mid-century climate change is projected to become a major driver of land cover change (Leadley *et al.*, 2010). Non-climate environmental changes such as nitrogen deposition, air pollution and altered disturbance regimes are also implicated in LUCC. Some of the underlying drivers of LUCC are also direct or indirect drivers of climate change (Cui and Graf, 2009; McAlpine *et al.*, 2009; Mishra *et al.*, 2010; Schwaiger and Bird, 2010; van der Molen *et al.*, 2011; Groisman *et al.*, 2012); this cause-and-effect entanglement of climate change and LUCC can confound the detection of climate change and make attribution to one or the other difficult. Local-to-regional climate change was at least partly attributed to LUCC in 14 of 26 studies reviewed for this chapter, generally with *limited evidence* and *low confidence*. (Direct climate effects attributed to LUCC: Tseng and Chen, 2008; Cui and Graf, 2009; Li *et al.*, 2009; McAlpine *et al.*, 2009; Zhang *et al.*, 2009; Fall *et al.*, 2010; Graiprab *et al.*, 2010; Jin *et al.*, 2010; Mishra *et al.*, 2010; Schwaiger and Bird, 2010; Wu *et al.*, 2010; Gao and Liu, 2011; Carmo *et al.*, 2012; Groisman *et al.*, 2012. No climate effects attributed: Suarez *et al.*, 1999; Saurral *et al.*, 2008; Wang *et al.*, 2008; Cochrane and Barber, 2009; Jia *et al.*, 2009a; Rounsevell and Reay, 2009; Martin *et al.*, 2010; Wiley *et al.*, 2010; Clavero *et al.*, 2011; Dai *et al.*, 2011; Viglizzo *et al.*, 2011; Yoshikawa and Sanga-Ngoie, 2011).

LUCC (and land use itself) contributes to changes in the climate through altering the greenhouse gas concentrations in the atmosphere, surface and cloud albedos, surface energy balance, wind profiles and evapotranspiration, among other mechanisms. The phrase "biophysical effects" is shorthand for the effect vegetation has on the climate other than through its role as a source or sink of greenhouse gases. These effects are now well documented, significant and are increasingly included in models of global and regional climate change. The greenhouse gas and biophysical effects of vegetation can be opposite in sign (de Noblet-Ducoudre *et al.*, 2012) and operate at different scales. For instance, conversion of forest to non-forest generally releases carbon dioxide from biomass and soils to the atmosphere (causing warming globally); but may result in an increase in seasonally-averaged albedo (local and global cooling, Davin *et al.*, 2007) and a decrease in transpiration (local, but not global warming). Findell *et al.* (2007) concluded on the basis of model studies that the non-GHG climate impacts of LUCC were generally minor, but nevertheless significant in some regions. Brovkin *et al.* (2013), projecting the overall effect of LUCC on climate change for the 21st century, found LUCC to be small driver globally, but locally important. Most global climate models suggest local average cooling effects following forest conversion to croplands and pastures (Pitman *et al.*, 2009; Longobardi *et al.*, 2012). Satellite observations suggest that the effect of conversion of the Brazilian savannas (*cerrado*) to pasture was to induce a local warming which was partly reversed when the pasture was subsequently converted to sugarcane (Loarie *et al.*, 2011). Several modelling studies suggest that the global surface air temperature response to deforestation depends on the latitude at which deforestation occurs. High latitude deforestation results in global cooling, low latitude deforestation causes global warming and that the mid latitude response is mixed (Bathiany *et al.*, 2010; Davin and de Noblet-Ducoudre, 2010; van der Molen *et al.*, 2011; Longobardi *et al.*, 2012), with some exceptions documented for boreal forests (Spracklen *et al.*, 2008). Boreal and tropical forests influence the climate for different reasons: boreal forests have low albedo (i.e., reflect less solar radiation, especially in relation to a snowy background; Levis, 2010; Mishra *et al.*, 2010; Longobardi *et al.*, 2012) and tropical forests pump more water and aerosols into the atmosphere than non-forest systems in similar climates (Davin and de Noblet-Ducoudre, 2010; Delire *et al.*, 2011; Pielke *et al.*, 2011). The implications of these findings for afforestation as a climate mitigation action are discussed in Section 4.3.4.5. Forests may also influence regional precipitation through biophysical effects (Butt *et al.*, 2011; Pielke *et al.*, 2011; see Section 4.3.3). In summary, changes in land cover have biophysical effects on the climate, sometimes opposite in direction to greenhouse gas mediated effects, which can materially alter the net outcome of the land cover change on the global climate (*high certainty*).

In summary, changes in land cover have biophysical effects on the climate, sometimes opposite in direction to greenhouse gas mediated effects, which can materially alter the net outcome of the land cover change on the global climate (*high confidence*).

Box 4-1. Future Land Use Changes

Assessment of climate change effects on terrestrial and inland freshwater ecosystems requires the simultaneous consideration of LUCC. The world is undergoing important shifts in land use, driven by accelerating demand for food, feed, fibre, and fuel. The main underlying driver is the rate at which *per capita* consumption is growing, particularly in emerging economies (Tilman *et al.*, 2011). Policy shifts in developed countries favouring biofuel production have also contributed (Searchinger *et al.*, 2008; Lapola *et al.*, 2010; Miyake *et al.*, 2012). Agricultural commodity prices have risen and may stay high through 2020 (OECD/FAO, 2010), due to: a) demand growth outpacing supply growth, exacerbated by climate-related crop failure (Lobell *et al.*, 2011); b) decline in the rate of improvement in agricultural productivity (Ray *et al.*, 2012); c) shortage of arable land not already under cultivation, especially in the temperate zone; d) growing pressure on as-yet uncultivated ecosystems on soils that are potentially suitable for cultivation and that are concentrated in tropical latitudes, especially South America and Africa (Lambin and Meyfroidt, 2011); and e) declining area under cultivation in temperate zones, mainly in developed countries. The shortage of arable land in temperate systems could put pressure on marginal or sensitive landscapes, mainly in Latin America's *cerrados* and grasslands (Brazil, Argentina) and in African savannahs (Sudan, Democratic Republic of the Congo, Mozambique, Tanzania, Madagascar) (Lambin and Meyfroidt, 2011).

Deforestation in developing countries is correlated with the export of agricultural commodities (DeFries *et al.*, 2010). Future LUCC remains uncertain, since it depends on economic trends and policies themselves dependent upon complex political and social processes, including climate policy. By 2012, the deforestation rate in the Brazilian Amazon had declined by 77% below its 1996-2005 average (INPE, 2013; Nepstad *et al*., 2009) as a result of policy and market signals (Soares-Filho *et al.*, 2010). This single trend represents a 1.5% reduction in global anthropogenic carbon emissions (Nepstad *et al.*, 2013).

[INSERT TABLE 4-2 HERE
Table 4-2: Summary of drivers and outcomes of LUCC scenarios associated with Representative Concentration Pathways (Hurtt *et al.*, 2011). RCPs are identified with the radiative forcing by 2100 (8.5, 6.0, 4.5 and 2.6 Wm^{-2}) and by the name of the model used to generate the associated land use/cover scenarios (MESSAGE, AIM, GCAM and IMAGE; see Hurtt *et al*. (2011) for further details).]

Each of the four main RCPs used for future climate projections has a spatially-explicit future land use scenario consistent with both the emissions scenario and the underlying associated socio-economic scenario simulated by integrated assessment models, as well as conditions in 2005 (Hurtt *et al.*, 2011; Table 4-2; Figure 4-2; Figure 4-3). In scenarios where cropland and pasture are projected to decrease, they are replaced with secondary vegetation. Tropical and boreal forest regions are both projected to undergo declining primary forest cover in most RCPs, but in RCP6.0 total forest area remains approximately constant and in RCP4.5 total forest area expands due to increased secondary forest. The extent to which primary vegetation is replaced by secondary vegetation, crops or pasture varies between the RCPs (Figure 4-3), with no simple linear relationship between the extent of vegetation change and the level of total radiative forcing. Larger reductions in primary vegetation cover are projected in RCP8.5, due to a general absence of pro-active measures to control land cover change in that scenario. Large reductions are also projected in RCP2.6 due to widespread conversion of land to biofuel crops (Figure 4-2). Smaller reductions are foreseen in RCP6.0 and RCP4.5, with the latter involving conservation of primary forest and afforestation as mitigation measures.

[INSERT FIGURE 4-3 HERE
Figure 4-3: Proportion of global land cover occupied by primary and secondary vegetation (forest and non-forest), cropland, pasture and urban land, from satellite data and historical reconstructions up to 2005 (Klein Goldewijk *et al.*, 2010; Klein Goldewijk *et al.*, 2011), and from scenarios associated with the RCPs from 2005 to 2100 (Hurtt *et al.*, 2011).]

4.2.4.2. Nitrogen Deposition

The global nitrogen (N) cycle has been strongly perturbed by human activity over the past century (Gruber and Galloway, 2008; Canfield *et al.*, 2010). Activities such as fertilizer production and fossil fuel burning currently transform 210 TgN/year of nitrogen gas in the atmosphere into reactive forms of nitrogen (N_r) that can be readily used by plants and microorganisms in land and in the ocean, slightly more than the non-anthropogenic transformation of 203 TgN/year (Fowler *et al.*, 2013). Most of the transformations of anthropogenic N_r are on land (Fowler *et al.*, 2013). The human-caused flow from land to oceans in rivers is 40-70 TgN/year, additional to the estimated natural flux of 30 TgN/year (Galloway *et al.*, 2008; Fowler *et al.*, 2013). Many of the sources of additional reactive nitrogen share root causes with changes in the carbon cycle, such as increased use of fossil fuels and expansion and intensification of global agriculture. N deposition, CO_2 concentrations and temperatures are therefore increasing together at global scales (Steffen *et al.*, 2011). Regional trends in N fluxes differ substantially: N fertilizer use and N deposition are stable or declining in some regions, such as Western Europe; but N deposition and its impacts on biodiversity and ecosystem functioning are projected to increase substantially over the next several decades in other regions, especially in the tropics (Galloway *et al.*, 2008) due to increased needs for food and energy for growing populations in emerging economies (e.g., Zhu *et al.*, 2005).

Experiments and observations, most of which are in temperate and boreal Europe and North America, show a consistent pattern of increase in the dominance of a few nitrogen-loving plant species and loss of overall plant species richness at N deposition loads exceeding between 5 and 20 kgN/ha/year (Power *et al.*, 2006; Clark and Tilman, 2008; Bobbink *et al.*, 2010; but see Stevens *et al.*, 2010a). N deposition is currently above these limits in much of Europe, eastern North America, and Southern Asia (Galloway *et al.*, 2008), including in many protected areas (Bleeker *et al.*, 2011).

The impacts of N deposition are often first manifested in freshwater ecosystems, since they collect and concentrate the excess N (and phosphorus, P) from the land, as well as from sewage and industrial effluents. Primary production in freshwater ecosystems can be either N and P limited or both (Elser *et al.*, 2007), but the biodiversity and capacity of freshwater ecosystems to deliver high quality water, recreational amenity and fisheries services is severely reduced by the addition of nutrients beyond their capacity to process them. Excessive loading of N and P is widespread in the lakes of the Northern Hemisphere (Bergström and Jansson, 2006), although reduced N loading including deposition was observed between 1988 and 2003 in Sweden (Weyhenmeyer *et al.*, 2007). The observed symptoms include a shift from nitrogen limitation of phytoplankton in lakes to phosphorus limitation (Elser *et al.*, 2009).

Since the AR4 report, an increasing number of studies have models, observations and experiments to understand and predict the interactive effects of N deposition, climate change and CO_2 on ecosystem function. Interactions between nitrogen and other global change factors are widespread, strong and complex (Rustad, 2008; Thompson *et al.*, 2008; Langley and Megonigal, 2010; Gaudnik *et al.*, 2011; Eisenhauer *et al.*, 2012; Hoover *et al.*, 2012; but see Zavaleta *et al.*, 2003 for evidence of additive effects). In a study of plant-pollinator relationships, the combination of N deposition, CO_2 enrichment and warming resulted in larger negative impacts on pollinator populations than could be predicted from the individual effects (Hoover *et al.*, 2012). In a perennial grassland species, N limitation constrained the response to rising CO_2 (Reich *et al.*, 2006). Broadly, the overall body of research shows that ecosystem function is mediated by complex interactions between these factors, such that many ecosystem responses remain difficult to understand and predict (Churkina *et al.*, 2010; Norby and Zak, 2011).

In forests in many parts of the world, experiments, observations and models suggest that the observed increase in productivity and carbon storage is due to combinations of N deposition, climate change, fertilization effects of rising CO_2, and forest management (Huang *et al.*, 2007; Magnani *et al.*, 2007; Pan *et al.*, 2009; Churkina *et al.*, 2010; Bellassen *et al.*, 2011; Bontemps *et al.*, 2011; de Vries and Posch, 2011; Eastaugh *et al.*, 2011; Norby and Zak, 2011; Shanin *et al.*, 2011; Lu *et al.*, 2012). N deposition and rising CO_2 appear to have generally dominated in much of the Northern Hemisphere. However, the direct effects of rising temperature and changes in precipitation may exceed N and CO_2 as key drivers of ecosystem primary productivity in a few decades time. In grasslands, however, experiments show that plant productivity is increased more by N addition (within the projected range for this century) than by elevated CO_2, also within its projected range; and that N effects increase with increasing precipitation (Lee *et al.*, 2010).

In contrast to forests and temperate grasslands, N deposition and warming can have negative effects on productivity in other terrestrial ecosystems, such as moss-dominated ecosystems (Limpens *et al.*, 2011). The interactions between N deposition and climate change remain difficult to understand and predict (Menge and Field, 2007; Ma *et al.*, 2011), in part due to shifts in plant species composition (Langley and Megonigal, 2010) and the complex dynamics of coupled C, N and P cycles (Menge and Field, 2007; Niboyet *et al.*, 2011).

Analyses using the multi-factor biodiversity change model GLOBIO3 suggest that N deposition will continue to be a significant contributing factor to terrestrial biodiversity loss in the first third of the century but will be a less important factor than climate change in this period, and a much smaller driver than habitat loss due expansion of agricultural lands (Alkemade *et al.*, 2009). Models that explicitly take into account interactive effects of climate change and N deposition on plant communities project that N deposition impacts will continue to be important, but climate change effects will begin to dominate other factors by the middle of the 21st century (Belyazid *et al.*, 2011).

4.2.4.3. Tropospheric Ozone

The concentration of ozone in the troposphere (the part of the atmosphere adjacent to the Earth's surface) has risen over the past 150 years from a global average of 20-30 ppb to 30-50 ppb, with high spatial and temporal variability (Horowitz, 2006; Oltmans *et al.*, 2006; Cooper *et al.*, 2010; WGI AR5 Figure 2.7). This is due to a) increasing anthropogenic emissions of gases which react in the atmosphere to form ozone (Denman *et al.*, 2007) and b) the increased mixing of stratospheric ozone into the troposphere as a result of climate change (Hegglin and Shepherd, 2009). The key ozone-precursor gases are volatile organic compounds (VOCs) and oxides of nitrogen (NO_x). Intercontinental transport of these precursors contributes to rising global background ozone concentrations, including in regions where local ozone-precursor emissions are decreasing (Dentener *et al.*, 2010). Global sources of VOC are predominantly biogenic (BVOC), and especially forests (Hoyle *et al.*, 2011).

Negative effects of the current levels of ozone have been widely documented (Mills *et al.*, 2011). A meta-analysis of over 300 articles addressing the effect of ozone on tree growth (Wittig *et al.*, 2009) - largely focused on Northern-Hemisphere temperate and boreal species - concluded that current levels of tropospheric ozone suppress growth by 7% relative to pre-industrial levels. Modelling studies which extrapolate experimentally-measured dose-response relationships suggest a 14 to 23% contemporary reduction in Gross Primary Productivity (GPP) worldwide, with higher values in some regions (Sitch *et al.*, 2007) and 1-16% reduction of Net Primary Productivity (NPP) in temperate forests (Ainsworth *et al.*, 2012).

The mechanisms by which ozone affects plant growth are now better known (Hayes *et al.*, 2007; Ainsworth *et al.*, 2012). Chronic exposure to ozone at levels above about 40 ppb generally reduces stomatal conductance and impairs the activity of photosynthetic enzymes (The Royal Society, 2008), although in some cases ozone exposure increases stomatal conductance (Wilkinson and Davies, 2010). For the species studied, carbon assimilation rates and leaf area are generally reduced, while respiration increases and leaf senescence accelerated - all leading to a reduction in NPP.

Conifers are less sensitive than broad-leafed species. In a modelling study, lower stomatal conductance due to ozone exposure increased river runoff by reducing the loss of soil moisture through transpiration, but observational studies that measured runoff in relation to ozone exposure show divergent trends on this issue (McLaughlin *et al.*, 2007; Wittig *et al.*, 2007; Mills *et al.*, 2009; Huntingford *et al.*, 2011).

A modelling study (Sitch *et al.*, 2007) suggests that the negative effects of rising O_3 on plant productivity could offset 17 to 31% of the projected increase in global carbon storage due to increasing CO_2 concentrations over the 21st century, but the possible interactive effects between CO_2 and O_3 are poorly understood (The Royal Society, 2008). Reduced stomatal conductance, widely observed under elevated CO_2, should help protect plants from ozone damage. Some chamber experiments (Bernacchi *et al.*, 2006) and model studies (Klingberg *et al.*, 2011) suggest this to be the case. The one plot-scale study of CO_2 and O_3 interactions in a temperate forest (Karnosky *et al.*, 2005; Hofmockel *et al.*, 2011) suggests that the effects of O_3 and CO_2 are not independent and may partly compensate for one another.

There is genotypic variation in plant sensitivity to O_3 (Ainsworth *et al.*, 2012). Other than changing cultivars or species, few management actions promoting adaptation to higher levels of O_3 are currently available (Wilkinson and Davies, 2010; Teixiera *et al.*, 2011). Research into developing ozone resistant varieties and chemical protectants against damage may provide management options in the future (Wilkinson and Davies, 2010; Ainsworth *et al.*, 2012).

4.2.4.4. Rising CO_2

Rising atmospheric CO_2 concentrations directly affect ecosystems and through biological and chemical processes. The consequences for the global carbon cycle are discussed in WGI AR5 Box 6.3; the discussion here focusses on impacts on terrestrial and inland water systems. Paleo records over the Late Quaternary (past million years) show that changes in the atmospheric CO_2 content between 180 and 280 ppmv had ecosystem-scale effects worldwide (Prentice and Harrison, 2009).

In contrast to the oceans, changes in CO_2 concentrations in inland waters are primarily influenced by biological processes, such as inputs of terrestrial organic matter (particularly DOC) and bacterial respiration (van de Waal *et al.*, 2010; Aufdenkampe *et al.*, 2011). Carbon can, however, become limiting during intense algal blooms, especially in the surface waters of stratified lakes and reservoirs, and rising atmospheric CO_2 concentrations may stimulate higher algal production under these conditions (van de Waal *et al.*, 2010). Higher CO_2 concentrations can lead to increases in the C:N and C:P ratios of phytoplankton, though the trophic consequences of this are difficult to predict because zooplankton may alter their feeding behaviour to select higher quality forms of algae or increase feeding rate (Urabe *et al.*, 2003; van de Waal *et al.*, 2010).

Over the past two decades, and especially since AR4, experimental investigation of elevated CO_2 effects on plants and ecosystems has mainly used Free Air CO_2 Enrichment (FACE) techniques (Leakey *et al.*, 2009). FACE is considered more realistic than earlier approaches using enclosed chambers, because plant community and atmospheric interactions and below-ground conditions are more like those of natural systems. Plants with a C3 photosynthetic system, which includes most species but excludes warm-region grasses, show an increase in photosynthesis under elevated CO_2, the precise magnitude of which varies between species. Acclimation (“down-regulation”) occurs under long-term exposure, leading to cessation of effects in some (Norby and Zak, 2011) but not all studies (Leakey *et al.*, 2009). The C4 photosynthetic system found in most tropical grasses and some important crops is not directly affected by elevated CO_2, but C4 plant productivity generally increases under elevated CO_2 due to increased water use efficiency (WUE). Transpiration is decreased under elevated CO_2 in many species, due to reduced opening of stomatal apertures, leading to greater WUE (Leakey *et al.*, 2009; Leuzinger and Körner, 2010; De Kauwe *et al.*, 2013). Increasing WUE is corroborated by studies of stable carbon isotopes (Barbosa *et al.*, 2010; Koehler *et al.*, 2010; Silva *et al.*, 2010; Maseyk *et al.*, 2011). The WUE increase does not acclimate to higher CO_2 in the medium term, *i.e.* over several years (Leakey *et al.*, 2009). Satellite observations from 1982-2010 show an 11% increase in green foliage cover in warm, arid environments (where WUE is most important) after correcting for the effects of precipitation variability (Donohue *et al.*, 2013); gas exchange theory predicts 5 to 10% greening resulting from rising CO_2 over this period.

The interactive effects of elevated CO_2 and other global changes (such as climate change, nitrogen deposition and biodiversity loss) on ecosystem function are extremely complex. Generally, nitrogen use efficiency is increased under higher CO_2 (Leakey *et al.*, 2009), although in some tree FACE experiments, productivity increases as a result of enhanced CO_2 were sustained by increased nitrogen uptake rather than increased nitrogen use efficiency (Finzi *et al.*, 2007). In one ten-year temperate grassland experiment in Minnesota, elevated CO_2 halved the loss of species richness expected from nitrogen addition (Reich, 2009), whereas no such benefit was reported for an alpine grassland in France (Bloor *et al.*, 2010) or a Danish heathland ecosystem (Kongstad *et al.*, 2012).

Elevated CO_2 can affect plant response to other stresses, such as high temperature (Lloyd and Farquhar, 2008) and drought. Ozone exposure decreases with lower stomatal conductance (Sitch *et al.*, 2007). In savannas, faster growth rates under higher CO_2 can allow woody plants to grow tall enough between successive fires to escape the flames (Bond and Midgley, 2001; Scheiter and Higgins, 2009). Differential species responses to elevated CO_2 appear to be altering competition (Dawes *et al.*, 2011), for example, increasing the likelihood of faster-growing species such as lianas out-competing slower-growing species such as trees (Potvin *et al.*, 2007; Lewis *et al.*, 2009a; Mohan *et al.*, 2006).

Experimental studies have shown that elevated CO_2 leads to increased leaf C:N ratios in woody plants, forbs and C3 grasses (but not C4 grasses), which may decrease their quality as food and increase herbivorous insect feeding rates and changes to their density and community structure (Sardans *et al.*, 2012). Plants may also become more toxic to herbivores under elevated CO_2 levels, through increased concentrations of C-based and N-based defences (Lindroth, 2010; Cavagnaro *et al.*, 2011).

Our understanding of ecosystem responses to elevated CO_2 is incomplete in some respects. The majority of FACE experiments apply upper CO_2 concentrations of approximately 550 ppmv, which is below the concentrations projected by 2100 under higher emissions scenarios. The physiology of photosynthesis suggests that direct CO_2 effects saturate at levels of approximately 700 ppmv (Long *et al.*, 2004). Most elevated CO_2 experiments impose a sudden increase of CO_2 concentration as opposed to the gradual rise experienced in reality. Most large-scale FACE experiments have been carried in temperate locations (e.g., Hickler *et al.*, 2008); there are currently no large-scale tropical or boreal FACE experiments. The magnitude of CO_2 effects decreases as the spatial scale of study increases (Leuzinger *et al.*, 2011).The scale of controlled experiments is limited to approximately 100 m^2. Extrapolation to larger scales ignores large-scale atmospheric feedbacks (Körner *et al.*, 2007) and catchment-scale hydrological effects (see Cross-Chapter Box CC-VW). Overall, there is *medium confidence* (*much evidence, medium agreement*) that increases in CO_2 up to about 600 ppm will continue to enhance photosynthesis and plant water-use efficiency, but at a diminishing rate.

CO_2 effects are a first-order influence on model projections of ecosystem and hydrological responses to anthropogenic climate change (Sitch *et al.*, 2008; Lapola *et al.*, 2009; Friend *et al.*, in press).The direct effect of CO_2 on plant physiology, independent of its role as a greenhouse gas, means that assessing climate change impacts on ecosystems and hydrology solely in terms of global mean temperature rise, (or equivalently, expressing greenhouse gas effects solely in terms of radiative forcing) is an oversimplification (Huntingford *et al.*, 2011; Betts *et al.*, 2012). A 2°C rise in global mean temperature, for example, may have a different net impact on ecosystems depending on the change in CO_2 concentration accompanying the rise (e.g., Good *et al.*, 2011a). A high climate sensitivity and/or a higher proportion of non-CO_2 GHGs would imply a relatively low CO_2 rise at 2°C global warming, so the offsetting effects of CO_2 fertilization and increased water use efficiency would be smaller than for low climate sensitivity and/or a lower proportion of non-CO_2 GHGs.

4.2.4.5. Diffuse and Direct Radiation

The quantity and size-distribution of aerosols in the atmosphere alters both the amount of solar radiation reaching the Earth's surface and the proportions of direct versus diffuse radiation. In some regions, direct radiation has been reduced by up to 30 W m^{-2} over the industrial era, with an accompanying increase in diffuse radiation of up to 20 W m^{-2} (Kvalevåg and Myhre, 2007). The global mean direct and diffuse radiation changes due to aerosols are −3.3 and +0.9 W m^{-2}, respectively (Kvalevåg and Myhre, 2007). For a constant total radiation, an increased fraction received as diffuse radiation theoretically increases net photosynthesis because a smaller fraction of the vegetation canopy is light-saturated, making photosynthesis more light efficient at the canopy scale (Knohl and Baldocchi, 2008; Kanniah *et al.*, 2012). In a global model which included this effect, an increase in diffuse fraction of solar radiation due to volcanic and anthropogenic aerosols and cloud cover was simulated to lead to approximately a 25% increase in the strength of the global land carbon sink between 1960 and 1999; however, under a scenario of climate change and *decreased* anthropogenic aerosol concentration, this enhancement declined to near zero by the end of the 21st century (Mercado *et al.*, 2009), All RCPs project decreased aerosol concentrations due to air quality protection measures, as already seen in some countries. The influence of the form of radiation on plant growth and the land carbon budget is a potentially important unintended consequence of solar radiation management schemes that involve the injection of aerosols into the stratosphere to reduce radiant forcing (see WGI AR5 7.7); but this topic is presently insufficiently researched for adequate assessment.

4.2.4.6. Invasive and Alien Species

Since the IPCC AR4, the number of observations of the spread and establishment of alien species attributed to climate change has increased for several taxa (e.g., Walther *et al.*, 2009) and for particular areas, including mountain tops and polar regions (McDougall *et al.*, 2011; Chown *et al.*, 2012). Species invasions have increased over the last several decades (*very high confidence*), and the aggressive expansion of plant and animal species beyond their historical range is having increasingly negative impacts on ecosystem services and biodiversity (*high confidence*, Brook, 2008; Burton *et al.*, 2010; McGeoch *et al.*, 2010; Simberloff *et al.*, 2013). Climate change will exacerbate some invasion impacts and ameliorate others (Peterson *et al.*, 2008; Bradley *et al.*, 2009; Britton *et al.*, 2010; Bellard *et al.*, 2013). Although there is increasing evidence that some species invasions have been assisted by climate change, there is *low confidence* that species invasions have in general been assisted by recent climatic trends because of the overwhelming importance of human facilitated dispersal in mediating invasions. The spread of alien species has several causes, including habitats made favourable by climate change (Walther *et al.*, 2009), deliberate species transfer and accidental transfer due to increased global movement of goods.

In most cases climate change increases the likelihood of the establishment, growth, spread and survival of invasive species populations (Dukes *et al.*, 2009; Walther *et al.*, 2009; Bradley *et al.*, 2010; Huang *et al.*, 2011; Chown *et al.*, 2012). Some degree of climate/habitat match has been found to be a pre-requisite of establishment success across seven major plant and animal groups (Hayes and Barry, 2008). A range of alien species responses and local consequences are expected (e.g., Rahel and Olden, 2008; Frelich *et al.*, 2012; Haider *et al.*, 2012; West *et al.*, 2012). Invasive species, compared to native species, may have traits that favour their survival, reproduction and adaptation under changing climates; invasive plants in particular tend to have faster growth rates and are particularly favoured when resources are not limited (*medium to high confidence*, van Kleunen *et al.*, 2010; Willis *et al.*, 2010b; Buswell *et al.*, 2011; Davidson *et al.*, 2011; Zerebecki and Sorte, 2011; Haider *et al.*, 2012; Matzek, 2012). Some invasive plants are more drought tolerant (Crous *et al.*, 2012; Matzek, 2012; Perry *et al.*, 2012), and on average they have higher overall metabolic rates, foliar nitrogen concentrations and photosynthetic rates than their native counterparts (Leishman *et al.*, 2007).

Extreme climate events provide opportunities for invasion by generating disturbances and redistributing available resources (Diez *et al.*, 2012) and changing connectivity between different ecosystems. Current warming has already enabled many invasive alien species, including plant, vertebrate, invertebrate and single cell taxa, to extend their distributions into new areas (*high confidence* for plants and insects, Walther *et al.*, 2009; Smith *et al.*, 2012). However, population declines and range contractions are predicted for some invasive species in parts of their ranges (Bradley *et al.*, 2009; Bertelsmeier *et al.*, 2012; Sobek-Swant *et al.*, 2012; Taylor *et al.*, 2012). The expansion of invasive species in some areas and contraction in others will contribute to community re-organisation and the formation of novel ecosystems and interactions in both terrestrial and freshwater habitats (*high confidence*, e.g., Kiesecker, 2011; Britton *et al.*, 2010; Martinez, 2012; see also Section 4.3.2.5). For example, invasive grasses may be favoured over native ones with increasing temperatures (Parker-Allie *et al.*, 2009; Chuine *et al.*, 2012; Sandel and Dangremond, 2012).

In a few cases, benefits to biodiversity and society may result from the interactive effects of climate change and invasive species, such as increases in resources available to some threatened species (Caldow *et al.*, 2007), forest structural recovery (Bolte and Degen, 2010) and available biomass for timber and fuel (van Wilgen and Richardson, 2012). The effect of invasions on net changes in carbon stocks are situation specific and may be either positive or negative (Williams *et al.*, 2007a). Rising CO_2 levels will increase the growth rates of most invasive plant species (Mainka and Howard, 2010; but see Section 4.2.4.4).The effectiveness of invasive alien species management for sequestering carbon is uncertain and context specific (Peltzer *et al.*, 2010). Longer term, indirect effects of invasive alien species will be more important than direct, short-term effects; for instance as a result of changes in soil carbon stocks and tree community composition (*low-medium confidence*, Peltzer *et al.*, 2010).

Synergistic interactions occur between climate change and invasive alien species, along with landscape change, habitat disturbance and human-facilitated breakdown of dispersal barriers (Brook, 2008; Angeler and Goedkoop, 2010; Bradley *et al.*, 2010; Winder *et al.*, 2011a; Cahill *et al.*, 2013). Climate change and invasive alien plant species generally increase the risk and intensity of fire, and the interaction is being reported more frequently as a direct result of higher temperatures and increased invasive plant biomass (*high confidence*, Abatzoglou and Kolden, 2011). In freshwater systems, alien species establishment and survival, species interactions and disease virulence will change as a result of changes in frequency of high-flow events, increasing water temperature, water properties and water demand (*medium confidence*, Schnitzler *et al.*, 2007; Rahel and Olden, 2008; Britton *et al.*, 2010).

A range of climate change-related variables (extreme events, changes in precipitation, temperature and CO_2) will continue to exacerbate the establishment and spread of pests, vectors and pathogens and negatively impact production systems (*medium confidence*, Robinet and Roques, 2010; Clements and Ditommaso, 2011). Warming has contributed to the spread of many invasive insect species, such as the mountain pine bark beetle, and resulted in forest destruction (*high confidence*, Raffa *et al.*, 2008). The interactions between crop growth, climate change and pest dynamics are difficult to predict (West *et al.*, 2012). Management strategies may become less effective as a consequence of the decoupling of biocontrol relationships and less effective mechanical control as biomass and/or population size of invasive species increases (*low to -medium confidence*, Hellmann *et al.*, 2008).

4.3. Vulnerability of Terrestrial and Freshwater Ecosystems to Climate Change

The vulnerability of ecosystems to climate change, i.e. their propensity to be adversely affected, is determined by the sensitivity of ecosystem processes to the particular elements of climate undergoing change and the degree to which the system (including its coupled social elements) can maintain its structure, composition and function in the presence of such change, either by tolerating or adapting to it. Tolerance and adaptability both interact with exposure, which in the case of terrestrial and freshwater ecosystems means the magnitude and rate of climate change relative to ranges of climatic conditions and rates of change under which the ecosystem developed and its organisms evolved. Chapter 19 provides a full discussion on vulnerability concepts.

4.3.1. Changes in the Disturbance Regime

The species composition at a given location is determined by three considerations: the ability of species to reach the location; the physiological tolerance of the species in relation to the range of conditions experienced there; and interactions with other species, including competitors, symbionts, predators, prey and pathogens. Occasional disturbances relieve competition, create opportunities for the establishment and success of less-dominant species; and may facilitate dispersal. Moderate disturbance is thus important in maintaining diversity and ecosystem function (Connell, 1978). Exposure to disturbances keeps tolerance of disturbance in the population high. Fire, floods and strong winds are all examples of biodiversity-sustaining climate disturbances, provided that their frequency and intensity does not deviate greatly above or below the regime to which the species are adapted. Average environmental conditions may be less of a determinant of species range and abundance than the extreme conditions, such as the occurrence of exceptionally cold or hot days or droughts exceeding a certain duration (Zimmermann *et al.*, 2009). The projected changes in probability of extremes are typically disproportionately larger than the projected changes in the mean (see IPCC, 2012; but also Diffenbaugh *et al.*, 2005). Biotic disturbances, such as pest and pathogen outbreaks are also often implicated in with ecosystem change, and may be enabled by climate change.

It is suggested that ecosystem regime shifts resulting from climate change (alone or in interaction with other factors) will often be triggered by changes in the disturbance regime, rather than by physiological tolerance for the mean conditions (Thonicke *et al.*, 2008). A "disturbance regime" refers to the totality of different types of disturbance events in a system, each characterized by their probability of occurrence, intensity and other relevant attributes, such as their seasonal pattern. A corollary is that disturbance-related change is abrupt rather than gradual. Change in the fire disturbance regime is emerging as a key proximal mechanism and early indicator of terrestrial ecosystem change (Girardin *et al.*, 2009; Johnstone *et al.*, 2010). Changes in the fire regime have in some cases been attributed to climate change (Westerling *et al.*, 2006; Littell *et al.*, 2009; Turetsky *et al.*, 2011; Westerling *et al.*, 2011; Moritz *et al.*, 2012). Regional trends in fire occurrence have been observed since 2000 (Giglio *et al.*, 2013), but interpreting their significance requires a longer term perspective (e.g., Bergeron *et al.*, 2010).

4.3.2. Observed and Projected Change in Ecosystems

This section highlights key observed changes in terrestrial and freshwater ecosystems over the recent past, as well as changes projected during the 21st century. For observations, we assess the degree of confidence that change has been detected, and separately the confidence we have in attributing the change to climate change (Figure 4-4). Confidence in detection is considered to be *very high* when there is *high agreement* between many independent studies, species, ecosystems or regions and where there is *robust evidence* that the changes over time are statistically significant (see Chapter 18; Mastrandrea *et al.*, 2010). Note that a slightly different definition of detection is used here than in Chapter 18, because detection here is based solely on the presence of a temporal trend and does not attempt to distinguish natural from climate related variation. Confidence in attribution to climate change is *very high* when three tests are satisfied: changes correspond to a sound mechanistic understanding of responses to climate change; the time series of observations is sufficiently long to detect trends correlated with climate change; and confounding factors can be accounted for or are of limited importance. In the sections that provide the details of the assessment of detection and attribution, estimated levels of confidence are given even in cases where the capacity for detection or attribution capacity is *low* or *very low*, because changes in these ecosystem properties or processes could have large impacts on biodiversity or ecosystem services at regional to global scales. In all cases the estimates of confidence levels are based on global and cross-taxon assessments, so the positioning may be different for specific taxa or regions. Some of the sections include assessments of model-based projections of future change; the confidence assessment of detection and attribution does not extend to these.

A key message arising from the analysis of *detection* and *attribution* is that climate impacts on the functioning of organisms and ecosystems are clearest when temperature is a principal driver, changes are relatively rapid and confounding factors play a small role. At one end of the spectrum, the large warming signal over the last several decades in much of the Arctic tundra combined with minimal human impacts is associated with *high confidence* in detection of an increase in shrubs and permafrost thawing and *high confidence* in the attribution to climate warming (Section 4.3.3.1.1). Likewise, the phenology of most organisms is sensitive to temperature, confounding effects are often small and the response is rapid, leading to *high confidence* in detection and attribution of changes in phenology to warming (Section 4.3.2.1). At the opposite end of the spectrum, species extinctions are very difficult to attribute to climate change (Section 4.3.2.5), in part because other factors dominate recent extinctions. This does not mean that climate has not played an important contributing role; indeed it has been argued that the low level of confidence in attribution is due to the lack of studies looking for climate signals in extinctions (Cahill *et al.* 2013). Similarly there is very good evidence that species composition is changing in cultural landscapes, but the important role of other factors, e.g., land management, nitrogen deposition, makes attribution of a contribution to recent warming difficult. This analysis indicates that responses in most species and ecosystem levels will become more apparent over time because i) observed organism level changes will have long term impacts on ecosystem functioning (*high confidence,* Sections 4.3.2.1, 4.3.2.5, 4.3.3) and ii) warming signals can be detected in ecosystems where the recent warming has been strong and confounding factors are minimal. In addition, the absence of observed changes does not preclude confident projections of future change for three reasons: climate change projected for the 21st century substantially exceeds the changes experienced over the past century in medium to high scenarios (all but RCP 2.6); ecosystem responses to climate change may be non-linear; and change may only be apparent after considerable time lags (Jones *et al.*, 2009).

[INSERT FIGURE 4-4 HERE
Figure 4-4: Confidence in detection of change and attribution of observed responses of terrestrial ecosystems to climate change. Confidence levels are based on expert judgment of the available literature following the IPCC uncertainty guidance (Mastrandrea *et al.*, 2010), attribution criteria outlined in Chapter 18 and detection criteria defined in the text. The symbols in the figure represent global and cross-taxon assessments; the positioning may be different for specific taxa or regions. The following sections provide the details of the assessments that were used in positioning each of the points Phenology, Section 4.3.2.1; Primary Productivity, Section 4.3.2.2; Biomass and C stocks, Section 4.3.2.3; Evapotranspiration, Section 4.3.2.4; Species distributions, Section 4.3.2.5**;** Global species extinctions, Section 4.3.2.5**;** Invasive and alien species**,** Section 4.2.4.6**;** Tree mortality, Section 4.3.3.1, Box 4-2; Boreal forest regime shift, Section 4.3.3.1.1, Box 4-4; Amazon forest regime shift, Section 4.3.3.1.3, Box 4-3; Tundra regime shift, Section 4.3.3.4, Box 4-4; Woody encroachment, Section 4.3.3.2.2; Cultural landscapes, Section 4.3.3.5.3; Evolutionary and genetic adaptation, Section 4.4.1.2.]

4.3.2.1. Phenology

Further evidence from ground-based and satellite studies, mainly focused on the Northern Hemisphere, supports the AR4 conclusion that shifts in phenology have occurred over recent decades. “Spring advancement” - earlier occurrence of spring events, such as breeding, bud burst, breaking hibernation, flowering, migration - is seen in hundreds of plant and animal species in many regions (Menzel *et al.*, 2006; Cleland *et al.*, 2007; Parmesan, 2007; Primack *et al.*, 2009; Cook *et al.*, 2012a; Peñuelas *et al.*, 2013) although magnitudes of change vary considerably and some species show no change (Parmesan, 2007). Apparent discrepancies between two estimates of overall Northern-Hemisphere spring advancement noted in AR4 (2.3 days per decade, Parmesan and Yohe, 2003; 5.1 days per decade, Root *et al.*, 2003) are largely resolved when methodological differences are accounted for, particularly the inclusion of species that do not show phenological changes (Parmesan, 2007). A combined analysis of 203 species suggests Northern Hemisphere spring advancement of 2.8±0.35 days per decade (Parmesan, 2007).

Plants – Spring advancement in is seen across the Northern Hemisphere including North America (e.g., Cook *et al.*, 2008; Cook *et al.*, 2012b), Europe (e.g., Menzel *et al.*, 2006; Cook *et al.*, 2012b), Asia (e.g., Primack *et al.*, 2009; Ma and Zhou, 2012) and the High Arctic (Høye *et al.*, 2007). Changes are generally larger at higher latitudes. A meta-analysis indicates mean spring Northern Hemisphere spring advancement of -1.1 ± 0.16 days per decade for herbs and grasses (85 species), -1.1 ± 0.68 days per decade for shrubs (6 species) and -3.3 ± 0.87 days per decade for trees (16 species), over a record period of 35-132 years, depending on the study. The warming trends detected in the well-mixed surface waters (epilimnion) of many lakes in North America, Eurasia and Africa (Adrian *et al.*, 2009) are associated with the earlier onset of spring phytoplankton blooms (Winder and Schindler, 2004; Winder and Sommer, 2012). Satellite data also indicate a general tendency of spring advancement, though there is variation between satellite studies, especially at local scales, due to the use of different instruments and methods (e.g., White *et al.*, 2009). A study using the Advanced Very High Resolution Radiometer (AVHRR) suggests that for vegetation between 30ºN and 80ºN, the start of the growing season advanced by -5.2 days between 1999 and 1982 and advanced a further -0.2 days by 2008; while the growing season end was delayed by 6.6 days between 1982 and 2008 (Jeong *et al.*, 2011). Studies with a more recent satellite instrument, Moderate Resolution Imaging Spectrometer (MODIS) also show spring advancement (e.g., Ahl *et al.*, 2006). The relatively short duration of satellite observations makes trend detection particularly sensitive to the choice of analysis period.

Animals – Many new studies provide further evidence of changes in animal phenology (e.g., amphibians: Kusano and Inoue, 2008; Phillimore *et al.*, 2010; birds: Pulido, 2007; Thorup *et al.*, 2007; mammals: Adamik and Kral, 2008; Lane *et al.*, 2012; insects: Robinet and Roques, 2010; freshwater plankton: Adrian *et al.*, 2009). Changes in breeding phenology are reported from various regions and different taxa (e.g., Parmesan, 2006; Parmesan, 2007; Post *et al.*, 2008; Primack *et al.*, 2009). In the Northern Hemisphere several studies show advancements of egg laying dates in birds (e.g., Parmesan, 2007: -3.7 ± 0.7 days/decade, in 41 species). In contrast, a delay of the mean breeding date by 2.8 to 3.7 days between 1950 and 2004 was seen for two of nine seabirds in the Eastern Antarctic, linked to decreased sea ice extent (Barbraud and Weimerskirch, 2006). Spring arrival dates have advanced for many migratory birds (e.g., Thorup *et al.*, 2007). Patterns of changes in autumn migration in birds are mostly not consistent (delayed, advanced, no change) across analyzed species and regions and appear to be highly related to non-climatic variables (e.g., Sokolov, 2006; Adamik and Pietruszkova, 2008).

A large body of evidence therefore shows that Northern Hemisphere temperate, boreal and Arctic regions, spring advancement has occurred in many plant and animal species over the last several decades (*high confidence* due to *robust evidence* but only *medium agreement* when examined across all species and regions, Figure 4-4).

Understanding of the drivers of phenological change has also improved further since AR4. Many observational studies find a correlation with higher temperatures (Cook et al 2012a). Experimental manipulation generally supports this (e.g., plants, Cleland *et al.*, 2012; bird egg-laying, Visser *et al.*, 2009; insects, Musolin *et al.*, 2010; Kollberg *et al.*, 2013). Some individual studies find good agreement between experimental warming and *in situ* observations (e.g., Gunderson *et al.*, 2012) although a meta-analysis suggests that experiments can substantially under-predict advances in the timing of flowering and leafing of plants in comparison with observational studies (Wolkovich *et al.*, 2012). Observational data can also be affected by methodological issues; for example, flipper-tagging of penguins can alter their migratory behaviour (Saraux *et al.*, 2011). Rates of warming across a season may also be important (Schaper *et al.*, 2012). Models can be used to explain relationships between observed phenological changes and environmental variables. For example, a model based on water temperature captured the observed temporal and spatial variation in *Daphnia* phenology in Northern Hemisphere lakes (Straile *et al.*, 2012). Other environmental factors related to temperature, such as timing of snowmelt, snow cover and snow depth, can play a role. Snowmelt changes led to earlier flowering and appearances of plants and arthropods in Greenland between 1996 and 2005 (Høye *et al.*, 2007) and earlier flowering in an alpine plant in the Rocky Mountains, USA between 1975 and 2008 (Hülber *et al.*, 2010; Lambert *et al.*, 2010). Earlier snowmelts decreased floral resources and hence affected insect population dynamics in mountain ranges in the USA in the years 1980, 1985, 1986 and 1989 (Boggs and Inouye, 2012). In Colorado, USA, the yellow-bellied marmot emerge earlier from hibernation due to snowmelts becoming earlier over 1976-2008 (Ozgul *et al.*, 2010) while in Alberta, Canada, Columbian ground squirrels emerged later over 1992-2012 due to delayed snowmelts associated with increased late-season snowstorms (Lane *et al.*, 2012). Delayed emergence from hibernation was associated with decreased population growth rate (Lane *et al.*, 2012). Food availability can be important; for example, in the Yukon area, Canada, the date of giving birth in North American squirrels (*Tamiascurus hudsonicus*) advanced by an average of -18 days over the period 1989-1998, coinciding with increasing abundance of white spruce cones, their major food source (Réale *et al.*, 2003).

Phenological response can differ with migration strategy in birds, for example short-distance migrants show greater advancements in spring arrivals than long distant migrants (e.g., Saino *et al.*, 2009; but see Parmesan, 2006 for different patterns). In a temperate region (Massachusetts, USA), declining sizes of populations and migrating cohorts of North American Passerine birds account for a large part of the variation in migration times between 1970 and 2002 (Miller-Rushing *et al.*, 2008). The remaining variation was explained by climatic variables, migration distance and date. The variation in bird migration phenology change can also be related to differing patterns of feather changes during moulting times, food availability at stop-over places and differing health conditions of individual species (Gordo, 2007).

Although a number of non-climatic influences on phenology are also identified, an increased number of observational and experimental studies, across many organism types, suggest that warming has contributed to the overall spring advancement observed in the Northern Hemisphere (*high confidence* due to *high agreement* and *medium evidence*).

4.3.2.2. Primary Productivity

Primary production, the process of plant growth, is fundamental to the global carbon cycle (see Section 4.3.2.3. below) and t underpins provisioning ecosystem services such as food, timber and grazing. Trends in the amount, seasonal timing, variability, location and type of primary production are therefore important indicators of ecosystem function. Well-established theory, experimentation and observation all agree that primary production is directly sensitive to most aspects of climate change, is indirectly affected via the effects of climate on pests and diseases, and is responsive to many of the other changes simultaneously taking place in the world, such as the described in Section 4.2.4. The diverse and frequently non-linear form of responses to the factors influencing primary production, combined with the complexity of interactions between them, means that at a given location the net outcome can be an increase, no change or a decrease in productivity.

The concentration of CO_2 in the atmosphere shows clear patterns in space and time largely related to the primary productivity of the land and oceans. The contribution by terrestrial ecosystems to these patterns can be estimated using isotope measurements, emission databases and models (Canadell *et al.*, 2007). It consists of a sink term, due to increased net ecosystem production, plus a source term due to land-use change. During the decade 2000 to 2009, land net primary productivity at the global scale continued to be enhanced about 5% relative to the estimated pre-industrial level, leading to a land sink of 2.6 $\pm$ 1.2 PgC/y (these values are from WGI AR5 6.3.2.6; the uncertainty range is two standard deviations; for the primary literature see also Raupach *et al.*, 2008; Le Quéré *et al.*, 2009). The net uptake of carbon by the land is highly variable year-to-year, mainly in response to climate variation and major volcanic eruptions (Peylin *et al.*, 2005; Sitch *et al.*, 2008; Mercado *et al.*, 2009). Given the uncertainty range, it is not possible to conclude whether the rate of carbon uptake by the residual land sink has increased or decreased over the past two decades (Raupach *et al.*, 2008; WGI AR5 6.3.2.6). CMIP5 model projections, using the RCP scenarios, suggest that the rate of net carbon uptake by terrestrial ecosystem will decrease during the 21st century except under the RCP4.0 scenario, and by the greatest amount under RCP8.5. There is greater uncertainty between models than between scenarios; in some models terrestrial ecosystems become a net source of CO_2 to the atmosphere (WGI AR5 Section 6.4.3.2, especially Figure 6.26).

It is possible to downscale the land sink estimate continentally, using inversion modelling techniques and the growing network of precision atmospheric observations. There is *high agreement and medium evidence* that the net land uptake in natural and semi-natural terrestrial ecosystems is broadly distributed around the world, almost equally between forested and non-forested ecosystems, but is offset in the tropics by a large carbon emission flux resulting from land-use change, principally deforestation (Pan *et al.*, 2011).

The observed trends in NDVI, a satellite proxy for primary productivity, are discussed under various ecosystem-specific discussions above and below. In some cases the trends are sufficiently strong and consistent to support a confident statement about the underlying phenomenon, but in many cases they are not. This may mean that no change has occurred, or simply reflect inadequacies in the indicator, method of analysis and length of the record in relation to the high inter-annual variability. AR4 reported a trend of increasing seasonally-accumulated NDVI ("greening") at high northern latitudes (Fischlin *et al.*, 2007; based on Sitch *et al.*, 2007), but subsequent observations show a lower rate and no geographical uniformity (Goetz *et al.*, 2007). More than 25% of high latitude North American forest areas, excluding areas recently disturbed by fire, showed a decline in greenness and no systematic change in growing season length, particularly after 2000 (Goetz *et al.*, 2007). NDVI trend analyses in rangelands show varying patterns around the world, with substantial disagreement between studies (Millennium Ecosystem Assessment, 2005a; Bai *et al.*, 2008; Beck *et al.*, 2011a; Fensholt *et al.*, 2012). There is agreement that the Sahel showed widespread NDVI increase between the mid-1980s and about 2000, along with an increase in rainfall, but no consensus on whether the detected signal represents increased productivity by grasses, trees or herbs; and to what degree it reveals land management efforts or responses to climate (Anyamba and Tucker, 2005; Prince *et al.*, 2007; Hellden and Tottrup, 2008; Seaquist *et al.*, 2009). In the period 2000 to 2009 no NDVI trend was apparent in the Sahel (Samanta *et al.*, 2011).

Tree rings record changes in tree growth over approximately the past millennium. Many tree ring records show accelerated tree growth during much of the 20th century (Briffa *et al.*, 2008), which often correlates with rising temperature. Variations in tree ring width, density and isotopic composition arise from many factors, including temperature, moisture stress, CO_2 fertilization, N deposition and ozone damage, but also stand structure and management. Direct CO_2 effects, inferred from the ring record once the effects of drought and temperature have been accounted for, have been proposed for approximately 20% of the sites in the International Tree Ring Data Base (Gedalof and Berg, 2010) and studied in detail at some sites (Koutavas, 2008). Since the 1980s, a number of tree ring records show a decline in tree growth (Wilson *et al.*, 2007). Several possible causes have been suggested for this, including increasing water stress and ozone damage; but the most recent rings in most published tree ring chronologies date from before the 1990s (Gedalof and Berg, 2010) so tree ring-based conclusions for the past two decades are based on a relatively small body of evidence and may therefore be biased. Recent tree ring studies were often specifically designed to examine growth in response to environmental changes (Gedalof and Berg, 2010) and may therefore not be representative of global tree growth. Direct repeated measurements of tree girth increment in forest monitoring plots (discussed in Section 4.3.2.3) are an alternate data source for recent decades.

Primary production in freshwater lakes has been observed to increase in some arctic (Michelutti *et al.*, 2005) and boreal lakes, but decrease in Lake Tanganyika in the tropics (O'Reilly *et al.*, 2003). In both cases the changes were attributed by the authors to climate change.

In summary, there is *high confidence* that net terrestrial ecosystem productivity at the global scale has increased relative to the pre-industrial era (Figure 4-4). There is *low confidence* in attribution of these trends to climate change. Most studies speculate that rising CO_2 concentrations are contributing to this trend through stimulation of photosynthesis, but there is no clear, consistent signal of a climate change contribution (Figure 4-4).

4.3.2.3. Biomass and Carbon Stocks

The forest biomass carbon stock can be estimated from the routine forest monitoring that takes place for management and research purposes. Forest inventories were generally designed to track timber volumes; inferring total biomass and ecosystem carbon stocks requires further information and assumptions, which make absolute values less certain, but have a lesser effect on trend detection. Forest inventory systems are well-developed for Northern Hemisphere temperate and boreal forest (Nabuurs *et al.*, 2010; Ryan *et al.*, 2010; Wang *et al.*, 2010a). Data for tropical and Southern Hemisphere forests and woodlands also exist (Maniatis *et al.*, 2011; Tomppo *et al.*, 2010) but are typically less available and comprehensive (Romijn *et al.*, 2012). More and better data may become available due to advances in remote sensing (e.g., Baccini *et al.*, 2012) and increased investment in forest monitoring through initiatives such as the Reduced Emissions from Deforestation and Degradation (REDD) of the UNFCCC.

Forests have increased in biomass and carbon stocks over the past half century in Europe (Ciais *et al.*, 2008; Luyssaert *et al.*, 2010) and the USA (Birdsey *et al.*, 2006). Canadian managed forests increased in biomass only slightly during 1998-2008, because growth was offset by significant losses due to fires and beetle outbreaks (Stinson *et al.*, 2011). Several dozen sites across the moist tropics have been monitored to estimate forest biomass changes. In the Amazon (Phillips *et al.*, 2009) forest biomass has generally increased in recent decades, dropping temporarily after a drought in 2005. Globally, for the period 2000-2007, recently-undisturbed forests are estimated to have withdrawn 2.30 ± 0.49 PgC/y from the atmosphere, while formerly-cleared tropical forests, now regrowing, withdrew an additional 1.72 ± 0.54 PgC/y (Pan *et al.*, 2011). The global terrestrial carbon sink is partly offset by the losses of forest carbon stocks to the atmosphere through land use change, largely in the tropics, of 1.1 ± 0.8 PgC/y (2000-2009, WGI AR5 6.3.2.6).

The carbon stock in global soils, including litter and peatlands is 1500-2400 PgC, with permanently frozen soils adding another 1700 PgC (Davidson and Janssens, 2006). The soil carbon stock is thus more than ten times greater than the carbon stock in forest biomass (Kindermann *et al.*, 2008). Changes in the size of the soil carbon stock result from changes in the net balance of inputs and losses over a period of many years. Inputs derive from primary production, discussed in Section 4.3.2.2, and are mostly modestly increasing under climate change. Losses result principally through the respiration of soil microbes, which increases with increasing temperature. The present and future temperature sensitivity of microbial respiration remains uncertain (Davidson and Janssens, 2006). An analysis of long-term respiration measurements from the soil around the world suggests that it has increased over the past two decades by an amount of 0.1PgC/y, some of which may be due to increased productivity (Bond-Lamberty and Thomson, 2010). If soil respiration were to exceed terrestrial net primary production globally and on a sustained basis, the present net terrestrial sink would become a net source, accelerating the rate of CO_2 build up in the atmosphere (Luo, 2007).

The carbon stock in freshwater systems is also quite high in global terms. Annual rates of storage (0.03 – 0.07 Pg C/yr) may be trivial compared with sequestration by soils and terrestrial vegetation, but lake sediments are preserved over longer time scales (+10,000 years compared with decades to centuries), and Holocene storage of C in lake sediments has been estimated at 820 Pg (Cole *et al.*, 2007). Manmade impoundments represent an increasing and short-lived additional carbon store with conservative annual estimates of 0.16 – 0.2 Pg C/yr (Cole *et al.*, 2007).

A short-duration study of the temperature sensitivity of decomposition in flooded coastal soils, extrapolated to the 21st century, suggested that increases in respiration would exceed increases in production in future (Kirwan and Blum, 2011). Further detail on wetland soil carbon stocks can be found in Section 4.3.3.3 on peatlands; and on permafrost carbon stocks in Box 4-4 and in Chapter 28.

In summary, biomass and soil carbon stocks in terrestrial ecosystems are currently increasing (*high confidence*) but are vulnerable to loss to the atmosphere as a result of rising temperature, drought and fire projected in the 21st century (Figure 4-4). Measurements of increased tree growth over the last several decades, a large sink for carbon, are consistent with this but confounding factors such as N deposition, afforestation and land management make attribution of these trends to climate change difficult (*low confidence*).

4.3.2.4. Evapotranspiration and Water Use Efficiency

Evapotranspiration (ET) includes evaporation from the ground and vegetation surfaces, and transpiration through plant stomata. Both are affected by multiple factors (Luo *et al.*, 2008) including temperature, solar (shortwave) and thermal (longwave) radiation, humidity, soil moisture and terrestrial water storage; transpiration is additionally affected by CO_2 concentration through its influence on plant stomatal conductance. Studies using lysimeters, evaporation pans, the balance of observed precipitation and runoff, and model reconstructions, indicate both increases and decreases in ET in different regions and between approximately 1950 and the present (Huntington, 2008; Teuling *et al.*, 2009; Douville *et al.*, 2013). Flux tower records have at most 15 years duration (FLUXNET, 2012) so there are insufficient data to calculate large-scale, long-term trends. ET can also be estimated from meteorological observations or simulated with models constrained by observations. Estimates of ET from 1120 globally (but non-uniformly) distributed stations indicate that global land mean ET increased by approximately 2.2% between 1982 and 2002, a rate of increase of 0.75 mm yr^{-2} (Wang *et al.*, 2010b). Other studies, using data-constrained models indicated global ET rises of between 0.25 - 1.1 mm yr^{-2} during the 1980s and 1990s (Jung *et al.*, 2010; Vinukollu *et al.*, 2011; Zeng *et al.*, 2012), possibly linked with increased surface solar radiation and thermal radiation (Wild *et al.*, 2008) or warming (Jung *et al.*, 2010). There has been no significant ET trend since approximately 2000 (Jung *et al.*, 2010; Vinukollu *et al.*, 2011; Zeng *et al.*, 2012), possibly due to soil moisture limitation (Jung *et al.*, 2010). Overall, there is *low confidence* in both detection and attribution of long-term trends in ET (Figure 4-4).

Experiments show that rising CO_2 decreases transpiration and increases intrinsic water use efficiency (iWUE, the ratio of photosynthesis to stomatal conductance, Leakey *et al.*, 2009). Some modelling studies suggest that over the last century, the effects of CO_2 on decreasing transpiration are of comparable size but opposite to the effects of rising temperature (Gerten *et al.*, 2008; Peng *et al.*, 2013). However the observed general increase in ET argues that reduced transpiration cannot be the dominant factor (Huntington, 2008). A meta-analysis of studies at 47 sites across 5 ecosystem types (Peñuelas *et al.*, 2011) suggests that iWUE for mature trees increased by 20.5% between the 1970s and 2000s. Increased iWUE since pre-industrial times (1850 or before) has also been found at several forest sites (Andreu-Hayles *et al.*, 2011; Gagen *et al.*, 2011; Loader *et al.*, 2011; Nock *et al.*, 2011) and also in a temperate semi-natural grassland since 1857 (Koehler *et al.*, 2010), although in one boreal tree species iWUE ceased to increase after 1970 (Gagen *et al.*, 2011).

4.3.2.5. Changes in Species Range, Abundance and Extinction

Species respond to climate change through genotypic adaptation and phenotypic plasticity; by moving out of unfavourable and into favourable climates; or by going locally or globally extinct (Dawson *et al.*, 2011; Bellard *et* *al.*, 2012; Peñuelas *et al.*, 2013; Section 4.2.3). These responses to climate change can potentially have large impacts on biodiversity and ecosystem services. Genotypic adaptation in the face of strong selection pressure from climate change is typically accompanied by large reductions in abundance (see Section 4.4.1.2). Species range shifts are accompanied by changes in abundance, local extinctions and colonization that can alter ecosystem services when they affect dominant species such as trees, keystone species such as pollinators, or species that are vectors for disease (Zarnetske *et al.*, 2012). Global extinctions result in the permanent loss of unique forms of life.

Substantial evidence has accumulated since AR4 reinforcing the conclusion that the geographical ranges of many terrestrial and freshwater plant and animal species have moved over the last several decades in response to warming and that this movement is projected to accelerate over the coming decades under high rates of climate change. Some changes in species abundances appear to be linked to climate change in a predictable manner, with species abundances increasing in areas where climate has become more favourable and vice versa. In contrast, uncertainties concerning attribution to climate change of recent global species extinctions, and in projections of future extinctions, have become more apparent since the AR4 report.

Observed species range shifts - The number of studies looking at observed range shifts and the breadth of species examined has greatly increased since AR4. The most important advances since AR4 concern improvements in understanding the relationship between range shifts and changes in climate over the last several decades. The "uphill and poleward" view of species range shifts in response to recent warming (Parmesan and Yohe, 2003; Parmesan, 2006; Fischlin *et al.*, 2007; Chen *et al.*, 2011) is a useful simplification of species responses; however, responses to warming are conditioned by changes in precipitation, land use, species interactions and many other factors. Investigations of the mechanisms underlying observed range shifts show that climate signals can often be detected, but the impacts of and interactions between changing temperature, precipitation and land use often result in range shifts that are downhill or away from the poles (Rowe *et al.*, 2010; Crimmins *et al.*, 2011; Hockey *et al.*, 2011; McCain and Colwell, 2011; Rubidge *et al.*, 2011; Pauli *et al.*, 2012; Tingley *et al.*, 2012; Zhu *et al.*, 2012). There are large differences in the ability of species groups (i.e., broad taxonomic categories of species) and species within these groups to track changes in climate through range shifts (Angert *et al.*, 2011; Mattila *et al.*, 2011; Chen *et al.*, 2011). For example, butterflies appear to be able track climate better than birds (community shifts: Devictor *et al.*, 2012; but see Chen *et al.*, 2011 for range shifts) while some plants appear to be lagging far behind climate trends except in mountainous areas (Bertrand *et al.*, 2011; Doxford and Freckleton, 2012; Gottfried *et al.*, 2012; Zhu *et al.*, 2012; Telwala *et al.*, 2013). There is growing evidence that responses at the “trailing edge” of species distributions (i.e., local extinction in areas where climate has become unfavourable) are often less pronounced than responses at the “leading edge” (i.e., colonization of areas where climate has become favourable), which may be related to differences in the rates of local extinction vs. colonization processes (Doak and Morris, 2010; Chen *et al.*, 2011; Brommer *et al.*, 2012; Sunday *et al.*, 2012) and difficulties in detecting local extinction with confidence (Thomas *et al.*, 2006).

Rising water temperatures are also implicated in species range shifts in river fish communities (e.g., Comte and Grenouillet, 2013), combined with a decrease in recruitment and survival as well as range-contraction of cold-water species such as salmonids (Bartholow, 2005; Bryant, 2009; Ficke *et al.*, 2007; Jonsson and Jonsson, 2009; Hague *et al.*, 2011). Shifts in freshwater fish species range towards higher elevation and upstream (Hickling et al., 2006; Comte and Grenouillet, 2013) also are not keeping pace with the rate of warming in streams and rivers. While these changes in river temperature regimes may also open up new habitat at higher latitudes (or altitudes) for migratory (Reist *et al.*, 2006) and cool- and warm-water species of fish (Tisseuil *et al.*, 2012), there is *high confidence* that range contraction threatens the long term persistence of some fully aquatic species.

Rates of recent climate change have varied greatly across the globe, ranging from rapid warming to cooling (Burrows *et al.*, 2011; Dobrowski *et al.*, 2013). Taking this spatial variation into account should enhance the ability to detect climate related range shifts. A recent synthesis of range shifts indicates that terrestrial animal species have moved at rates that correspond better with changes in temperature when climate is measured only in the regions where the range shifts were observed (Chen *et al.*, 2011), providing greater confidence in attribution of the range shifts to climate change. Average range shifts across taxa and regions in this study were ca. 17 km poleward and 11 m up in altitude per decade; velocities which are 2 to 3 times greater than previous estimates (compare with Parmesan and Yohe, 2003; Fischlin *et al.*, 2007), but these responses differ greatly among species groups. However, this approach remains a simplification, since the climate drivers of species range changes, e.g., temperature and precipitation, have frequently shifted in different geographical directions (Dobrowski *et al.*, 2013). Disentangling these conflicting climate signals can help explain complex responses of species ranges to changes in climate (Tingley *et al.*, 2012). Overall, studies since AR4 show that species range changes result from interactions among climate drivers and between climate and non-climate factors. It is the greater understanding of these interactions, combined with increased geographical scope that leads to *high confidence* that the ranges of several well-studied species groups, such as insects and birds, have shifted their ranges significant distances (10s of km or more) over the last several decades, and that these range shifts can be attributed to changes in climate. But for many other species groups range shifts are more difficult to attribute to changes in climate because the climate signal is small, there are many confounding factors, differences between expected and observed range shifts are large, or variability within or between studies is high. Thus there is only *medium confidence* in detection and attribution when examined across all species and all regions.

Future range shifts - Projections of climate change impacts on future species range shifts since the AR4 report have been dominated by studies using ecological niche models (ENMs) that project future ranges based on correlative models of current relationships between environmental factors and species distribution (Peterson *et al.*, 2011). A variety of process-based models are starting to be more widely used to make projections of future species distributions (Buckley *et al.*, 2010; Beale and Lennon, 2012; Cheaib *et al.*, 2012; Higgins *et al.*, 2012; Foden *et al.*, 2013). Model comparisons show that correlative models generally predict larger range shifts than process-based models for trees (Morin and Thuiller, 2009; Kearney *et al.*, 2010; Cheaib *et al.*, 2012). For other species groups that have been studied, differences in projections between model types show no clear tendency (Kearney *et al.*, 2009; Buckley *et al.*, 2010; Bateman *et al.*, 2012). There has been some progress in model validation: projected species shifts are broadly coherent with species responses to climate change in the paleontological record and with observed recent species shifts (see Section 4.2.2 and above), but further validation is needed (Green *et al.*, 2008; Pearman *et al.*, 2008; Nogues-Bravo *et al.*, 2010; Dawson *et al.*, 2011). Modelling studies typically do not account for a number of key mechanisms mediating range shifts, such as genetic adaptation and phenotypic plasticity (see Section 4.4.1.2), species interactions or human-mediated effects. An important limitation in most studies is that realistic species displacement rates are not accounted for (i.e., rates at which species are able to shift their ranges through dispersal and establishment); as such, they only indicate changes in the location of favourable and unfavourable climates, from which potential shifts in species distribution can be inferred, but not rates of change (Bateman *et al.*, 2013).

Analyses and models developed since AR4 permit the estimation of the ability of a wide range of species to track climate change. Figure 4-5 provides a synthesis of the projected abilities of several species groups to track climate change. This analysis is based on: i) past and future climate velocity, which is a measure of the rate of climate displacement across a landscape and provides an indication of the speed at which an organism would need to move in order to keep pace with the changing climatic conditions (Loarie *et al.*, 2009; Burrows *et al.*, 2011; Chen *et al.*, 2011; Sandel *et al.*, 2011; Feeley and Rehm, 2012; Dobrowski *et al.*, 2013); and ii) species displacement rates across landscapes for a broad range of species (e.g., Stevens *et al.*, 2010b; Nathan *et al.*, 2011; Barbet-Massin *et al.*, 2012; Kappes and Haase, 2012; Meier *et al.*, 2012; Schloss *et al.*, 2012; see additional references in Figure 4-5 legend). Comparisons of these rates indicate whether species are projected to be able to track climate as it changes. When species displacement capacity exceeds climate velocity it is inferred that species will be able to keep pace with climate change; when displacement capacity is lower than projected climate velocities then they will not, within the bounds of uncertainty of both parameters. This simplified analysis is coherent with more sophisticated model analyses of climate induced species displacement across landscapes, some of which have evaluated additional constraints such as demographics, habitat fragmentation or competition (e.g., Meier *et al.*, 2012; Schloss *et al.*, 2012).

Rates of climate change over the 20^{th} century and projected for the 21^{st} century are shown in Figure 4-5A. Rates of climate change for global land surfaces are given for IPCC AR5 climate projections under a wide range of greenhouse gas emissions scenarios (i.e. WGI AR5 Chapter 12; Knutti and Sedláček, 2012). Rates of global warming for land surfaces have averaged ca. 0.03 °C/yr since 1980, but have slowed over the last decade and a half (WGI Chapter 2). At the low end of projected future rates of warming, rates decrease over time, reaching near zero by the end of the century (RCP 2.6). At the high end, projected rates increase over time, exceeding 0.06 °C/yr by the end of the century (RCP 8.5), and perhaps above 0.08 °C/yr at the upper bound for this scenario.

Climate velocity is defined as the rate of change in climate over time (e.g., °C/yr, if only temperature is considered) divided by the rate of change in climate over distance (e.g., °C/km, if only temperature is considered) and therefore depends on regional rates of climate change and the degree of altitudinal relief (Figure 4-5B, Loarie *et al.*, 2009; Dobrowski *et al.*, 2013). For example, climate velocity for temperature is low in mountainous areas because the change in temperature over short distances is large (e.g., Rocky mountains, Andes, Alps, Himalayas, Figure 4-5B, leftmost axis). Climate velocity for temperature is generally high in flat areas because the rate of change in temperature over distance is low (e.g., parts of the US Mid-west, Amazon basin, West Africa, central Australia, Figure 4-5B, rightmost axis). In flat areas, climate velocity can exceed 8 km/yr for the highest rates of projected climate change (RCP 8.5). We have focused on climate velocity for temperature change, but several analyses also account for precipitation change.

Rates of displacement vary greatly within and among species groups (Figure 4-5C). Some species groups, notably herbaceous plants and trees, generally have very low displacement capacity. Other species groups such as butterflies, birds (not shown) and large vertebrates generally have a very high capacity to disperse across landscapes, nonetheless some species in these groups have low dispersal capacity. Current and future rates of climate change correspond to climate velocities that exceed rates of displacement for several species groups for most climate change scenarios. This is particularly true for mid- and late-successional trees that have maximum displacement rates that are on the order of 10s to a few 100s of m/yr. Overall, many plant species are foreseen to be able to track climates only in mountainous areas at medium to high rates of warming, though there is uncertainty concerning the potential role of long-distance dispersal (Pearson, 2006). Primates generally have substantially higher dispersal capacity than trees; however, a large fraction of primates are found in regions with very high climate velocities, in particular the Amazon basin, thereby putting them at high risk of being unable to track climates even at relatively low rates of climate change (Schloss *et al.*, 2012). On a global average, many rodents, as well as some carnivores and freshwater molluscs are projected to be unable to track climate at very high rates of climate change (i.e., >0.06°C/yr). These projected differences in species ability to keep pace with future climate change are broadly coherent with observations of species ability or inability to track recent global warming (see *Observed species range shifts* above).

Humans can increase species displacement rates by intentionally or unintentionally dispersing individuals or propagules. For example, many economically important tree species may be deliberately moved on large scales as part of climate adaptation strategies in forestry in some regions (Lindner *et al.*, 2010). Human activities can also substantially reduce displacement rates. In particular, habitat loss and fragmentation typically reduces displacement rates, sometimes substantially (Eycott *et al.*, 2012; Hodgson *et al.*, 2012; Meier *et al.*, 2012; Schloss *et al.*, 2012). The degree to which habitat fragmentation slows displacement depends on many factors, including the spatial pattern of the fragments and corridors, maximum dispersal distances, population dynamics and the suitability of intervening modified habitats as stepping-stones (Pearson and Dawson, 2003). Species and habitat dependencies may also speed or hinder species displacement. For example, host plants are projected to move much more slowly than most herbivorous insects, substantially slowing displacement of the insects if they are unable to switch host plants (Schweiger *et al.*, 2012). Likewise, many habitats are structured by slow moving plants, so habitat shifts are projected to lag behind climate change (Jones *et al.*, 2012; Hickler *et al.*, 2012) which will in turn mediate the movements of habitat specialists.

There are significant uncertainties in climate velocities, measured estimates of dispersal and establishment rates, and model formulations. Climate velocities are calculated using a variety of methods and spatial resolutions, making direct comparisons difficult and leading to *low confidence* in estimates of climate velocities in Figure 4-5B (*limited evidence* and *medium agreement*). The lowest estimates of global average climate velocity (Figure 4-5B, centre axis), are about half the best estimate values we show on the climate velocity axes (Loarie *et al.*, 2009), while the highest estimates are about four times higher (Burrows *et al.*, 2011), but high estimates may be artefacts of using very large spatial resolutions (Dobrowski *et al.*, 2013). In addition, the climate velocities used in Figure 4-5 are based on temperature alone, and recent analyses indicate that including more climate factors increases climate velocity (Feeley and Rehm, 2012; Dobrowski *et al.*, 2013). Species displacement rates are calculated based on a very wide range of methods including rates of displacement in the paleontological record, rates of current range shifts due to climate warming, models of dispersal and establishment, maximum observed dispersal distances and genetic analyses (e.g., Kinlan and Gaines, 2003; Stevens *et al.*, 2010b). There are often large differences in estimates of dispersal rates across methods due to intrinsic uncertainties in the methods and differences in the mechanisms included (Kinlan and Gaines, 2003; Stevens *et al.*, 2010b). For example, estimates of tree displacement rates are frequently based on models or observations that explicitly or implicitly include both dispersal of seeds and biotic and abiotic factors controlling establishment of adult trees. Displacement rates of trees are often more strongly limited by establishment than dispersal (Higgins *et al.*, 2003; Meier *et al.*, 2012). It is reasonable to expect that limits on establishment could also be important for other species groups, but often only dispersal rates have been calculated, leading to an overestimation of displacement rates. For trees there is *medium confidence* in projections of their displacement rates due to the large number of studies of past, current and future displacement rates (*robust evidence* and *medium agreement*). Less is known for other broad species groups such as mammals, so there is only *low confidence* in estimates of their displacement capacity. Estimates for other groups, such as freshwater molluscs are based on very little data, so estimates of their dispersal capacity are poorly constrained.

Despite large uncertainties in displacement capacity and climate velocity, the rates of displacement required to track the highest rates of climate change (RCP8.5) are so high that many species will be unable to do so (*high confidence*). Moderate rates of projected climate change (RCP4.5 and RCP6.0) would allow more species to track climate, but would still exceed the capacity of many species to track climate (*medium confidence*). The lowest rates of projected climate change (RCP2.6) would allow most species to track climate towards the end of the century (*high confidence*). This analysis highlights the importance of rates of climate change as an important component of climate change impacts on species and ecosystems. For example, differences in the magnitude of climate change between scenarios are small at mid-century (WGI Chapter 12), but the differences in rates of climate change are large. At mid-century, it is projected that species would need to move little at the lowest rates of climate change (RCP 2.6), but will need to move approximately 70 km/decade in flat areas in order to track climate at the highest rates of climate change (RCP 8.5).

Species that cannot move fast enough to keep pace with the rate of climate change will lose favourable climate space and experience large range contractions (Warren *et al.*, 2013), whereas displacement that keeps pace with climate change greatly increases the fraction of species that can maintain or increase their range size (Menéndez *et al.*, 2008; Pateman *et al.*, 2012). Mountains provide an extremely important climate refuge for many species because the rate of displacement required to track climate is low (Figure 4-5B, Colwell *et al.*, 2008; Engler *et al.*, 2011; Gottfried *et al.*, 2012; Pauli *et al.*, 2012; but see Dullinger *et al.*, 2012). However, species that already occur near mountaintops (or other boundaries) are among the most threatened by climate change because they cannot move upwards (Ponniah and Hughes, 2004; Thuiller *et al.*, 2005; Raxworthy *et al.*, 2008; Engler *et al.*, 2011; Sauer *et al.*, 2011). The consequences of losing favourable climate space are not yet well understood. The extent to which adaptive responses might allow persistence in areas of unfavourable climates is discussed in Section 4.4.1.2. In the absence of adaptation, losing favourable climate space is projected to lead to reduced fitness, declining abundance and local extinction, with potentially large effects on biodiversity and ecosystem services (see evidence of early signs of this for trees in Box 4-2).

[INSERT FIGURE 4-5 HERE
Figure 4-5: (A) Rates of climate change, (B) corresponding climate velocities and (C) rates of displacement of several terrestrial and freshwater species groups in the absence of human intervention. Horizontal and vertical pink bands illustrate the interpretation of this figure. Climate velocities for a given range of rates of climate change are determined by tracing a band from the range of rates in panel A to the points of intersection with the three climate velocity scalars in panel B. Comparisons with species displacement rates are made by tracing vertical bands from the points of intersection on the climate velocity scalars down to the species displacement rates in panel C. Species groups with displacement rates below the band are projected to be unable to track climate in the absence of human intervention. (A) Observed rates of climate change for global land areas are derived from CRUTEM4 climate data reanalysis, all other rates are calculated based on the average of CMIP5 climate model ensembles for the historical period (grey shading indicates model uncertainty) and for the future based on the four RCP emissions scenarios. Data were smoothed using a 20-year sliding window, and rates are means of between 17 and 30 models using one member per model. Global average temperatures at the end of the 21st century for the four RCP scenarios are from WGI AR5 Chapter 12. (B) Estimates of climate velocity for temperature were synthesized from historical and

projected future relationships between rates of temperature change and climate velocity (historical: Burrows *et al.*, 2011; Chen *et al.*, 2011; Dobrowski *et al.*, 2013; projected future: Loarie *et al.*, 2009; Sandel *et al.*, 2011; Feeley and Rehm, 2012). The three scalars are climate velocities that are representative of mountainous areas (left), averaged across global land areas (centre), and large flat regions (right). (C) Rates of displacement are given with an estimate of the median (black bars) and range (boxes = ca. 95% of observations or models for herbaceous plants, trees and plant-feeding insects or median ± 1.5 inter-quartile range for mammals). Displacement rates for herbaceous plants were derived from paleobotanical records, modern plant invasion rates and genetic analyses (Kinlan and Gaines, 2003). Displacement estimates for trees are based on reconstructed rates of tree migration during the Holocene (Clark, 1998; Clark *et al.*, 2003; Kinlan and Gaines, 2003; McLachlan *et al.*, 2005; Nathan, 2006; Pearson, 2006) and modelled tree dispersal and establishment in response to future climate change (Higgins *et al.*, 2003; Iverson *et al.*, 2004; Epstein *et al.*, 2007; Goetz *et al.*, 2011; Nathan *et al.*, 2011; Meier *et al.*, 2012; Sato and Ise, 2012). Displacement rates for mammals were based on modelled dispersal rates of a wide range of mammal species (mean of Schloss *et al.*, 2012 for Western Hemisphere mammals and rates calculated from global assessments of dispersal distance by Santini *et al.*, 2013 and generation length by Pacifici *et al.*, 2013). Displacement rates for phytophagous insects are based on observed dispersal distances and genetic analyses (Peterson and Denno, 1998; Kinlan and Gaines, 2003; Schneider, 2003; Berg *et al.*, 2010; Chen *et al.*, 2011). The estimate of median displacement rate for this group exceeds the highest rates on the axis. These displacement rates do not take into account limitations imposed by host plants. Displacement estimates for freshwater molluscs correspond to the range of passive plus active dispersal rates for upstream movement (Kappes and Haase, 2012).]

Observed changes in abundance and local extinctions - Observations of range shifts imply changes in abundance; i.e., colonization at the “leading edge” and local extinction at the “trailing edge” of ranges. Evidence that the attribution of these responses to recent changes in climate can be made with *high confidence* for several species groups is reviewed here (Section 4.3.2.5), in AR4 and by Cahill *et al.* (2013). Changes in abundance, as measured by changes in the population size of individual species or shifts in community structure within existing range limits, have also occurred in response to recent global warming (*high confidence*, Thaxter *et al.*, 2010; Bertrand *et al.*, 2011; Naito and Cairns, 2011; Rubidge *et al.*, 2011; Devictor *et al.*, 2012; Tingley *et al.*, 2012; Vadadi-Fulop *et al.*, 2012; Cahill *et al.*, 2013; Ruiz-Labourdette *et al.*, 2013). Confident attribution to recent global warming is hindered by confounding factors such as disease, land use change and invasive species (Cahill *et al.*, 2013). New tentative conclusions since AR4 is that climate related changes in abundance and local extinctions appear to be more strongly related to species interactions than to physiological tolerance limits (*low confidence*, Cahill *et al.*, 2013) and that precipitation can be a stronger driver of abundance change than temperature in many cases (Tian *et al.*, 2011; Tingley *et al.*, 2012). This gives weight to concerns that biological interactions, which are poorly known and modelled, may play a critical role in mediating the impacts of future climate change on species abundance and local extinctions (Dunn *et al.*, 2009; Bellard *et al.*, 2012; Hannah, 2012; Urban *et al.*, 2012; Vadadi-Fulop *et al.*, 2012).

A few examples illustrate the types of change in abundance that are being observed and the challenges in attributing these to recent global warming. Some of the clearest examples of climate-related changes in species populations come from high latitude ecosystems where non-climate drivers are of lesser importance. For example, both satellite data and a large number of long-term observations indicate that shrub abundance is generally increasing over broad areas of Arctic tundra, which is coherent with predicted shifts in community structure due to warming (Epstein *et al.*, 2007; Goetz *et al.*, 2011; Myers-Smith *et al.*, 2011). In the Antarctic, two native vascular plants, Antarctic pearlwort (*Colobanthus quitensis*) and Antarctic hair grass (*Deschampsia antarctica*) have become more prolific over recent decades, perhaps because they benefit more from warming of soils than do mosses (Hill *et al.*, 2011). Penguin populations have declined in several areas of the Antarctic, including a recent local extinction of an Emperor penguin *(Aptenodytes forsteri)* population that has been attributed to regional changes in climate (Trathan *et al.*, 2011). The attribution of these declines to changes in regional climate is well supported, but the link to global warming is tenuous (Barbraud *et al.*, 2011).

Mountains also provide good examples of changes in abundance that can be linked to climate because very strong climate gradients are found there. AR4 highlighted these responses and the case for changes in abundance, in particular plants, has become stronger since then. For example, Pauli *et al.* (2012) reported an increase in species richness from plant communities of mountaintops in the European boreal and temperate zones due to increasing temperatures and a decrease in species richness on the Mediterranean mountain tops, probably due to a decrease in the water availability in Southern Europe. An increase in the population size of warm adapted species at high altitudes also appears to be attributable to increasing temperatures (Gottfried *et al.*, 2012). However, these attributions are complicated by other anthropogenic influences such as changes in grazing pressure, atmospheric nitrogen deposition, and forest management practices (Gottfried *et al.*, 2012). Altitudinal gradients in local and global extinctions of amphibians also contributed to the attribution of these extinctions to recent global warming, although this attribution remains controversial (see below).

Projected changes in abundance and local extinction - Ecological niche models do not predict population changes, but the shifts in suitable climates can be used to infer areas where species populations might decline or increase. These models project that local extinction risk by the end of the 21st century due to climate change will vary widely, ranging from almost no increase in local extinction risk within the current range for some species or species groups to greatly increased risk of local extinctions in more than 95% of the present-day range for others (Settele *et al.*, 2008; Bellard *et al.*, 2012). Projected local colonization rates are equally variable. There has been progress in coupling species distribution models and species abundance models for a wide range of organisms (Keith *et al.*, 2008; Midgley *et al.*, 2010; Matthews *et al.*, 2011; Schippers *et al.*, 2011; Oliver *et al.*, 2012a; Renwick *et al.*, 2012). These hybrid approaches predict extinction risk directly, rather than by inference from changes in climate suitability (Fordham *et al.*, 2012). The main conclusions from these studies are that changes in species abundance and local extinction risk as a result of climate change can range from highly positive to highly negative, and are determined by a combination of factors, including its environmental niche, demographics and life history traits, as well as interactions among these factors (Aiello-Lammens *et al.*, 2011; Clavero *et al.*, 2011; Conlisk *et al.*, 2012; Fordham *et al.*, 2012; Swab *et al.*, 2012).

Changes in abundances will also be accompanied by changes in genetic diversity (see also Section 4.4.1.2). At the intraspecific level, future climate change is projected to induce losses of genetic diversity when it results in range contraction (Balint *et al.*, 2011; Pauls *et al.*, 2013). In addition, there is theoretical and observational evidence this loss of genetic diversity will depend on rates of migration and range contraction (Arenas *et al.*, 2012). In these cases, reductions in genetic diversity may then decrease the ability of species to adapt to further climate change or other global changes. Climate change may also compound losses of genetic diversity that are already occurring due other global changes such as the introduction of alien species or habitat fragmentation (Winter *et al.*, 2009; Section 4.2.4.6.).

Observed global extinctions - Global species extinctions, many of them caused by human activities, are now at rates that approach or exceed the upper limits of observed natural rates of extinction in the fossil record (Barnosky *et al.*, 2011). However, across all taxa there is only *low confidence* that rates of species extinctions have increased over the last several decades (Szabo *et al.*, 2012 - birds; but see Kiesecker, 2011 - amphibians). Most extinctions over the last several centuries have been attributed to habitat loss, overexploitation, pollution or invasive species, and these are the most important current drivers of extinctions (Millennium Ecosystem Assessment, 2005b; Hofmann and Todgham, 2010; Cahill *et al.*, 2013). Of the more than 800 global extinctions documented by the IUCN, only 20 have been tenuously linked to recent climate change (Cahill *et al.*, 2013; see also Hoffmann *et al.*, 2011; Szabo *et al.*, 2012). Molluscs, especially freshwater molluscs, have by far the highest rate of documented extinctions of all species groups (Barnosky *et al.*, 2011). Mollusc extinctions are primarily attributed to invasive species, habitat modification and pollution — changes in climate are rarely evoked as a driver (Lydeard *et al.*, 2004; Regnier *et al.*, 2009; Chiba and Roy, 2011; but see a few cases in Kappes and Haase, 2012; Cahill *et al.*, 2013). Freshwater fish have the highest documented extinction rates of all vertebrates, and again very few have been attributed to changing climate, even tenuously (Burkhead, 2012; Cahill *et al.*, 2013). In contrast, changes in climate have been identified as one of the key drivers of extinctions of amphibians (Pounds *et al.*, 2006). There have been more than 160 probable extinctions of amphibians documented over the last two decades, many of them in Central America (Pounds *et al.*, 2006; Kiesecker, 2011). The most notable cases have been the golden toad (*Bufo periglenes*) and Monteverde harlequin frog (*Atelopus varius*) of Central America, which belong to a group of amphibians with high rates of extinction previously ascribed to global warming with “very high confidence” (Pounds *et al.*, 2006; Fischlin *et al.*, 2007). This case has raised a number of important issues about attribution since i) the proximate causes of extinction of these and other Central American frogs appear to be an extremely virulent invasive fungal infection and land use change, with regional changes in climate as a potential contributing factor, and ii) changes in regional climate may have been related to natural climate fluctuations rather than anthropogenic climate change (Sodhi *et al.*, 2008; Lips *et al.*, 2008; Anchukaitis and Evans, 2010; Bustamante *et al.*, 2010; Collins, 2010; Vredenburg *et al.*, 2010; Kiesecker, 2011; McKenzie and Peterson, 2012; McMenamin and Hannah, 2012). Due to *low agreement* among studies there is only *medium confidence* in detection of extinctions and attribution of Central American amphibian extinctions to climate change. While this case highlights difficulties in attribution of extinctions to recent global warming, it also points to a growing consensus that it is the interaction of climate change with other global change pressures that poses the greatest threat to species (Brook *et al.*, 2008; Pereira *et al.*, 2010; Hof *et al.*, 2011b). Overall, there is *very low confidence* that observed species extinctions can be attributed to recent climate warming, due to the very low fraction of global extinctions that have been ascribed to climate change and tenuous nature of most attributions.

Projected Future Species Extinctions - Projections of future extinctions due to climate change have received considerable attention since AR4. AR4 stated with *medium confidence* “that approximately 20-30% of the plant and animal species assessed to date are at increasing risk of extinction as global mean temperatures exceed a warming of 2-3°C above pre-industrial levels” (Fischlin *et al.*, 2007). All model-based analyses since AR4 broadly confirm this concern, leading to *high confidence* that climate change will contribute to increased extinction risk for terrestrial and freshwater species over the coming century (Pereira *et al.*, 2010; Sinervo *et al.*, 2010; Pearson, 2011; Warren *et al.*, 2011; Bellard *et al.*, 2012; Hannah, 2012; Ihlow *et al.*, 2012; Sekercioglu *et al.*, 2012; Wearn *et al.*, 2012; Foden *et al.*, 2013; Warren *et al.*, 2013). Most studies indicate that extinction risk rises rapidly with increasing levels of climate change, but some do not (Pereira *et al.*, 2010). The limited number of studies that have directly compared land use and climate change drivers have concluded that projected land use change will continue to be a more important driver of extinction risk throughout the 21st century (Pereira *et al.*, 2010). There is, however, broad agreement that land use, and habitat fragmentation in particular, will pose serious impediments to species adaptation to climate change as it is projected to reduce the capacity of many species to track climate (see above). These considerations lead to the assessment that future species extinctions are a high risk because the consequences of climate change are potentially severe, widespread and irreversible since extinctions constitute the permanent loss of unique life forms.

There is, however, *low agreement* concerning the overall fraction of species at risk, the taxa and places most at risk, and the time scale for climate-change driven extinctions to occur. Part of this uncertainty arises from differences in extinction risks within and between modelling studies: this uncertainty has been evaluated in AR4 and subsequent syntheses (Pereira *et al.*, 2010; Warren *et al.*, 2011; Bellard *et al.*, 2012; Cameron, 2012). All studies project increased extinction risk by the end of the 21st century due to climate change, but as indicated in AR4 the range of estimates is large. Recent syntheses indicate that model-based estimates of the fraction of species at substantially increased risk of extinction due to 21st century climate change range from below 1% to above 50% of species in the groups that have been studied (Pereira *et al.*, 2010; Bellard *et al.*, 2012; Cameron, 2012; Foden *et al.*, 2013). Differences in modelling methods, species groups, and climate scenarios between studies make comparisons between estimates difficult (Pereira *et al.*, 2010; Warren *et al.*, 2011; Cameron, 2012).

Many papers published since AR4 argue that the uncertainty may be even higher than indicated in syntheses of model projections, due to limitations in the ability of current models to evaluate extinction risk (e.g., Kuussaari *et al.*, 2009; Pereira *et al.*, 2010; Dawson *et al.*, 2011; McMahon *et al.*, 2011; Pearson, 2011; Araujo and Peterson, 2012; Bellard *et al.*, 2012; Fordham *et al.*, 2012; Hannah, 2012; Kramer *et al.*, 2012; Zurell *et al.*, 2012; Halley *et al.*, 2013; Moritz and Agudo, 2013). Models frequently do not account for genetic and phenotypic adaptive capacity, dispersal capacity, population dynamics, the effects of habitat fragmentation and loss, community interactions, micro-refugia and the effects of rising CO_2 concentrations, all of which could play a major role in determining species vulnerability to climate change, causing models to either over- or under-estimate risk. In addition, difficulties in model validation, large variation in the climate sensitivity of species groups and uncertainties about timescales linking extinction risks to range reductions also lead to large uncertainty in model-based estimates of extinction risk.

A variety of studies since AR4 illustrate how accounting for these factors alters estimates of extinction risk. Accounting for biotic interactions such as pollination or predator-prey networks can increase modelled extinction risks, at least for certain areas and species groups (Schweiger *et al.*, 2008; Urban *et al.*, 2008; Hannah, 2012; Nakazawa and Doi, 2012), or can decrease extinction risk (Menéndez *et al.*, 2008; Pateman *et al.*, 2012).

Accounting for climatic variation at fine spatial scales may increase (Randin *et al.*, 2009; Gillingham *et al.*, 2012; Suggitt *et al.*, 2012; Dobrowski *et al.*, 2013; Franklin *et al.*, 2013) or decrease (Trivedi *et al.*, 2008; Engler *et al.*, 2011; Shimazaki *et al.*, 2012) the persistence of small populations under future climate change. Several recent studies indicate that correlative species distribution models (the type of model most frequently used for evaluating species extinction risk) tend to be much more pessimistic concerning plant species range contractions and the inferred extinction risks due to climate change when compared to mechanistic models that explicitly account for the interactions between climate change and protective effects of rising CO_2 concentrations on plants (Morin and Thuiller, 2009; Kearney *et al.*, 2010; Cheaib *et al.*, 2012). Models that account for population dynamics indicate that some species populations, like those of polar bears (Hunter *et al.*, 2010), will decline precipitously over the course of the next century due to climate change, greatly increasing extinction risk, while others may not (Keith *et al.*, 2008). Phenotypic plasticity in one very well-studied temperate bird population has been estimated to be sufficient to keep extinction risk low even with projected warming exceeding 2-3°C (Vedder *et al.*, 2013), but this and other studies suggest that capacity for adaptation is often substantially lower in species with long generation times (see Section 4.4.1.2). There is evidence that interactions between physiological tolerances and regional climate change will lead to large taxonomic and spatial variation in extinction risk (Deutsch *et al.*, 2008; Sinervo *et al.*, 2010). Even species whose populations are not projected to decline rapidly over the next century can face a substantial "extinction debt"; i.e., will be in unfavourable climates that over a period of many decades to many centuries, leading to large projected reductions in population size (Dullinger *et al.*, 2012). Finally, evidence from the paleontological record indicating very low extinction rates over the last several hundred thousand years of substantial natural fluctuations in climate — with a few notable exceptions such as large land animal extinctions during the Holocene — has led to concern that forecasts of very high extinction rates due entirely to climate change may be overestimated (Botkin *et al.*, 2007; Dawson *et al.*, 2011; Hof *et al.*, 2011a; Willis and MacDonald, 2011; Moritz and Agudo, 2013). However, as indicated in Section 4.2.3, no past climate changes are precise analogues of future climate change in terms of speed, magnitude and spatial scale; nor did they occur alongside the habitat modification, over-exploitation, pollution, and invasive species that are characteristic of the twenty-first century. Therefore the paleontological record cannot easily be used to assess future extinction risk due to climate change.

4.3.3. Impacts on and Risks for Major Systems

This section covers impacts of climate change on broad categories of terrestrial and freshwater ecosystems of the world. We have placed a particular emphasis on those ecosystems that have high exposure to climate change or that may be pushed past thresholds or "tipping points" by climate change.

Two geographical regions of particularly high risk have been identified in recent studies: i) tropics, due to the limited capacity of species to adapt to moderate global warming and ii) high northern latitude systems, because temperature increases are projected to be large. There has been a tendency to oppose these two points of view, but there is a high risk in *both* types of systems, albeit for different reasons (Corlett, 2011). Tropical species, which experienced low inter and intra-annual climate variability, have evolved within narrow thermal limits, and are already near their upper thermal limits (ectotherms: Deutsch *et al.*, 2008; Huey *et al.*, 2012; birds: Sekercioglu *et al.*, 2012; trees: Corlett, 2011). On this basis, tropical species and ecosystems are predicted to be more sensitive to climate change than species and ecosystems that have evolutionary histories of climatic variability (e.g., Arctic and boreal ecosystems; Beaumont *et al.*, 2011). However, there are physiological, evolutionary and ecological arguments that tropical species and ecosystem sensitivities to climate change are complex and may not be particularly high compared to other systems (Gonzalez *et al.*, 2010; Corlett, 2011; Laurance *et al.*, 2011; Gunderson and Leal, 2012; Walters *et al.*, 2012). High latitude systems have the greatest projected exposure to rising temperatures (WGI AR5 Chapter 12; Diffenbaugh and Giorgi, 2012), which all else being equal would put them at higher risk. The greatest degree of recent climate warming has occurred at high northern latitudes (Burrows *et al.*, 2011) and the strongest and clearest signals of recent climate warming impacts on ecosystems come from these regions. A comparison of modelled biome level vulnerability indicated that temperate and high northern latitude systems are also the most vulnerable in the future (Gonzalez *et al.*, 2010).

Several potential tipping points (see Section 4.2.1) with regional and global consequences have been identified (Scheffer, 2009); two are elaborated in Boxes 4-3 (Amazon die-back) and 4-4 (Tundra-boreal regime shift).

An assessment by the authors of this chapter of the top risks in relation to climate change and terrestrial and freshwater ecosystems, is presented in Table 4-3.

[INSERT TABLE 4-3 HERE
Table 4-3: Key risks for terrestrial and freshwater ecosystems from climate change and the potential for reducing risk through mitigation and adaptation. Key risks are identified based on assessment of the literature and expert judgments by chapter authors, with evaluation of evidence and agreement in supporting chapter sections. Each key risk is characterized as very low to very high. Risk levels are presented in three timeframes: the present, near-term (here, assessed over 2030-2040), and longer-term (here, assessed over 2080-2100). For the near-term era of committed climate change, projected levels of global mean temperature increase do not diverge substantially across emission scenarios. For the longer-term era of climate options, risk levels are presented for global mean temperature increase of 2°C and 4°C above preindustrial levels. For each timeframe, risk levels are estimated for a continuation of current adaptation and for a hypothetical highly adapted state. Relevant climate variables are indicated by icons. For a given key risk, change in risk level through time and across magnitudes of climate change is illustrated, but because the assessment considers potential impacts on different physical, biological, and human systems, risk levels should not necessarily be used to evaluate relative risk across key risks, sectors, or regions.]

4.3.3.1. Forests and Woodlands

Forests and woodlands are principal providers of timber, pulp, bioenergy, water, food, medicines and recreation opportunities and can play prominent roles in cultural traditions. Forests are the habitat of a large fraction of the earth's terrestrial plant and animal species, with the highest concentrations and levels of endemism found in tropical regions (Gibson *et al.*, 2011). Climate change and forests interact strongly; air temperature, solar radiation, rainfall and atmospheric CO_2 concentrations are major drivers of forest productivity and forest dynamics, and forests help control climate through the large amounts of carbon they can remove from the atmosphere or release, through absorption or reflection of solar radiation (albedo), cooling through evapotranspiration and the production of cloud-forming aerosols (Arneth *et al.*, 2010; Pan *et al.*, 2011; Pielke *et al.*, 2011).

Combinations of ground based observations, atmospheric carbon budgets and satellite measurements indicate with *high confidence* that forests are currently a net sink for carbon at the global scale. It is estimated that intact and regrowing forests currently contain 860±70 PgC and sequestered 4.0 ± 0.7 Pg C $year^{-1}$ globally between 2000 and 2007 (WGI AR5 Chapter 6; Canadell *et al.*, 2007; Pan *et al.*, 2011; Le Quéré *et al.*, 2012). The carbon taken up by intact and regrowing forests was counterbalanced by a release due to land-use change of 2.8±0.4 Pg C $year^{-1}$ over this same period due mostly to tropical deforestation and forest degradation associated with logging and fire, resulting in a net C balance for global forests of 1.1±0.8 Pg C $year^{-1}$.

The future of the interaction between climate and forests is unclear. The carbon taken up by intact and regrowing forests appears to have stabilized compared to the 1990s, after having increased in the 1970s and 1980s (Canadell *et al.*, 2007; Pan *et al.*, 2011). There is *medium confidence* that the terrestrial carbon sink is weakening. The drivers behind the forest carbon sink vary greatly across regions. They include forest regrowth and stimulation of C sequestration by climate change, rising atmospheric CO_2 concentrations and N deposition (Pan *et al.*, 2011; Sections 4.2.4.1; 4.2.4.2; 4.2.4.4). Most models suggest that rising temperatures, drought and fires will lead to forests becoming a weaker sink or a net carbon source before the end of the century (Sitch *et al.*, 2008; Bowman *et al.*, 2009). Fires play a dominant role in driving forest dynamics in many parts of the world; forest susceptibility to fire is projected to change little for the lowest emissions scenario (RCP 2.6), but substantially for the high emissions scenario (RCP 8.5, Figure 4-6). There is *low agreement* on whether climate change will cause fires to become more or less frequent in individual locations (Figure 4-6). Climate change-mediated disease and insect outbreaks could exacerbate climate-driven increases in fire susceptibility (Kurz *et al.*, 2008). The greatest risks for large positive feedbacks from forests to climate through changes in disturbance regimes arise from widespread tree mortality and fire in tropical forests and low latitude areas of boreal forests, as well as northward expansion of boreal forests into arctic tundra (Lenton *et al.*, 2008; Kriegler *et al.*, 2009; Good *et al.*, 2011b).

[INSERT FIGURE 4-6 HERE
Figure 4-6: Projected changes in meteorological fire danger, fire probability and fire frequency with different methods and climate models. (a)-(e) 30-year annual mean MacArthur Forest Fire Danger Index (FFDI) and change simulated with the HadGEM2-ES Earth System Model, with areas of no vegetation excluded (Betts *et al.*, 2013; (a) FFDI 1970-2000; (b) FFDI 2070-2100, RCP2.6; (c) change in FFDI by 2070-2100 relative to 1970-2000, RCP2.6;(d) FFDI 2070-2100; RCP8.5 (e) change in FFDI by 2070-2100 relative to 1970-2000, RCP8.5. (f) Change in fire frequency by 2100 relative to 2004, SRES B1, simulated using climate and land cover projections from the GISS GCM and IMAGE IAM (Pechony and Shindell, 2010). (g) Change in fire frequency by 2051-2100 relative to 1951-2000, SRES A1B, simulated with the MC1 vegetation model driven by 3 GCMs (CSIRO-Mk3.0, HadCM3, MIROC 3.2medres; mean over 3 simulations; Gonzalez et al., 2010). (h) Agreement on changes in fire probability simulated with a statistical model using climate projections from 16 CMIP3 GCMs, SRES A2 (i) Change in fire frequency by 2100 relative to 2004, SRES A2, simulated using climate and land cover projections from the GISS GCM (AR4 version) and IMAGE IAM (Pechony and Shindell, 2010). Changes in FFDI (a)-(e) and fire probability (h) arise entirely from changes in meteorological quantities, whereas changes in fire frequency (f) (g) (i) depend on both meteorological quantities and vegetation.]

Recent evidence suggests (*low confidence*) that the stimulatory effects of global warming and rising CO_2 concentrations on tree growth may have already peaked in many regions (Charru *et al.*, 2010; Silva *et al.*, 2010; Silva and Anand, 2013) and that warming and changes in precipitation are increasing tree mortality in a wide range of forest systems, acting *via* heat stress, drought stress, pest outbreaks and a wide range of other indirect impact mechanisms (Allen *et al.*, 2010a; Box 4-2). Detection of a coherent global signal is hindered by the lack of long-term observations in many regions, and attribution to climate change is difficult due to the multiplicity of mechanisms mediating mortality (Allen *et al.*, 2010a).

Deforestation has slowed over the last decade (Meyfroidt and Lambin, 2011). This includes substantial reductions in tropical deforestation in some regions, such as the Brazilian Amazon, where deforestation rates declined rapidly after peaking in 2005 (Nepstad *et al.*, 2009; INPE, 2013). Growing pressure for new crop (Section 4.4.4) and grazing land will continue to drive tropical deforestation (*medium confidence*) although recent policy experiments and market-based interventions in land use demonstrate the potential to reduce deforestation (Meyfroidt and Lambin, 2011; Westley *et al.*, 2011; Nepstad *et al.*, 2013).

_____ START BOX 4-2 HERE _____

Box 4-2. Tree Mortality and Climate Change

Extensive tree mortality and widespread forest dieback (high mortality rates at a regional scale) linked to drought and temperature stress have been documented recently on all vegetated continents (Allen *et al.*, 2010a; Figure 4-7). However, appropriate field data sets are currently lacking for many regions (Anderegg *et al.*, 2013a), leading to *low confidence* in our ability to detect a global trend. Nevertheless, long-term increasing tree mortality rates associated with temperature increases and drought have been documented in boreal and temperate forests in western North America (van Mantgem *et al.*, 2009; Peng *et al.*, 2011). Increased levels of tree mortality following drought episodes have also been detected in multiple tropical forests (Kraft *et al.*, 2010; Phillips *et al.*, 2010) and Europe (Carnicer *et al.*, 2011). Episodes of widespread die-back (high mortality rates at a regional scale) have been observed in multiple vegetation types, particularly in western North America, Australia, and southern Europe (Raffa *et al.*, 2008; Carnicer *et al.*, 2011; Anderegg *et al.*, 2013a). Some widespread die-back events have occurred concomitant with infestation outbreaks (Hogg *et al.*, 2008; Michaelian *et al.*, 2011; Raffa *et al.*, 2008), where insect populations are also directly influenced by climate, such as population release by warmer winter temperatures (Bentz *et al.*, 2010). While strong attribution of extensive tree mortality to recent warming has been made in a few studies, the paucity of long-term studies of the mechanisms driving mortality means that there is *low confidence* that this attribution can be made at the global scale.

Forest dieback has influenced the species composition, structure and age demographics, and successional trajectories in affected forests, and in some cases led to decreased plant species diversity and increased risk of invasion (Kane *et* *al.*, 2011; Anderegg *et al.*, 2012). Widespread tree mortality also has multiple effects on biosphere-atmosphere interactions and could play an important role in future carbon-cycle feedbacks through complex effects on forest biophysical properties and biogeochemical cycles (Breshears *et al.*, 2005; Kurz *et al.*, 2008; Anderson *et al.*, 2011).

Projections of tree mortality due to climate stress and potential thresholds of widespread forest loss are currently highly uncertain (McDowell *et al.*, 2011). Most current vegetation models have little-to-no mechanistic representation of tree mortality (Fisher *et al.*, 2010; McDowell *et al.*, 2011). Nonetheless, a global analysis of tree hydraulic safety margins found that 70% of surveyed tree species operate close to their limits of water stress tolerance (Choat *et al.*, 2012), indicating that vulnerability to drought and temperature stress will not be limited to arid and semi-arid forests. Furthermore, timescales of tree and plant community recovery following drought are largely unknown, but preliminary evidence from several forests indicates that full recovery times may be longer than drought return intervals, leading to "compounding" effects of multiple droughts (Mueller *et al.*, 2005; Anderegg *et al.*, 2013b; Saatchi *et al.*, 2013). Projected increases in temperature are also expected to facilitate expansion of insect pest outbreaks poleward and in altitude which may also cause or contribute to tree mortality (Bentz *et al.*, 2010).

[INSERT FIGURE 4-7 HERE
Figure 4-7: Locations of substantial drought- and heat-induced tree mortality around the globe since 1970 (global forest cover and other wooded regions based on FAO, 2005). Studies compiled through 2009 (red dots) are summarized and listed in Allen *et al.* (2010a). Localities and measurement networks not included in Allen *et al.* (2010a), which are largely from post-2009 publications, have been added to this map (white dots and shapes). New locality references by region: Africa – Mehl *et al.*, 2010, van der Linde *et al.*, 2011; Fauset *et al.*, 2012; Gonzalez *et al.*, 2012; Kherchouche *et al.*, 2012; Asia – Dulamsuren *et al.*, 2009; Kharuk *et al.*, 2013; Liu *et al.*, 2013; Zhou *et al.*, 2013; Australasia – Brouwers *et al.*, 2012; Fensham *et al.*, 2012; Keith *et al.*, 2012; Matusick *et al.*, 2012; Brouwers *et al.*, 2013; Matusick *et al.*, 2013; Europe – Innes, 1992; Peterken and Mountford, 1996; Linares *et al.*, 2009; Galiano *et al.*, 2010; Vennetier and Ripert, 2010; Aakala *et al.*, 2011; Carnicer *et al.*, 2011; Linares *et al.*, 2011; Sarris *et al.*, 2011; Marini *et al.*, 2012; Cailleret *et al.*, 2013; Vilà-Cabrera *et al.*, 2013; North America – Fahey, 1998; Minnich, 2007; Klos *et al.*, 2009; Ganey and Vojta, 2011; Michaelian *et al.*, 2011; Peng *et al.*, 2011; DeRose and Long, 2012; Fellows and Goulden, 2012; Kaiser *et al.*, 2012; Millar *et al.*, 2012; Garrity *et al.*, 2013; Kukowski *et al.*, 2013; Williams *et al.*, 2013; Worrall *et al.*, 2013; South America – Enquist and Enquist, 2011; Lewis *et al.*, 2011; Saatchi *et al.*, 2013.]

_____ END BOX 4-2 HERE _____

4.3.3.1.1. Boreal forests

Most projections suggest a poleward expansion of forests into tundra regions, accompanied by a general shift in composition towards more temperate plant functional types (e.g., evergreen needleleaf being replaced by deciduous broadleaf; or in colder regions, deciduous needleleaf replaced by evergreen needleleaf (Lloyd *et al.*, 2011; Pearson *et al.*, 2013). Projections of climate-driven changes in boreal forests over the next few centuries remain uncertain on some issues, partly as a result of different processes of change being considered in different models. In particular, the inclusion or exclusion of fire and insects makes a big difference, possibly making the boreal forest more susceptible to a rapid, non-linear or abrupt decline in some regions (Bernhardt *et al.*, 2011; Mann *et al.*, 2012; Scheffer *et al.*, 2012; see WGI AR5 Chapter 12). Recent observed change (Box 4-2) and dynamic vegetation modelling (e.g., Sitch *et al.*, 2008) suggest that regions of the boreal forest could experience widespread forest dieback, although there is *low confidence* due to conflicting results (Sitch *et al.*, 2008; Gonzalez *et al*, 2010) and poor understanding of relevant mechanisms (WG1 AR5 Section 12.5.5.6.2). If such shifts were to occur, they would put the boreal carbon sink at risk (Pan *et al.*, 2011; Mann *et al.*, 2012).

Whereas boreal forest productivity has been expected to increase as a result of warming (Hari and Kulmata, 2008; Bronson *et al.*, 2009; Zhao and Running, 2010; Van Herk *et al.*, 2011), and early analyses of satellite observations confirmed this trend in the 1980s (*medium confidence*), more recent and longer-term assessments indicate with *high confidence* that many areas of boreal forest have instead experienced productivity declines (*high confidence*, Goetz *et al.*, 2007; Parent and Verbyla, 2010; Beck *et al.*, 2011b; de Jong *et al.*, 2011). The best evidence to date indicates that these “browning trends” are due to warming-induced drought, specifically the greater drying power of air (vapour pressure deficit, Williams *et al.*, 2013), inducing photosynthetic down-regulation of boreal tree species, particularly conifer species, most of which are not adapted to the warmer conditions (Welp *et al.*, 2007; Bonan, 2008; Van Herk *et al.*, 2011). Satellite evidence for warming-induced productivity declines has been corroborated by tree ring studies (Barber *et al.*, 2000; Hogg *et al.*, 2008; Beck *et al.*, 2011b; Porter and Pisaric, 2011; Griesbauer and Green, 2012) and long-term tree demography plots in more continental and densely forested areas (Peng *et al.*, 2011; Ma *et al.*, 2012). Conversely, productivity has increased at the boreal-tundra ecotone where more mesic (moist) conditions may be generating the expected warming-induced positive growth response (Rupp *et al.*, 2001; McGuire *et al.*, 2007; Goldblum and Rigg, 2010; Beck *et al.*, 2011b). The complexity of boreal forest response also involves tree age and size, with younger trees and stands perhaps being more able to benefit from warming where other factors are not limiting (Girardin *et al.*, 2011; Girardin *et al.*, 2012).

Where they occur, warming and drying, coupled with productivity declines, insect disturbance and associated tree mortality, also favour greater fire disturbance (*high confidence*). The boreal biome fire regime has intensified regionally in recent decades, exemplified by increases in the extent of area burned but also a longer fire season and more episodic fires that burn with greater energy output or intensity (Girardin and Mudelsee, 2008; Macias Fauria and Johnson, 2008; Kasischke *et al.*, 2010; Turetsky *et al.*, 2011; Mann *et al.*, 2012; Girardin *et al.*, 2013a). The latter is particularly important because more severe burning consumes soil organic matter to greater depth, often to mineral soil, providing conditions that favour recruitment of deciduous species that in some regions of the North American boreal forest replace what was previously evergreen conifer forest (Johnstone *et al.*, 2010; Bernhardt *et al.*, 2011). Fire-mediated composition changes in post-fire succession influence a host of ecosystem feedbacks to climate, including changes in net ecosystem carbon balance (Bond-Lamberty *et al.*, 2007; Goetz *et al.*, 2007; Welp *et al.*, 2007; Euskirchen *et al.*, 2009) as well as albedo and energy balance (Randerson *et al.*, 2006; Jin *et al.*, 2012; O'Halloran *et al.*, 2012). The extent to which the net effect of these feedbacks will exacerbate or mitigate additional warming is not well known over the larger geographic domain of the boreal biome, except via modelling studies that are relatively poorly constrained due to sparse *in situ* observations.

The vulnerability of the boreal biome to this cascading series of interacting processes (Wolken *et al.*, 2011), and their ultimate influence on climate feedbacks, differs between North America and northern Eurasia (*high confidence*). The latter is dominated by deciduous conifer (larch) forest, extending from western Russia across central to eastern Siberia – a region more than twice the size of the North American boreal biome, most of it underlain by permafrost. In terms of post-fire succession analogous to the North American boreal biome, larch function more like deciduous species than evergreen conifers, with greater density and biomass gain in more severely burned areas, given adequate seed survival through fire events or post-fire seed dispersal (Zyryanova, 2007; Osawa *et al.*, 2010; Alexander *et al.*, 2012). Although the fire regime has intensified in the last 100 years in Siberia, as well as in parts of North America (Soja *et al.*, 2007; Ali *et al.*, 2012; Mann *et al.*, 2012; Marlon *et al.*, 2013), the likelihood of regime shifts in larch forests is currently unknown, partly because larch are self-replacing (albeit at different densities) and partly because it is largely dependent on the fate of permafrost across the region. In summary, an increase in tree mortality is observed in many boreal forests, with the clearest indicators of this in North America. However, tree health in boreal forests varies greatly among regions, which coupled with insufficient temporal coverage means that there is *low confidence* in the detection and attribution of a clear temporal trend in tree morality at the global scale (Figure 4-4).

The vulnerability of permafrost to thawing and degradation with climate warming is critical not only for determining the rate of a boreal-tundra biome shift and its associated net feedback to climate, but also for predicting the degree to which the mobilization of very large carbon stores frozen for centuries could provide additional warming (*high confidence*; Schuur *et al.*, 2008; 2009; Tarnocai *et al.*, 2009; Romanovsky *et al.*, 2010; Schaefer *et al.*, 2011; see WGI AR5 Chapters 6 and 12; see also Section 4.3.3.4). The extent and rate of permafrost degradation varies with temperature gradients from warmer discontinuous permafrost areas to colder, more continuous areas; but also with the properties of the soil composition and biology (e.g., Mackelprang *et al.*, 2011). The degree of thermokarsting (melting of ice-rich soil) associated with different substrates and associated topographic relief is variable because boreal vegetation in latter successional stages (evergreen conifers in North America) insulate permafrost from air temperature increases; soils with differing silt and gravel content tend to have different ice content that, when melted, produces different degradation and deformation rates; and other factors such as the reduction of insulation provided by vegetation cover and soil organic layers due to increased fire (Jorgenson *et al.*, 2010; Grosse *et al.*, 2011). This variability and vulnerability is poorly represented in earth system models (McGuire *et al.*, 2012) and is thus the emphasis of research initiatives currently underway. Carbon management strategies to keep permafrost intact, for example by removing forest cover to expose the land surface to winter temperatures (Zimov *et al.*, 2009), are impractical, not only because of the vast spatial domain underlain by permafrost, but also because of the broad societal and ecological impacts that would result.

4.3.3.1.2. Temperate forests

The largest areas of temperate forest are found in eastern North America, Europe and eastern Asia. The overall trend for forests in these regions has until recently been an increase in growth rates of trees and in total carbon stocks. This has been attributed to a combination of increasing growing season length, rising atmospheric CO_2 concentrations, nitrogen deposition and forest management – specifically regrowth following formerly more intensive harvesting regimes (Ciais *et al.*, 2008). The relative contribution of these factors has been the subject of substantial and unresolved debate (Boisvenue and Running, 2006). Most temperate forests are managed such that any change is and will be to a large extent anthropogenic.

The world's temperate forests act as an important carbon sink (*high confidence* due to *robust evidence and high agreement)*, absorbing 0.7±0.08 Pg C year^{-1} from 1990 to 1999 and 0.8±0.09 from 2000 to 2007 (Pan *et al.*, 2011).This represents 34% of global carbon accumulation in intact forests and 65% of the global net forest carbon sink (total sink minus total emissions from land use).

Recent indications are that temperate forests and trees are beginning to show signs of climate stress, including a reversal of tree growth enhancement in some regions (North America: Silva *et al.*, 2010; Silva and Anand, 2013; Europe: Charru *et al.*, 2010; Bontemps *et al.*, 2011; Kint *et al.*, 2012), increasing tree mortality (Allen *et al.*, 2010a; Box 4-2), and changes in fire regimes, insect outbreaks and pathogen attacks (Adams *et al.*, 2012; Edburg *et al.*, 2012). In north-eastern France, widespread recent declines in growth rates of European beech (*Fagus sylvatica L.*) have been attributed to decreasing water availability (Charru *et al.*, 2010). These trends threaten the substantial role of temperate forests as net carbon sinks, but it is still unclear to what extent the observations are representative for temperate forests as a whole. Several studies find that tree growth rates in temperate forests passed their peak in the late 20th century and that the decline in tree growth rates can be attributed to climatic factors, especially drought or heatwaves (Charru *et al.*, 2010; Silva *et al.*, 2010). Extreme climate events have had a major impact on temperate forests over the last decade (Ciais *et al.*, 2005; Witte *et al.*, 2011; Kasson and Livingston, 2012). Extensive forest fires occurred in Russia during the exceptionally hot and dry summer of 2010 (Witte *et al.*, 2011). The complex interactions between climate and forest management in determining susceptibility to extreme events make it difficult to unequivocally attribute these events to recent climate warming (Allen *et al.*, 2010a). There is *low confidence (limited evidence; medium agreement)* that climate change is threatening the temperate forest carbon sink directly or indirectly.

At the biome level, there remains considerable uncertainty in the sign and the magnitude of the carbon cycle response of temperate forests to climate change. A comparison of DGVM models showed that for identical end of 21st century climate projections, temperate forests are variously projected to substantially increase in total (biomass plus soil) carbon storage, especially through gains in forest cover; or decrease due to reductions in total carbon storage per hectare and loss of tree cover (Sitch *et al.*, 2008). Projections for eastern Asia are less variable: temperate forests remain carbon sinks over the coming century, with carbon storage generally peaking by mid-century and then declining (He *et al.*, 2007; Sitch *et al.*, 2008; Peng *et al.*, 2009; Ni, 2011). However, regional vegetation models for China predict a substantial northward shift of temperate forest (Weng and Zhou, 2006; Ni, 2011). There is little indication from either models or observations that the responses of temperate forests to climate change are characterized by tipping points (Bonan, 2008). There is *low confidence (medium evidence, low agreement)* on long-term, climate-driven changes in temperate forest biomass and geographical range shifts.

At the species level, models predict that the potential climatic space for most tree species will shift poleward and to higher altitude in response to climate change (Dale *et al.*, 2010; Ogawa-Onishi *et al.*, 2010; Hickler *et al.*, 2012).

Associated long-term projected range shifts generally vary from several km to several tens of km per decade, most probably faster than natural migration (e.g., Chmura *et al.*, 2011; see also Section 4.3.2.5). Therefore, assisted migration has been suggested as an adaptation measure (see Section 4.4.2.4). Such shifts would alter biodiversity and ecosystem services from temperate forests (e.g., Dale *et al.*, 2010). Multi-model comparisons for temperate forests, however, illustrate that there are differences in species response and that models differ greatly in the severity of projected climate change impacts on species ranges (Morin and Thuiller, 2009; Kearney *et al.*, 2010; Kramer *et al.*, 2010; Cheaib *et al.*, 2012). Tree growth models project increased tree growth at the poleward and high altitudinal range limits over most of the 21st century in China (Ni, 2011). New approaches to modelling tree responses, based on the sensitivity of key life-history stages, suggest that climate change impacts on reproduction could be a major limitation on temperate tree distributions (Morin *et al.*, 2007). Comparisons with paleoecological data have helped improve confidence in the ability of models to project future changes in species ranges (Pearman *et al.*, 2008; Allen *et al.*, 2010b; Garreta *et al.*, 2010). Model projections are qualitatively coherent with observations that temperate forest species are moving up in altitude, probably due to climate warming at the end of the 20th century (Lenoir *et al.*, 2008). There is *medium confidence (medium evidence, medium agreement)* that temperate tree species are migrating poleward and to higher altitudes.

4.3.3.1.3. Tropical forests

Climate change effects on tropical forests interact with the direct influences of humans and are understood largely through field studies of the responses of forests to extreme weather events and through models that are able to simulate a growing number of ecological and atmospheric processes (Malhi *et al.*, 2008; Davidson *et al.*, 2012).

A key uncertainty in our understanding of future impacts of climate change on tropical forests is the strength of direct CO_2 effects on photosynthesis and transpiration (see Section 4.3.2.4). These responses will play an important role in determining tropical forest trends as temperatures and atmospheric CO_2 concentrations rise. There is a physiological basis for arguing that photosynthesis will increase sufficiently to offset the inhibitory effects of higher temperatures on forest productivity (Lloyd and Farquhar, 2008) although heightened photosynthesis does not necessarily translate into an increase in overall forest biomass (Körner and Basler, 2010). DGVMs and the current generation of Earth System Models, including those used within CMIP5 (e.g., Jones *et al.*, 2011; Powell *et al.*, 2013) generally use formulations for CO_2 effects on photosynthesis and transpiration based on laboratory-scale work (Jarvis, 1976; Farquhar *et al.*, 1980; Ball *et al.*, 1987; Stewart, 1988; Collatz *et al.*, 1992; Leuning, 1995; Haxeltine and Prentice, 1996; Cox *et al.*, 1998) that pre-dates larger ecosystem-scale studies, although some models have been calibrated on the basis of more recent data (Jones *et al.*, 2011).

A second important source of uncertainty is the rate of future CO_2 rise and climate change (Betts *et al.*, 2012). Modelled simulations of future climate in tropical forest regions indicate with *high confidence (robust evidence, high agreement*) that temperature will increase. Future precipitation change, in contrast, is highly uncertain and varies considerably between climate models (WGI AR5 Annex 1: Atlas of Global and Regional Climate Projections), although there is *medium confidence* (*medium evidence, medium agreement*) that some tropical regions, such as the eastern Amazon Basin, will experience lower precipitation and more severe drought (Malhi *et al.*, 2009a; Shiogama *et al*. 2011). The range of possible shifts in the moist tropical forest envelope is large, sensitive to the responsiveness of water use efficiency (WUE) to rising concentrations of atmospheric CO_2, and varies depending on the climate and vegetation model that is used (Scholze *et al.*, 2006; Zelazowski *et al.*, 2011) (Sitch *et al.*, 2008). Recent model studies (Malhi *et al.*, 2009a; Cox *et al.*, 2013; Huntingford *et al.*, 2013) indicate that the future geographical range of moist tropical forests as determined by its shifting climatological envelope is less likely to undergo major retractions or expansions by 2100 than was suggested in AR4. Since AR4, there is new evidence of more frequent severe drought episodes in the Amazon region that are associated with sea surface temperature increases in the tropical North Atlantic (*medium confidence*, Marengo et al. 2010). There is *low confidence*, however, that these droughts or the observed sea surface temperatures can be attributed to climate change.

Networks of long-term forest plots reveal that lianas and fast-growing tree species are increasing, as is forest biomass (Phillips *et al.*, 2002; Phillips *et al.*, 2005; Lewis *et al.*, 2009a; Lewis *et al.*, 2009b; Lewis *et al.*, 2011). Faster tree growth is consistent with increasing WUE associated with the rising concentration of CO_2, but also with changes in solar radiation and the ratio of diffuse to direct radiation (Lewis *et al.*, 2009a; Mercado *et al.*, 2009; Brando *et al.*, 2010; Section 4.2.4.5). There is *low confidence* (*limited evidence, medium agreement*) that the composition and biomass of Amazon and African forests are changing through the rise in atmospheric CO_2. The potential suppression of photosynthesis and tree growth in tropical forests through rising air temperatures is supported by physiological and eddy covariance studies (Doughty and Goulden, 2008; Lloyd and Farquhar, 2008; Wood *et al.*, 2012), but is not yet observed as changes in forest biomass (except Clark *et al.*, 2003).

Since AR4, there is new experimental and observational evidence of ecological thresholds of drought and fire in moist tropical forests that points to an important indirect role of climate change in driving large-scale changes in these ecosystems, and to the importance of extreme drought events (see Box 4-3). Forest tree mortality increased abruptly above a critical level of soil moisture depletion in two rainfall exclusion experiments (Nepstad *et al.*, 2007; Fisher *et al.*, 2008) and above a critical level of weather-related fire intensity in a prescribed burn experiment (Brando *et al.*, 2012). These experimental results were corroborated by observations of increased tree mortality during the severe 2005 drought in the Amazon (Phillips *et al.*, 2009) and extensive forest fire (Alencar *et al.*, 2006; Aragão *et al.*, 2008; Alencar *et al.*, 2011; Box 4-3). There is *high confidence* (*medium evidence, high agreement*) that moist tropical forests have many tree species that are vulnerable to drought- and fire-induced mortality during extreme dry periods.

There is also a growing body of evidence that severe weather events interact with land use to influence moist tropical forest fire regimes. Many moist tropical forests are not susceptible to fire during typical rainfall years because of high moisture content of fine fuels (Cochrane, 2003). Selective logging, drought, and fire itself, can reduce this fire resistance by killing trees, thinning the canopy and allowing greater heating of the forest interior (Uhl and Kauffman, 1990; Curran *et al.*, 2004; Ray *et al.*, 2005; Box 4-3). Land use also often increases the ignition sources in tropical landscapes (Silvestrini *et al.*, 2011). These relationships are not yet represented fully in coupled climate-vegetation models. There is *high confidence* (*robust evidence, high agreement*) that forest fire frequency and severity is increasing through the interaction between severe droughts and land use. There is *medium confidence* (*medium evidence, high agreement*) that tree mortality in the Amazon region is increasing through severe drought and increased forest fire occurrence and *low confidence* that this can be attributed to warming (Figure 4-4).

Dry tropical forests are defined by strong seasonality in rainfall distribution (Mooney *et al.*, 1995) and have been reduced to an estimated one million km^2 globally through human activities (Miles *et al.*, 2006). Half of the world's remaining dry tropical forests are located in South America. Using five climate model simulations for the 2040-2069 period under the IS92a "business as usual scenario", Miles et al. (2006) found that approximately one third of the remaining area of tropical dry forests in the Americas will be exposed to higher temperatures and lower rainfall through climate change. Climate change, deforestation, fragmentation, fire, or human pressure place virtually all (97%) of the remaining tropical dry forests at risk of replacement or degradation (Miles *et al.*, 2006). In a regional study a dynamic vegetation model (IBIS) under A2 and B2 scenarios projected by a global climate model (HADRM3) found that most of the dry forests of India would be outside of their climate envelopes later this century (Chaturvedi *et al.*, 2011). There is *low confidence* in our understanding of climate change effects on dry forests globally.

_____ START BOX 4-3 HERE _____

Box 4-3. A Possible Amazon Basin Tipping Point

Since AR4, our understanding of the potential of a large-scale, climate-driven, self-reinforcing transition of Amazon forests to a dry stable state (known as the Amazon "forest dieback") has improved. Modelling studies indicate that the likelihood of a climate-driven forest dieback by 2100 is lower than previously thought (Malhi *et al.*, 2009b; Cox *et al.*, 2013; Good *et al.*, 2013; Huntingford *et al.*, 2013), although lower rainfall and more severe drought is expected in the eastern Amazon (Malhi *et al.*, 2009a). There is now *medium confidence* (*medium evidence, medium agreement*) that climate change alone (that is, through changes in the climate envelope, without invoking fire and land use) will not drive large-scale forest loss by 2100 although shifts to drier forest types are predicted in the eastern Amazon (Mahli et al. 2009a). Meteorological fire danger is projected to increase (Golding and Betts, 2008; Betts *et al.*, 2013; Figure 4-6). Field studies and regional observations have provided new evidence of critical ecological thresholds and positive feedbacks between climate change and land-use activities that could drive a fire-mediated, self-reinforcing dieback during the next few decades (Figure 4-8). There is now *medium confidence* (*medium evidence, high agreement*) that severe drought episodes, land use, and fire interact synergistically to drive the transition of mature Amazon forests to low-biomass, low-statured fire-adapted woody vegetation.

Most primary forests of the Amazon Basin have damp fine fuel layers and low susceptibility to fire, even during annual dry seasons (Uhl and Kauffman, 1990; Ray *et al.*, 2005). Forest susceptibility to fire increases through canopy thinning and greater sunlight penetration caused by tree mortality associated with selective logging (Uhl and Kauffman, 1990; Ray *et al.*, 2005; Barlow and Peres, 2008), previous forest fire (Balch *et al.*, 2008; Brando *et al.*, 2012), severe drought (Alencar *et al.*, 2006), or drought-induced tree mortality (Nepstad *et al.*, 2007; da Costa *et al.*, 2010). The impact of fire on tree mortality is also weather-dependent. Under very dry, hot conditions, fire-related tree mortality can increase sharply (Brando *et al.*, 2012). Under some circumstances, tree damage is sufficient to allow light-demanding, flammable grasses to establish in the forest understory, increasing forest susceptibility to further burning (Veldman and Putz, 2011). There is *high confidence* (*robust evidence, high agreement*) that logging, severe drought, and previous fire increase Amazon forest susceptibility to burning.

Landscape level processes further increase the likelihood of forest fire. Fire ignition sources are more common in agricultural and grazing lands than in forested landscapes (Silvestrini *et al.*, 2011) (*high confidence: robust evidence, high agreement*), and forest conversion to grazing and crop lands can inhibit regional rainfall through changes in albedo and evapotranspiration (Costa *et al.*, 2007; Butt *et al.*, 2011; Knox *et al.*, 2011) (*low confidence: medium evidence, low agreement*) or through smoke, that can inhibit rainfall under some circumstances (Andreae *et al.*, 2004) (*medium confidence*: *medium evidence, medium agreement*). Apart from these landscape processes, climate change could increase the incidence of severe drought episodes (Mahli et al. 2009b; Shiogama *et al.*, 2011).

If recent patterns of deforestation (through 2005), logging, severe drought, and forest fire continue into the future, more than half of the region's forests will be cleared, logged, burned or exposed to drought by 2030, even without invoking positive feedbacks with regional climate, releasing 20±10 Pg of carbon to the atmosphere (Nepstad *et al.*, 2008) (*low confidence: low evidence, medium agreement*) (Figure 4-8). The likelihood of a tipping point being reached may decline if extreme droughts (such as 1998, 2005, and 2010) (Marengo *et al.*, 2011) become less frequent, if land management fires are suppressed, if forest fires are extinguished on a large scale (Soares-Filho *et al.*, 2012), if deforestation declines, or if cleared lands are reforested (Nepstad *et al.*, 2008). The 77% decline in deforestation in the Brazilian Amazon with 80% of the region's forest still standing (INPE, 2013) demonstrates that policy-led avoidance of a fire-mediated tipping point is plausible.

[INSERT FIGURE 4-8 HERE
Figure 4-8: The forests of the Amazon Basin are being altered through severe droughts, land use (deforestation, logging), and increased frequencies of forest fire. Some of these processes are self-reinforcing through positive feedbacks, and create the potential for a large-scale tipping point. For example, forest fire kills trees, increasing the likelihood of subsequent burning. This effect is magnified when tree death allows forests to be invaded by flammable grasses. Deforestation provides ignition sources to flammable forests, contributing to this dieback. Climate change contributes to this tipping point by increasing drought severity, reducing rainfall and raising air temperatures, particularly in the eastern Amazon Basin (*medium confidence; medium evidence, medium agreement).*]

_____ END BOX 4-3 HERE _____

4.3.3.2. Dryland Ecosystems: Savannas, Shrublands, Grasslands, and Deserts

The following sections treat a wide range of terrestrial ecosystems covering a large part of the land surface, whose common features are that they typically exhibit strong water stress for several months each year and grass-like plants and herbs are a major part of their vegetation cover. Thus the principle land use often involves grazing by domestic livestock or wild herbivores.

4.3.3.2.1. Savannas

Savannas are mixtures of coexisting trees and grasses, covering about a quarter of the global land surface, including tropical and temperate forms. Savannas are characterized by annual to decadal fires (Archibald *et al.*, 2009) of relatively low intensity, which are an important factor in maintaining the tree-grass proportions (Beerling and Osborne, 2006), but also constitute a major and climate-sensitive global source of fire-related emissions from land to atmosphere (Schultz *et al.*, 2008; van der Werf *et al.*, 2010). The geographical distribution of savannas is determined by temperature, the seasonal availability of water, fire and soil conditions (Ellery *et al.*, 1991; Walker and Langridge, 1997; Staver *et al.*, 2011) and is therefore inferred to be susceptible to climate change. In parts of Central Africa, forests have been observed to be moving into adjacent savannas and grasslands (Mitchard *et al.*, 2009), possibly due to depopulation and changes in the fire regime. In northern Australia, forest is expanding into former savanna areas (Brook and Bowman, 2006; Bowman *et al.*, 2011; Tng *et al.*, 2012). It has been projected that drying and greater seasonality, acting in conjunction with increased fire, could lead to former forested areas becoming savannas in parts of the Amazon basin (Malhi *et al.*, 2009b; Box 4-3) In many places around the world the savanna boundary is moving into former grasslands on elevation gradients, in other words into areas inferred to be formerly too cool for trees (Breshears, 2006).

The proportion of trees and grasses in savannas is considered unstable under some conditions (DeMichele *et al.*, 2011; Staver *et al.*, 2011; Wake, 2012). The differential effects of climate change, rising CO_2, fire and herbivory on trees and grasses have the potential to alter the cover of trees savannas, possibly abruptly. There is evidence from many parts of the world that the tree cover and biomass in savannas has increased over the past century and in some places, on all continents, continues to do so (*high agreement, robust evidence*, Moleele *et al.*, 2002; Angassa and Oba, 2008; Cabral *et al.*, 2009; Wigley *et al.*, 2009; Witt *et al.*, 2009; Lunt *et al.*, 2010; Rohde and Hoffman, 2012). The general consequences are more carbon stored per unit land area in form of tree biomass and soil organic matter (Hughes *et al.*, 2006; Liao *et al.*, 2006; Knapp *et al.*, 2007; Throop and Archer, 2008; Boutton *et al.*, 2009), changes in hydrology (Muñoz-Robles *et al.*, 2011) and reduced grazing potential (Scholes and Archer, 1997). Increasing tree cover in savannas has been attributed to changes in land management (Joubert *et al.*, 2008; Van Auken, 2009), rising CO_2 (Bond and Midgley, 2012; Buitenwerf *et al.*, 2012), climate variability and change (Eamus and Palmer, 2007; Fensham *et al.*, 2009) or two or more of these factors acting in combination (Ward, 2005; Bond *et al.*, 2008). As yet, there are no studies that definitively attribute the relative importance of the climate- and non-climate-related causes of woody plant biomass increase in savannas (and the invasion of trees into former grasslands), but there is *medium agreement* and *robust evidence* that climate change and rising CO_2 are contributing factors in many cases. The increased growth rate of C3 photosynthetic system trees relative to C4 grasses under by rising CO_2 could relieve the demographic bottleneck that keeps trees trapped within the flame zone of the grasses, a hypothesis supported by elevated CO_2 experiments with savanna saplings (Kgope *et al.*, 2010).

A model of grasslands, savannas and forests suggests that rising CO_2 does increase the likelihood of abrupt shifts to woodier states, but the transition will take place at different CO_2 concentrations in different environments (Higgins and Scheiter, 2012). On the other hand, observation of contrasts in the degree of savanna thickening between land parcels with the same CO_2 exposure but different land use histories, topographic position or soil depth (Wiegand *et al.*, 2005; Wu and Archer, 2005) imply that land management, water balance and microclimate are also important. Tree cover in savannas is rainfall-constrained (Sankaran *et al.*, 2005), suggesting that future increases in rainfall projected for most but not all savanna areas (WGI AR5 Annex I: Atlas of Global and Regional Climate Projections) – could lead to increased tree biomass.

4.3.3.2.2. Grasslands and shrublands

Rangelands (partly overlapping with savannas, above) cover approximately 30% of the earth's ice-free land surface and hold an equivalent amount of the world's terrestrial carbon (Booker *et al.*, 2013). Much evidence from around the world shows that dry grasslands and shrublands are highly responsive in terms of primary production, species composition and carbon balance to changes in water balance (precipitation and evaporative demand) within the range of projected climate changes (*robust evidence and confidence*) (e.g., Sala *et al.*, 1988; Snyman and Fouché, 1993; Fay *et al.*, 2003; Peñuelas *et al.*, 2004, 2007; Prieto *et al.*, 2009; Peters *et al.*, 2010; Martí-Roura *et al.*, 2011; Booker *et al.*, 2013; Wu and Chen, 2013). Rainfall amount and timing have large effects on a wide range of biological processes in grasslands and shrublands, including seed germination, seedling establishment, plant growth, flowering time, root mass, community composition, population and community dynamics production, decomposition and respiration, microbial processes and carbon, plant and soil nutrient contents (e.g., Fay *et al.*, 2003; Peñuelas *et al.*, 2004; Peñuelas *et al.*, 2007; Beier *et al.*, 2008; Sardans *et al.*, 2008a; Sardans *et al.*, 2008b; Sowerby *et al.*, 2008; Liu *et al.*, 2009; Miranda *et al.*, 2009; Albert *et al.*, 2011; Albert *et al.*, 2012; Selsted *et al.*, 2012; Walter *et al.*, 2012).

Precipitation changes were as important for mountain flora in Europe as temperature changes, and the greatest composition changes will probably occur when decreased precipitation accompany warming (Engler *et al.*, 2011). Responses of shrublands to drought may partly be driven by changes in the soil microbial community (Jensen *et al.*, 2003) or changes in soil fauna (Maraldo *et al.*, 2008). An increase in drought frequency, without an increase in drought severity, leads to loss of soil carbon in moist, carbon-rich moorlands, due to changes in soil structure or soil microbial community leading to increased hydrophobicity and soil respiration (Sowerby *et al.*, 2008; Sowerby *et al.*, 2010). Simulated increased spring temperature and decreased summer precipitation had a general negative effect on plant survival and plant growth, irrespective of the macroclimatic niche characteristics of the species. Against expectation, species with ranges extending into drier regions did not generally perform better under drier conditions (Bütof *et al.*, 2012).

Changing climate and land use have resulted in increased aridity and a higher frequency of droughts in drylands around the world, with increasing dominance of abiotic controls of land degradation (in contrast to direct human- or herbivore-driven degradation) and changes in hydrology and the erosion of soil by wind (Ravi *et al.*, 2010). In mixed shrub grasslands, the influence of drought periods could produce transient pulses of C that are much larger than the pulses produced by fire (Martí-Roura *et al.*, 2011). Most studies of changes in arid systems between grasslands and shrublands have focused on plant-soil feedbacks that favour shrubs growth. Summers drier than three-quarters of current rainfall decreased grass seedling recruitment to negligible values (Peters *et al.*, 2010). Management cannot reliably increase carbon uptake in arid and semiarid rangelands, which is most often controlled by abiotic factors not easily changed by management of grazing or vegetation (Booker *et al.*, 2013).

Other factors being equal, grasslands and shrublands in cool areas are expected to respond to warming with increased primary production, while those in hot areas are expected to show decreased production (*limited evidence, low confidence*). A shift to more woody vegetation states expected to occur (locally but not globally) in tropical grasslands of the African continent (Higgins and Scheiter, 2012). The response to warming and drought depends on site, year and plant species, as shown by manipulation experiments (Peñuelas *et al.*, 2004, 2007; Gao and Giorgi, 2008; Grime *et al.*, 2008; Shinoda *et al.*, 2010; Wu and Chen, 2013). In most temperate and arctic regions, the capacity to support richer (i.e. more diverse) communities is projected to increase with rising temperature, while decreases in water availability suggest a decline in capacity to support species-rich communities in most tropical and subtropical regions (Sommer *et al.*, 2010). Warming may cause an asymmetrical response of soil C and N cycles, causing N limitation that reduces acclimation in plant production (Beier *et al.*, 2008).

Some grasslands are exposed to elevated levels of nitrogen deposition, which alters species composition, increases primary production up to a point and decreases it thereafter (see Section 4.2.4.2; Bobbink *et al.*, 2010; Cleland and Harpole, 2010; Gaudnik *et al.*, 2011). In a study of 162 plots over 25 years, N deposition drove grassland composition at the local scale, in interaction with climate, whereas climate changes were the predominant driver at the regional scale (Gaudnik *et al.*, 2011). N mineralization in shrublands under either arid or wet conditions is more sensitive to periodic droughts than systems under more mesic conditions (Emmett *et al.*, 2004). Decreased tissue concentrations of phosphorus were also associated with warming and drought (Peñuelas *et al.*, 2004; Beier *et al.*, 2008; Peñuelas *et al.*, 2012). Strong interactions between warming and disturbances have been observed, leading to increased N leaching from shrubland ecosystems (Beier *et al.*, 2004).

Most grasslands and shrublands are characterized by relatively frequent but low-intensity fires, which affect their plant species composition and demographics (e.g., Gibson and Hulbert, 1987; Uys *et al.*, 2004; Gill *et al.*, 1999; de Torres Curth *et al.*, 2012). Species composition changes may be as important in determining ecosystem impacts as the direct effects of climate on plant (Suttle *et al.*, 2007). Fire frequency, duration and intensity are primarily influenced by climate and secondarily by management (Pitman *et al.*, 2007; Lenihan *et al.*, 2008; Archibald *et al.*, 2009; Giannakopoulos *et al.*, 2009; Armenteras-Pascual *et al.*, 2011), and are therefore sensitive to climate change; the duration of the fire season is also projected to broaden (Clarke *et al.*, 2013). Changes in fire frequency may interact with changes in rainfall seasonality: for instance, if fires are followed by rainy spring periods in in northwestern Patagonia, as occurs with more frequent ENSO phenomena, there are more recruitment windows for shrubs (Ghermandi *et al.*, 2010). Relatively little is known regarding the combined effect of climate change and increased grazing by large mammals, nor on the consequences for pastoral livelihoods that depend on rangelands (Thornton *et al.*, 2009).

4.3.3.2.3. Deserts

The deserts of the world, defined as land areas with an arid or hyperarid climate regime, occupy 35 % of the global land surface. Species composition in desert areas is expected to shift in response to climate warming (Ooi *et al.*, 2009; Kimball *et al.*, 2010), including night-time warming (Collins *et al.*, 2010). Deserts are sparsely populated, but the people who do live there are amongst the poorest in the world (Millennium Ecosystem Assessment, 2005a). There is *medium agreement* but *limited evidence* that the present extent of deserts will increase in the coming decades, despite the projected increase in rainfall at a global scale, as a result of the strengthening of the Hadley circulation which determines the location of the broad band of hot deserts approximately 15-30° N and S of the equator (Mitas and Clement, 2005; Seidel *et al.*, 2008; Johanson and Fu, 2009; Lu *et al.*, 2009; Zhou *et al.*, 2011). There may be a feedback to the global climate from an increase in desert extent, which differs in sign between deserts closer to the equator than 20° and those closer to the pole: in model simulations, extension of the near-equator 'hot deserts' causes warming, while extension of the near-boreal "cold deserts" causes cooling, in both cases largely through albedo-mediated effects (Alkama *et al.*, 2012). Deserts are expected to become warmer and drier at faster rates than other terrestrial regions (Lapola *et al.*, 2009; Stahlschmidt *et al.*, 2011). Most deserts are already extremely hot, and therefore further warming is likely to be physiologically injurious rather than beneficial. The ecological dynamics in deserts are rainfall event-driven (Holmgren *et al.*, 2006), often involving the concatenation of a number of quasi-independent events. Some desert tolerance mechanisms (e.g., biological adaptations by long-lived taxa) may be outpaced by global climate change (Lapola *et al.*, 2009; Stahlschmidt *et al.*, 2011).

4.3.3.2.4 Mediterranean-type ecosystems

Mediterranean-type ecosystems occur on most continents, and are characterised by cool, wet winters and hot, dry summers. They were identified as being among the most likely to be impacted by climate change in AR4 and received extensive coverage (Fischlin *et al.*, 2007). Since then, further evidence has accumulated of climate risks to these systems from rising temperature (Giorgi and Lionello, 2008), rainfall change (declining in most but not all cases), increased drought (Section 23.2.3, 25.2) and increased fire frequency (Section 23.4.4). There have been observed shifts in phenology (Gordo and Sanz, 2010), range contraction of Mediterranean species (Pauli *et al.*, 2012), declines in the health and growth rate of dominant tree species (Allen *et al.*, 2010a; Sarris *et al.*, 2011; Brouwers *et al.*, 2012; Section 23.4.4) and increased risk of erosion and desertification, especially in very dry areas (Lindner *et al.*, 2010; Shakesby, 2011). Model projections show further species range contractions in the 21st century under all climate change scenarios. This will result in losses of biodiversity (*medium confidence*) (Maiorano *et al.*, 2011; Kuhlmann *et al.*, 2012; 23.6.4, 25.1).

4.3.3.3. Rivers, Lakes, Wetlands, and Peatlands

Freshwater ecosystems are considered to be among the most threatened on the planet (Dudgeon *et al.*, 2006; Vörösmarty *et al.*, 2010). Fragmentation of rivers by dams and the alteration of natural flow regimes have led to major impacts on freshwater biota (Pringle, 2001; Bunn and Arthington, 2002; Nilsson *et al.*, 2005; Reidy Liermann *et al.*, 2012). Floodplains and wetland areas have become occupied for intensive urban and agricultural land use to the extent that many are functionally disconnected from their rivers (Tockner *et al.*, 2008). Pollution from cities and agriculture, especially nutrient loading, has resulted in declines in water quality and the loss of essential ecosystem services (Allan, 2004). As a direct consequence of these and other impacts, fresh waters have some of the highest rates of extinction of any ecosystem for those species groups assessed for the IUCN Red List (estimated as much as 4% per decade for some groups, such as crayfish, mussels, fishes and amphibians in North America) (Dudgeon *et al.*, 2006), with estimates that at least 10,000-20,000 freshwater species are extinct or imperilled as a consequence of human activity (Strayer and Dudgeon, 2010). This is a particular concern given that freshwater habitats support 6% of all described species (Dudgeon *et al.*, 2006), including approximately 40% of the world's fish diversity and a third of the vertebrate diversity (Balian *et al.*, 2008).

It is *very likely* that these stressors to freshwater ecosystems will continue to dominate as human demand for water resources grows, accompanied by increased urbanization and expansion of irrigated agriculture (Vörösmarty *et al.*, 2000; Malmqvist *et al.*, 2008; Dise, 2009). However, climate change will have significant additional impacts (*high confidence*), from altered thermal regimes, altered precipitation and flow regimes and, in the case of coastal wetlands, sea level rise. Specific aquatic habitats that are most vulnerable to these direct climate effects, especially rising temperatures, are those at high altitude and high latitude, including Arctic and subarctic bog communities on permafrost, and alpine and Arctic streams and lakes (see Section 4.3.3.4; Klanderud and Totland, 2005; Smith *et al.*, 2005; Smol and Douglas, 2007b). It is noteworthy that these high latitude systems currently experience a relatively low level of threat from other human activities (Vörösmarty *et al.*, 2010). It is *likely* that the shrinkage and disappearance of glaciers will lead to the reduction of local and regional freshwater biodiversity, with 11-38% of the regional macroinvertebrate species pool expected to be lost following complete disappearance of glaciers (Jacobsen *et al.*, 2012; CC-RF2). Shrinkage of glaciers and the loss of small glaciers will most likely reduce beta diversity at the species and the genetic level, as predicted for the Pyrenees (Finn *et al.*, 2013). Dryland rivers and wetlands, many already experiencing severe water stress from human consumptive use, are also *likely* to be further impacted by decreased and more variable precipitation and higher temperatures. Headwater stream systems in general are also vulnerable to the effects of warming because their temperature regimes closely track air temperatures (Caissie, 2006).

There is widespread evidence of rising stream and river temperatures over the past few decades (Langan *et al.*, 2001; Morrison *et al.*, 2002; Webb and Nobilis, 2007; Chessman, 2009; Ormerod, 2009; Kaushal *et al.*, 2010; van Vliet *et al.*, 2011; Markovic *et al.*, 2013– though see Arismendi *et al.*, 2012). Rising water temperature has been linked by observational and experimental studies to shifts in invertebrate community composition, including declines in cold stenothermic species (Brown *et al.*, 2007; Chessman, 2009; Durance and Ormerod, 2007; Ormerod, 2009). Rising temperature is also implicated in species range shifts (e.g., Comte and Grenouillet, 2013), implying changes in the composition of river fish communities (Daufresne and Boet, 2007; Buisson *et al.*, 2008; Comte *et al.*, 2013), especially in headwater streams where species are more sensitive to warming (e.g., Buisson and Grenouillet, 2009).

Rising temperatures in the well-mixed surface waters in many temperate lakes, resulting in reduced periods of ice formation (Livingstone and Adrian, 2009; Weyhenmeyer *et al.*, 2011) and earlier onset and increased duration and stability of the thermocline during summer (Winder and Schindler, 2004), are projected to favour a shift in dominance to smaller phytoplankton (Parker *et al.*, 2008; Winder *et al.*, 2009; Yvon-Durocher *et al.*, 2011) and cyanobacteria (Wiedner *et al.*, 2007; Jöhnk *et al.*, 2008; Paerl *et al.*, 2011), especially in those ecosystems experiencing high anthropogenic loading of nutrients (Wagner and Adrian, 2009); with impacts to water quality, food webs and productivity (O'Reilly *et al.*, 2003; Verburg *et al.*, 2003; Gyllström *et al.*, 2005; Parker *et al.*, 2008; Shimoda *et al.*, 2011). Prolonged stratification and associated anaerobic conditions near the sediment-water interface can increase the internal loading of phosphorus, particularly in eutrophic lakes (Søndergaard *et al.*, 2003; Wilhelm and Adrian, 2008; Wagner and Adrian, 2009).

In many freshwater ecosystems, the input of dissolved organic carbon through run-off from the catchment has increased, inducing changes in water colour (Hongve *et al.*, 2004; Evans *et al.*, 2005; Erlandsson *et al.*, 2008). Soil recovery from acidification and changed hydrological conditions (partly linked to increased precipitation) appear to be the main factors driving this development (Evans *et al.*, 2005; Monteith *et al.*, 2007). The resulting increased light attenuation can lead to lower algal concentrations and loss of submersed vegetation (Ask *et al.*, 2009; Karlsson *et al.*, 2009).

Emergent aquatic macrophytes *are likely* to expand their northward distribution and percentage cover in boreal lakes and wetlands, posing an increasing overgrowth risk for sensitive macrophyte species (Alahuhta *et al.*, 2011). Long-term shifts in macroinvertebrate communities have also been observed in European lakes where temperatures have increased (Burgmer *et al.*, 2007), noting that warming may increase species richness in smaller temperate water bodies, especially those at high altitude (Rosset *et al.*, 2010). While less studied, it has been proposed that tropical ectothermic ("cold blooded") organisms will be particularly vulnerable because they will approach critical maximum temperatures proportionately faster than species in high latitude environments, despite lower rates of warming (Deutsch *et al.*, 2008; Hamilton, 2010; Laurance *et al.*, 2011).

There is growing evidence that climate induced changes in precipitation will significantly alter ecologically important attributes of hydrologic regimes in rivers and wetlands, and exacerbate impacts from human water use in developed river basins (*high confidence* in detection, *medium confidence* in attribution, see Cross-Chapter Box CC-RF; Xenopoulos *et al.*, 2005; Aldous *et al.*, 2011). Freshwater ecosystems in Mediterranean-montane ecoregions (e.g., Australia, California and South Africa) are projected to experience a shortened wet season and prolonged, warmer summer season (Klausmeyer and Shaw, 2009), increasing the vulnerability of fish communities to drought (Magalhães *et al.*, 2007; Hermoso and Clavero, 2011) and floods (Meyers *et al.*, 2010). Shifts in hydrologic regimes in snow-melt systems, including earlier runoff and declining base flows in summer (Stewart *et al.*, 2005; Stewart, 2009), are projected to alter freshwater ecosystems, through changes in physical habitat and water quality (Bryant, 2009). Declining rainfall and increased inter-annual variability will most likely increase low-flow and dry-spell duration in dryland regions, leading to reduced water quality in remnant pools (Dahm *et al.*, 2003), reduction in floodplain egg- and seed-banks (Capon, 2007; Jenkins and Boulton, 2007), the loss of permanent aquatic refugia for fully aquatic species and water birds (Johnson *et al.*, 2005; Bond *et al.*, 2008; Sheldon *et al.*, 2010, altered freshwater food webs (Ledger *et al.*, 2013), and drying out of wetlands (Davis and Thompson, 2010).

Climate induced changes in precipitation will probably be an important factor altering peatland vegetation in temperate and boreal regions, with decreasing wetness during the growing season generally associated with a shift from a *Sphagnum* dominated to vascular plant dominated vegetation type and a general decline of C sequestration in the long term (Limpens *et al.*, 2008). Mire ecosystems (i.e. bogs, transition bogs and fens) in Central Europe face severe climate-induced risk, with increased summer temperatures being particularly important (Essl *et al.*, 2012). Decreased dry season precipitation and longer dry seasons in major tropical peatland areas in southeast Asia, are projected to result in lower water tables more often and for longer periods, with an increased risk of fire (Li *et al.*, 2007; Rieley *et al.*, 2008; Frolking *et al.*, 2011).

Peatlands contain large stocks of carbon that are vulnerable to change through land use and climate change. Although peatlands cover only about 3% of the land surface, they hold the equivalent of half of the atmosphere's carbon (as CO_2), or one third of the world's soil carbon stock (400-600 Pg) (Limpens *et al.*, 2008; Frolking *et al.*, 2011; Page *et al.*, 2011). About 14-20% of the world's peatlands are currently used for agriculture (Oleszczuk *et al.*, 2008) and many, particularly peat swamp forests in Southeast Asia, are undergoing rapid major transformations through drainage and burning in preparation for oil palm and other crops or through unintentional burning (Limpens *et al.*, 2008; Hooijer *et al.*, 2010). Deforestation, drainage and burning in Indonesian peat swamp forests can release 59.4 ± 10.2 Mg CO_2 $ha^{-1}.yr^{-1}$ over 25 years (Murdiyarso *et al.*, 2010), contributing significantly to global GHG emissions, especially during periods of intense drought associated with ENSO when burning is more common (Page *et al.*, 2002). Anthropogenic disturbance has changed peatlands from being a weak global carbon sink to a source (Frolking *et al.*, 2011), though inter-annual variability is large. Fluvial export can also be a significant contributor to carbon losses that has been largely overlooked to date, with recent estimates of DOC export from degraded tropical peatlands 50% higher than in intact systems (Moore *et al.*, 2013). Conserving peatland areas not yet developed for biofuels or other crops, or re-wetting and restoring degraded peatlands to preserve their carbon store are potential mitigation strategies.

Sea level rise will lead to direct losses of coastal wetlands with associated impacts on water birds and other wildlife species dependent on fresh water (BMT WBM, 2010; Pearlstine *et al.*, 2010; Traill *et al.*, 2010), but the impact will probably be relatively small compared with the degree of direct and indirect human-induced destruction (Nicholls, 2004). River deltas and associated wetlands are particularly vulnerable to rising sea level, and this threat is further compounded by trapping of sediment in reservoirs upstream and subsidence from removal of oil, gas and water

(Syvitski *et al.*, 2009; see Section 5.4.2.7). Lower river flows might exacerbate the impact of sea level rise and thus salinization on freshwater ecosystems close to the ocean (Ficke *et al.*, 2007).

4.3.3.4. Tundra, Alpine, and Permafrost Systems

The High Arctic region, with tundra-dominated landscapes, has warmed more than the global average over the last century (Kaufman *et al.*, 2009; see WGI AR5 Chapter 2). Changes consistent with warming are evident in the freshwater and terrestrial ecosystems and permafrost of the region (Hinzman *et al.*, 2005; Axford *et al.*, 2009; Jia *et al.*, 2009b; Post *et al.*, 2009; Prowse and Brown, 2010; Romanovsky *et al.*, 2010; Walker *et al.*, 2012). Most of the Arctic has experienced recent change in vegetation photosynthetic capacity, particularly adjacent to rapidly retreating sea ice (Bhatt *et al.*, 2010). Changes in terrestrial environments in Antarctica have also been reported. Vieira *et al.* (2010) show that in in the Maritime Antarctic permafrost temperatures are close to thaw. Permafrost warming in has been observed in continental Antarctica (Guglielmin and Cannone, 2012) and for the Palmer archipelago (Bockheim *et al.*, 2013).

Continued warming is projected to cause the terrestrial vegetation and lake systems of the Arctic to change substantially (*high confidence).* Continued expansion in woody vegetation cover in tundra regions over the 21st century is projected by the CMIP5 Earth System Models (Bosio *et al.*, 2012; see WGI AR5 Chapter 6); by dynamic global vegetation models driven by other climate model projections; and by observationally-based statistical models (Pearson *et al.*, 2013). Changes may be complex (see Box 4-4) and in some cases involve non-linear and threshold responses to warming and other climatic change (Hinzman *et al.*, 2005; Mueller *et al.*, 2009b; Bonfils *et al.*, 2012). Arctic vegetation change is expected to continue long after any stabilization of global mean temperature (see WGI AR5 Chapter 6; Falloon *et al.*, 2012). In some regions, reduced surface albedo due to increased vegetation cover is projected to cause further local warming even in scenarios of stabilized greenhouse gas concentrations (Falloon *et al.*, 2012).

In the Arctic tundra biome (in contrast to the boreal forests discussed in Section 4.3.3.1.1) vegetation productivity has systematically increased over the past few decades in both North America and northern Eurasia (Goetz *et al.*, 2007; Stow *et al.*, 2007; Jia *et al.*, 2009b; de Jong *et al.*, 2011; Myers-Smith *et al.*, 2011; Elmendorf *et al.*, 2012). This phenomenon is amplified by retreat of coastal sea ice (Bhatt *et al.*, 2010) and has been widely discussed in the context of increased shrub growth and expansion over the last half century (Forbes *et al.*, 2010; Myers-Smith *et al.*, 2011). Deciduous shrubs and graminoids respond to warming with increased growth (Walker, 2006; Epstein, 2008; Euskirchen *et al.*, 2009; Lantz *et al.*, 2010). Analyses of satellite time series data show the increased productivity trend is not unique to shrub-dominated tundra areas (Jia *et al.*, 2009b; Beck and Goetz, 2011), thus greening is a response shared by multiple vegetation communities and continued changes in the tundra biome can be expected irrespective of shrub presence. The very large spatial scale over which these changes are occurring, the strong warming signal over much of the Arctic for the last five decades (Burrows et al. 2011) and the absence of strong confounding factors means that detection these changes in Arctic systems and their attribution to global warming can be made with *high confidence*, despite the relatively short time frame of most observations (Figure 4-4).

Shrub expansion and height changes are particularly important because they trap snow, mediate winter soil temperature and summer moisture regimes, increase nutrient mineralization, and produce a positive feedback for additional shrub growth (Sturm *et al.*, 2005; Lawrence *et al.*, 2007; Bonfils *et al.*, 2012). Although increased shrub cover and height produce shadowing that reduce ground heat flux and active layer depth, they also reduce surface albedo, increase energy absorption and evapotranspiration (Chapin III *et al.*, 2005; Blok *et al.*, 2010), and produce feedbacks that reinforce shrub densification and regional warming (Lawrence and Swenson, 2011; Bonfils *et al.*, 2012). On balance, these feedbacks can act to partially offset one another, but when coupled with warmer and wetter conditions they act to increase active layer depth and permafrost thaw (Yi *et al.*, 2007; Bonfils *et al.*, 2012).

The Arctic tundra biome is experiencing increasing fire disturbance and permafrost degradation. Both of these processes facilitate conditions for woody species establishment in tundra areas, either through incremental migration or via more rapid long-distance dispersal to areas reinitialized by burning (Epstein *et al.*, 2007; Goetz *et al.*, 2011). When already present at the boreal-tundra ecotone, shrub and tree species show increased productivity with warmer conditions (Devi *et al.*, 2008; Andreu-Hayles *et al.*, 2011; Elmendorf *et al.*, 2012). Tundra fires not only emit large quantities of combusted carbon formerly stored in vegetation and organic soils (Mack *et al.*, 2011; Rocha and Shaver, 2011), but also increase active layer depth during summer months (Racine *et al.*, 2004; Liljedahl *et al.*, 2007; Jorgenson *et al.*, 2010), produce landforms associated with thawing of ice-rich permafrost, and can create conditions that alter vegetation succession (Racine *et al.*, 2004; Lantz *et al.*, 2009; Higuera *et al.*, 2011).

It is *virtually certain* that the area of Northern Hemisphere permafrost will continue to decline over the first half of the 21st century (see WGI Chapter 12) in all RCP scenarios (Figure 4-9; Caesar *et al.*, 2013; Koven *et al.*, 2013). In the RCP2.6 scenario of an early stabilization of CO_2 concentrations, the permafrost area is projected to stabilize at a level approximately 20% below the 20th century area, and then begin a slight recovering trend. In RCP4.5, in which CO_2 concentration is stabilized at approximately 550ppmv by the mid-21st century, the simulations that extend beyond 2100 show permafrost continuing to decline for at least another 250 years. In the RCP8.5 scenario of ongoing CO_2 rise, the permafrost area is simulated to approach zero by the middle of the 22nd century in simulations that extend beyond 2100. RCP8.5 simulations that ended at 2100 showed continued permafrost decline in the late 21st century, although at slower rates in some cases as the remaining permafrost area decreases (Figure 4-9.).

[INSERT FIGURE 4-9 HERE
Figure 4-9: CMIP5 multi-model simulated area of Northern Hemisphere permafrost in the upper 3m of soil, from 1850 to 2100 or 2300 depending on extent of individual simulations. Each panel shows historical (1850-2005) and projected (2005 to 2100 or 2300) simulations for (a) RCP2.6, (b) RCP4.5, and (c) RCP8.5. The observed current permafrost extent is 15×10^6 km^2. (Based on Koven *et al.*, 2013, with analysis extended to 2300 following Caesar *et al.*, 2013).]

Frozen soils and permafrost currently hold about 1700 PgC, more than twice the carbon than the atmosphere, and thus represent a particularly large vulnerability to climate change (i.e., warming) (see WGI AR5 Chapter 6). Although the Arctic is currently a net carbon sink, continued warming will act to turn the Arctic to a net carbon source, that will in turn create a potentially strong positive feedback to accelerate Arctic (and global) warming with additional releases of CO_2, CH_4, and perhaps N_2O, from the terrestrial biosphere into the atmosphere (*high confidence*, Schuur *et al.*, 2008; Schuur *et al.*, 2009; Maslin *et al.*, 2010; McGuire *et al.*, 2010; O'Connor *et al.*, 2010; Schaefer *et al.*, 2011; see WGI AR5 Chapter 6 for detailed treatment of biogeochemistry, including feedbacks). Moreover, this feedback is already accelerating due to climate-induced increases in fire (McGuire *et al.*, 2010; O'Donnell *et al.*, 2011). The rapid retreat of snow cover and resulting spread of shrubs and trees into areas currently dominated by tundra has begun, and will continue to serve as a positive feedback accelerating high latitude warming (Chapin III *et al.*, 2005; Bonfils *et al.*, 2012).

There is *medium confidence* that rapid change in the Arctic is affecting its animals. For example, seven of 19 sub-populations of the polar bear are declining in number, while four are stable, one is increasing and the remaining seven have insufficient data to identify a trend (Vongraven and Richardson, 2011). Declines of two of the sub-populations are linked to reductions in sea ice (Vongraven and Richardson, 2011). Polar bear populations are projected to decline greatly in response to continued Arctic warming (Hunter *et al.*, 2010; Stirling and Derocher, 2012), and it is expected that the populations of other Arctic animals will be affected dramatically by climate change, often in complex, but potentially dramatic ways (e.g., Post *et al.*, 2009; Sharma *et al.*, 2009; Gallant *et al.*, 2012; Gilg *et al.*, 2012; Post and Brodie, 2012; Gauthier *et al.*, 2013; Nielsen and Wall, 2013; Prost *et al.*, 2013; White *et al.*, 2013). Simple niche-based, or climatic envelope models have difficulty in capturing the full complexity of these future changes (MacDonald, 2010).

There is *high confidence* that alpine systems are already showing a high sensitivity to on-going climate change and will be highly vulnerable to change in the future. In western North America, warming, glacier retreat, snowpack decline and drying of soils is already causing a large increase in mountain forest mortality and wildfire, plus other ecosystem impacts (e.g., Westerling *et al.*, 2006; Crimmins *et al.*, 2009; van Mantgem *et al.*, 2009; Pederson *et al.*, 2010; Muhlfeld *et al.*, 2011; Brusca *et al.*, 2013; Williams *et al.*, 2013), and disturbance will continue to be an important agent of climate-induced change in this region (Littell *et al.*, 2010). Globally, tree line altitude appears to be changing, although not always in simple ways (Harsch *et al.*, 2009; Tingley *et al.*, 2012) and may sometimes be due to factors not related to climate change (Schwilk and Keeley, 2012). Responses to climate change in high-altitude ecosystems are taking place in Africa, Asia, Europe and elsewhere (Yasuda *et al.*, 2007; Cannone *et al.*, 2007, Cannone *et al.*, 2008; Lenoir *et al.*, 2008; Britton *et al.*, 2009; Chen *et al.*, 2009; Cui and Graf, 2009; Normand *et al.*, 2009; Allen *et al.*, 2010a; Eggermont *et al.*, 2010; Lenoir *et al.*, 2010; Chen *et al.*, 2011; Engler *et al.*, 2011; Kudo *et al.*, 2011; Laurance *et al.*, 2011; Dullinger *et al.*, 2012). For example, in a study of permanent plots from 1994 to 2004 in the Austrian high Alps, a range contraction of subnival to nival plant species was indicated at the downslope edge, and an expansion of alpine pioneer species at the upslope edge (Pauli *et al.*, 2007). Thermophilous vascular plant species were observed to colonize in alpine mountain-top vegetation across Europe during the past decade (Gottfried *et al.*, 2012). As with the Arctic, permafrost thawing in alpine systems could provide a strong positive feedback (e.g., Tibet; Cui and Graf, 2009).

Box 4-4. Boreal – Tundra Biome Shift

Changes in a suite of ecological processes currently underway across the broader arctic region are consistent with Earth system model predictions of climate-induced geographic shifts in the range extent and functioning of the tundra and boreal forest biomes (Figure 4-10). Until now, these changes have been gradual shifts across temperature and moisture gradients, rather than abrupt. Responses are expressed through gross and net primary production, microbial respiration, fire and insect disturbance, vegetation composition, species range expansion and contraction, surface energy balance and hydrology, active layer depth and permafrost thaw, and a range of other inter-related variables. Because the high northern latitudes are warming more rapidly than other parts of the Earth, due at least in part to arctic amplification (Serreze and Francis, 2006), the rate of change in these ecological processes are sufficiently rapid that they can be documented *in situ* (Hinzman *et al.*, 2005; Post *et al.*, 2009; Peng *et al.*, 2011; Elmendorf *et al.*, 2012) as well as from satellite observations (Goetz *et al.*, 2007; Beck *et al.*, 2011b; Xu *et al.*, 2013) and captured in Earth system models (McGuire *et al.*, 2010).

Gradual changes in composition resulting from decreased evergreen conifer productivity and increased mortality, as well as increased deciduous species productivity, can be facilitated by more rapid shifts associated with fire disturbance where it can occur (Mack *et al.*, 2008; Johnstone *et al.*, 2010; Roland *et al.*, 2013). Each of these interacting processes, as well as insect disturbance and associated tree mortality, are tightly coupled with warming-induced drought (Choat *et al.*, 2012; Ma *et al.*, 2012; Anderegg *et al.*, 2013a). Similarly, gradual productivity increases at the boreal-tundra ecotone are facilitated by long distance dispersal into areas disturbed by tundra fire and thermokarsting (Tchebakova *et al.*, 2009; Brown, 2010; Hampe, 2011). In North America these coupled interactions set the stage for changes in ecological processes, already documented, consistent with a biome shift characterized by increased deciduous composition in the interior boreal forest and evergreen conifer migration into tundra areas that are, at the same time, experiencing increased shrub densification. The net feedback of these ecological changes to climate is multi-faceted, complex, and not yet well known across large regions except via modelling studies, which are often poorly constrained by observations.

[INSERT FIGURE 4-10 HERE
Figure 4-10: Tundra-Boreal Biome Shift. Earth system models predict a northward shift of Arctic vegetation with climate warming, as the boreal biome migrates into what is currently tundra. Observations of shrub expansion in tundra, increased tree growth at the tundra-forest transition, and tree mortality at the southern extent of the boreal forest in recent decades are consistent with model projections. Vegetation changes associated with a biome shift, which is facilitated by intensification of the fire regime, will modify surface energy budgets, and net ecosystem carbon balance, permafrost thawing and methane emissions, with net feedbacks to additional climate change.]

_____ END BOX 4-4 HERE _____

4.3.3.5. Highly Human-Modified Systems

About a quarter of the land surface is now occupied by ecosystems highly modified by human activities. In this section we assess the vulnerability to climate change only of those modified systems not dealt with elsewhere, i.e. excluding agriculture (Chapter 7), freshwater fisheries (Chapter 3) and urban areas (Chapter 8).

4.3.3.5.1. Plantation forestry

Plantation forests are established through afforestation or reforestation, often with tree crop replacement (Dohrenbusch and Bolte, 2007; FAO, 2010). They differ from natural or semi-natural forests (Section 4.3.3.1) by generally being even-aged, having a reduced species diversity (sometimes of non-native species) and being dedicated to the production of timber, pulp and/or bioenergy. Plantation forests contribute 7% to the global forest area (FAO, 2010), an increase of five million ha between 2000 and 2010 (FAO, 2010). Most recent plantations have been established by afforestation of non-forest areas in the tropics and subtropics and some temperate regions, particularly China (Kirilenko and Sedjo, 2007; FAO, 2010) Afforestation usually results in net CO_2 uptake from the atmosphere (Canadell and Raupach, 2008; Van Minnen *et al.*, 2008) but does not necessarily result in a reduction in global warming (Bala *et al*., 2007; see Section 4.3.4.5).

Growth rates in plantation forests have generally increased during the last decades but the variability is large. In forests that are not highly water-limited, increased growth is consistent with higher temperatures and extended growing seasons. As in the case of forests in general, clear attribution is difficult because of the interaction of multiple environmental drivers as well as changes in forest management (e.g., Boisvenue and Running, 2006; Ciais *et al.*, 2008; Dale *et al.*, 2010; see also Section 4.3.3.1). In Europe much of the increase has been attributed to recovery following previously more intense harvesting (Ciais *et al.*, 2008; Lindner *et al.*, 2010).

Several studies using forest yield models suggest future increases in forest production (Kirilenko and Sedjo, 2007). These results may over-estimate the positive effects of elevated CO_2 (Kirilenko and Sedjo, 2007; see Section 4.2.4.4). The effects of disturbances such as wildfires, forest pests, pathogens and windstorms, which are major drivers of forest dynamics, are poorly represented in the models (Loustau, 2010; see also Section 4.3.3.1 and Box 4-2). The results from different models often differ substantially both regarding forest productivity (e.g., Sitch *et al.*, 2008; Keenan *et al.*, 2011) and potential species ranges (see Section 4.3.3.1.2). Decreased forest production is expected in already-dry forest regions for which further drying is projected, such as the south-western U.S. (Williams *et al.*, 2010b). Extreme drying may also decrease yields in forests currently not water-limited (e.g., Sitch *et al.*, 2008; see Section 4.3.3.1). Plantations in cold-limited areas could benefit from global warming, provided that increased fires, storms, pests and pathogens do not outweigh the potential direct climate effects on tree growth rates.

Low species diversity (and low genetic diversity within species where clones or selected provenances are used) renders plantation forests less resilient to climate change than natural forests (e.g., Hemery, 2008). Choosing provenances that are well adapted to current climates but pre-adapted to future climates is difficult because of uncertainties in climate projections at the timescale of a plantation forest rotation (Broadmeadow *et al.*, 2005). How forest pests and pathogens will spread as a result of climate change and other factors is highly uncertain. New pathogen-tree interactions may arise (e.g., Brasier and Webber, 2010). Adaptive management can decrease the vulnerability of plantation forests to climate change (Hemery, 2008; Bolte *et al.*, 2009; Seppälä, 2009; Dale *et al.*, 2010). For example, risk spreading by promoting mixed stands, containing multiple species or provenances, combined with natural regeneration (Kramer *et al.*, 2010), has been advocated as an adaptation strategy for temperate forests (Hemery, 2008; Bolte *et al.*, 2010) and tropical forests (Erskine *et al.*, 2006; Petit and Montagnini, 2006). Incomplete knowledge of the ecology of tropical tree species and little experience in managing mixed tropical tree plantations remains a problem (Hall *et al.*, 2011). Especially at the equator-ward limits of cold-adapted species, such as Norway spruce (*Picea abies*) in Europe, climate change will *very likely* lead to a shift in the main tree species used for forest plantations (Iverson *et al.*, 2008; Bolte *et al.*, 2010).

4.3.3.5.2. Bioenergy systems

The production of modern bioenergy is growing rapidly throughout the world in response to climate mitigation and energy security policies (Cochrane and Barber, 2009). WGIII AR5 Chapter 7 addresses the potential of bioenergy as a climate mitigation strategy. The vulnerability of bioenergy systems to climate change is similar to that of plantation forestry (Section 4.3.3.5.1) or food crops (Section 7.3): in summary, they remain viable in the future in most but not all locations, but their viability is increasingly uncertain for high levels of climate change (Ma and Zhou, 2012). Oliver *et al.* (2009a) suggested that rising CO_2 might contribute to increased drought tolerance in bioenergy crops (since it leads to improved plant water use efficiency).

The unintended consequences of large-scale land-use changes driven by increasing bioenergy demand are addressed in Section 4.4.4.

4.3.3.5.3. Cultural landscapes

Cultural landscapes are characterized by a long history of human-nature interactions, which results in a particular configuration of species and landscape pattern attaining high cultural significance (Rössler, 2006). Examples are grassland or mixed agriculture landscapes in Europe, rice landscapes in Asia (Kuldna *et al.*, 2009) and many others across the globe (e.g., Rössler, 2006; Heckenberger *et al.*, 2007). Such landscapes are often agricultural, but we deal with them here because their perceived value is only partly in terms of their agricultural products.

It has been suggested that protected area networks (such as Natura 2000 in Europe, which includes many cultural landscape elements) be adjusted to take into account climate change (Jin *et al.*, 2010; Heubes *et al.*, 2011). Conserving species in cultural landscapes (e.g., EU Council, 1992) generally depends on maintaining certain types of land use. Doing so under climate change requires profound knowledge of the systems and species involved, and conservation success so far has been limited (see Kirdyanov *et al.*, 2012 for a notable exception). Understanding the relative importance of climate change and land management change is critical (Settele and Kühn, 2009). To date land use changes have been the most obvious driver of change (Nowicki *et al.*, 2007); impacts have been attributed climate change (with *low* to *medium confidence*) in only a few examples (Devictor *et al.*, 2012). Even in these, combined land use-climate effects explain the pattern of observed threats better than either alone (Schweiger *et al.*, 2008; Clavero *et al.*, 2011; Schweiger *et al.*, 2012).

There is *very high confidence* that species composition and landscape structure are changing in cultural landscapes such as Satoyama landscapes in Japan or mixed forest, agricultural landscapes in Europe. Models and experiments suggest that climate change should be contributing to these observed changes. The land use and land management signal is so strong in these landscapes, that there is *very low confidence* that we can attribute these observations to climate change (Figure 4-4).

4.3.3.5.4. Urban ecosystems

Although urban areas (for definition see Section 8.1.2) cover only 0.5 % of Earth's land surface (Schneider *et al.*, 2009), over half of humanity lives there (increasing annually by 74 million people; United Nations *et al.*, 2012) and they harbour a large variety of species (McKinney, 2008). The frequency and magnitude of warm days and nights (heat waves) is *virtually certain* to increase globally the future it (IPCC, 2012); this trend is higher in urban than rural areas (Leonelli *et al.*, 2011). Heavy rainfall events are also projected to increase (IPCC, 2012), and although the hydrological conditions in urban areas make them prone to flooding *(medium confidence)*, there is *limited evidence* that they will be over-proportionally affected. It is *very likely* that sea level rise in future will contribute to flooding, erosion and salinisation of coastal urban ecosystems (IPCC, 2012). Climate change is projected to increase the frequency of landslides (UN Habitat, 2011). Climate change impacts on urban ecosystems and biodiversity have received comparatively little attention, with water availability being an exception (Hunt and Watkiss, 2011). Changes in water availability and quality either due to changes in precipitation, evaporation or in salinity regimes will especially affect urban freshwater ecosystems (Hunt and Watkiss, 2011). As in other ecosystems, climate change will leaded to a change in species composition, the frequency of traits and ecosystem services from urban ecosystems. Knapp *et al.* (2008b) found that trait composition of plant communities changes during urbanization towards adaptive characteristics of dry and warm environments (see also Sections 4.2.4.6 and 4.3.2.5). Urban areas are one of the main points of introduction of alien species (e.g., for plants through urban gardening; Li *et al.*, 2009). Increased damage by phytophagous insects to plants in urban environments is anticipated (Kollár *et al.*, 2009; Lopez-Vaamonde *et al.*, 2010; Tubby and Webber, 2010; see also Section 8.2.4.5).

4.3.4. Impacts on Key Ecosystem Services

Ecosystem services are the benefits which people derive from ecosystems (see glossary). Many ecosystem services are plausibly vulnerable to climate change. The Millennium Ecosystem Assessment classification (Millennium Ecosystem Assessment, 2003) recognises *provisioning services* such as food (Chapter 7), fibre (Section 4.3.4.2), bioenergy (Section 4.3.4.3) and water (Chapter 3); *regulating services* such as climate regulation (Section 4.3.4.5), pollination, pest and disease control (Section 4.3.4.4) and flood control (Chapter 3); *supporting services* such as primary production (Section 4.3.2.2) and nutrient cycling (Section 4.2.4.2, and indirectly Section 4.3.2.3); and *cultural services*, including recreation, aesthetic and spiritual benefits (Section 10.6). The following section focusses on ecosystem services not already covered in the sections referenced above.

4.3.4.1. Habitat for Biodiversity

Climate change can alter habitat for species by inducing: i) shifts in habitat distribution that are not followed by species, ii) shifts in species distributions that move them outside of their preferred habitats, and, iii) changes in habitat quality (Dullinger *et al.*, 2012; Urban *et al.*, 2012). Climate change impacts on habitats for biodiversity are already occurring (see the polar bear example in Section 28.2.2.1.3) but are not yet a widespread phenomenon. Models of future climate change-induced shifts in the distribution of ecosystems suggest that many species could be outside of their preferred habitats with the next few decades (Urban *et al.*, 2012; see Sections 4.3.2.5, 4.3.3, and Figure 4-1).

Hole *et al.* (2009) report that the majority of African birds would have to move large distances (up to several hundred kilometres) over the next 60 years (under SRES B2a), resulting in substantial turnover of species within protected areas (>50% turnover in more than 40% of Important Bird Areas of Africa). In order to reach suitable climates they will have to migrate across unfavourable habitats. Many may continue to find suitable climate within the protected area network, but will be forced to cope with new habitat constraints (Hole *et al.*, 2009). Araujo *et al.* (2011) estimate that by 2080 approximately 60% (58 ± 2.6%) of plants and vertebrate species will no longer have favourable climates within European protected areas, often pushing them into unsuitable or less preferred habitats (based on SRES A1, A2, B1 and A1FI scenarios). Wiens *et al.* (2011) project similar effects in the western US (until the year 2069, based on SRES A2 scenarios), but also find that climate change may open up new opportunities for protecting species in areas where climate is currently unsuitable. In some cases climate change may allow species to move into areas of lower current or future land use pressure including protected areas (Bomhard *et al.*, 2005). These studies strongly argue for a rethinking of protected areas networks and of the importance of the habitat matrix outside of protected areas as a key to migration and long-term survival of species (see Sections 4.4.2.2 and 4.4.2.3).

In the long term, some habitat types may disappear entirely due to climate change (see Section 4.3.3 and Figure 4-1). Climates are projected to occur in the future which at least in some features do not represent climates that existed in the past (Williams *et al.*, 2007b; Wiens *et al.*, 2011), and in the past climate shifts have resulted in vegetation types that have no current analogue (Section 4.2.3). The impacts of habitat change on species abundance and extinction risk is difficult to evaluate because at least some species are able to adapt to novel habitats (Prugh *et al.*, 2008; Oliver *et al.*, 2009b). The uncertainty in habitat specificity is one reason why quantitative projection of changes in extinction rates is difficult (Malcolm *et al.*, 2006).

The effects of climate change on habitat quality are less well studied than shifts in species or habitat distributions. Several recent studies indicate that climate change may have altered habitat quality already and will continue to do so (Iverson *et al.*, 2011; Matthews *et al.*, 2011). For example, decreasing snowfall in the southwestern US has negatively affected the habitat for songbirds (Martin and Maron, 2012).

4.3.4.2. Timber and Pulp Production

In most areas with forest plantations, forest growth rates have increased during the last decades, but the variability is large, and in some areas production has decreased (see Section 4.3.3.1). In forests that are not highly water-limited, these trends are consistent with higher temperatures and extended growing seasons, but, as in the case of forests in general, clear attribution is difficult because many environmental drivers and changes in forest management interact (e.g., Boisvenue and Running, 2006; Ciais *et al.*, 2008; Dale *et al.*, 2010; see also Section 4.3.3.1). In Europe a reduction in harvesting intensity has contributed (Ciais *et al.*, 2008; Lindner *et al.*, 2010).

Forest yield models project future increases in forest production under climate change, perhaps over-optimistically (Kirilenko and Sedjo, 2007; see Section 4.2.4.4. Using a model that accounts for fire effects and insect damage, Kurz *et al.* (2008) showed that the Canadian forest sector may have transitioned from a sink to a source of carbon.

4.3.4.3. Biomass-derived Energy

Bioenergy sources include traditional forms such as wood and charcoal from forests (see Section 4.3.3.1) and more modern forms such as the industrial burning of biomass wastes, the production of ethanol and biodiesel and plantations of bioenergy crops. While traditional biofuels have been in general decline as users switch to fossil fuels or electricity, they remain dominant energy sources in many less-developed parts of the world, such as Africa, and retain a niche in developed countries. Generally, potentials of bioenergy production under climate change may be high, but are very uncertain (Ma and Zhou, 2012).

4.3.4.4. Pollination, Pest, and Disease Regulation

It can be inferred that global change will result in new communities (Gilman *et al.*, 2010; Schweiger *et al.*, 2010). As these will have had little opportunity for coevolution, changes in ecological interactions, such as shifts herbivore diets, the range of prey of predators or in pollination networks are to be expected (Tylianakis *et al.*, 2008; Schweiger *et al.*, 2012). This may result in temporarily reduced effectiveness of the "regulating services", which generally depend on species interactions (Montoya and Raffaelli, 2010). Burkle *et al.* (2013) show that the loss of species reduces co-occurrence of interacting species and thus reduces ecosystem functions based on them.

Climate change tends to increase the abundance of pest species, particularly in previously cooler climates, but assessments of changes in impacts are hard to make (Payette, 2007). Insect pests are directly influenced by climate change, e.g. through a longer warm season during which to breed, and indirectly e.g. through the quality of food plants (Jamieson *et al.*, 2012) or *via* changes in their natural enemies (predators and parasitoids). Insects have well-defined temperature optima; warming towards the optimum leads to increased vitality and reproduction (Allen *et al.*, 2010a). Mild winters in temperate areas promote pests formerly controlled by frost sensitivity. For the vast majority of indirect effects, information is scarce. Further assessments of climate change effects on pest and disease dynamics are found in Sections 7.3.2.3 for agricultural pests and 11.5.1 for human diseases.

Climate change has severe negative impacts on pollinators (including honeybees) and pollination (Kjøhl *et al.*, 2011) (*medium confidence*). After land-use changes, climate change is regarded as the second most relevant factor responsible for the decline of pollinators (Potts *et al.*, 2010; for other factors see Biesmeijer *et al.*, 2006; Brittain *et al.*, 2010a; Brittain *et al.*, 2010b). The potential influence of climate change on pollination can be manifold (compare Hegland *et al.*, 2009; Schweiger *et al.*, 2010; Roberts *et al.*, 2011). There are a few observational studies, which mostly relate to the phenological de-coupling of plants and their pollinators (Gordo and Sanz, 2005; Bartomeus *et al.*, 2011). While Willmer (2012) states, based on experimental studies, that phenological effects may be less important than has been suggested, an analysis of phenological observations in plants by Wolkovich *et al.* (2012) shows that experimental data on phenology may grossly underestimate the actual phenological shifts.

Le Conte and Navajas (2008) state that the generally observed decline in honeybees is a clear indication of an increasing susceptibility to global change phenomena, with pesticide application, new diseases and stress (and a combination of these) as the most relevant causes. Climate change may contribute by modifying the balance between honeybees and their environment (including exposure or susceptibility to diseases). Honeybees show a high capacity to adjust to a variety of environments; their high genetic diversity should allow them to also cope with climatic change (Bartomeus *et al.*, 2011). The preservation of genetic variability within honeybees is regarded as a key adaptation strategy for pollination services (Le Conte and Navajas, 2008).

4.3.4.5. Moderation of Climate Change, Variability, and Extremes

The focus of this section is on processes operating at regional to global scales, rather than the well-known microclimatic benefits of ecosystems in smoothing day-night temperature variations and providing local evaporative cooling. In the decade 2000-2009, the global net uptake of CO_2 by terrestrial ecosystems was a large fraction of the anthropogenic CO_2 emissions to the atmosphere from all sources, reducing the rate of climate change proportionately (Section 4.3.2.3; WGI AR5 Section 6.3.2).

Afforestation or reforestation are a potential climate mitigation options (Van Minnen *et al.*, 2008; Vaughan and Lenton, 2011; Fiorese and Guariso, 2013; Singh *et al.*, 2013), but as discussed in Section 4.2.4.1, the net effect of afforestation on the global climate is mixed and context-dependent. Wickham *et al.* (2012) found significant positive correlations between the average annual surface temperature and the proportion of forest in the landscape and conclude that the climate benefit of temperate afforestation is unclear. Where low-albedo forest canopies replace higher-albedo surfaces such as soil, grassland or snow, the resultant increase in net radiative forcing counteracts the benefits of carbon sequestration to some degree (Arora and Montenegro, 2011). Where the cloud cover fraction is low and the albedo difference is large, i.e. outside the humid tropics, the long-term net result of afforestation can be global warming (Bala *et al.*, 2007; Bathiany *et al.*, 2010; Schwaiger and Bird, 2010). Accounting for changes in albedo and indirect greenhouse effects are not currently required in the formal rules for quantifying for the climate effects of land use activities (Schwaiger and Bird, 2010; Kirschbaum *et al.*, 2012). There are potential negative tradeoffs between afforestation for climate mitigation purposes and other ecosystem services, such as water supply (Jackson *et al.*, 2005) and biodiversity maintenance (CBD, 2012; Russell *et al.*, 2012).

It has been suggested (Ridgwell *et al.*, 2009) that planting large areas of crop varieties with highly reflective leaves could help mitigate global change. Model analyses indicate this “geo-engineering” strategy would be marginally effective at high latitudes, but have undesirable climate consequences at low latitudes. Measurements of leaf albedo in major crops show that the current range of variability is insufficient to make a meaningful difference to the global climate (Doughty *et al.*, 2011).

4.4. Adaptation and its Limits

4.4.1. Autonomous Adaptation by Ecosystems and Wild Organisms

Autonomous adaptation (see glossary under adaptation) refers to the adjustments made by ecosystems, including their human components, without external intervention, in response to a changing environment (Smit *et al.*, 2000); also called “spontaneous adaptation” (Smit *et al.*, 2007). In the context of human systems it is sometimes called “coping capacity”. The capacity for autonomous adaptation is part of resilience but is not exactly synonymous (Walker *et al.*, 2004).

All social and ecological systems have some capacity for autonomous adaptation. Ecosystems which have persisted for a long time can reasonably be inferred to have a high capacity for autonomous adaptation, at least with respect to the variability which they have experienced in the past. An environmental change that is more rapid than in the past or is accompanied by other stresses may exceed the previously-demonstrated adaptive capacity of the system. Adaptation at one level, for instance by organisms in a community, can confer greater resilience at higher organization levels, such as the ecosystem (Morecroft *et al.*, 2012). The mechanisms of autonomous adaptation of organisms and ecosystems consist of changes in the physiology, behaviour, phenology or physical form of organisms, within the range permitted by their genes and the variety of genes in the population; changes in the genetic composition of the populations; and change in the composition of the community, through in- or out-migration, or local extinction.

The ability to project impacts of climate change on ecosystems is complicated by the potential for species to adapt. Adaptation by individual species increases their ability to survive and flourish under different climatic conditions, possibly leading to lower risks of extinction than predicted from statistical correlations between current distribution and climate (Botkin *et al.*, 2007). It may also affect their interactions with other species leading to disruption of the biotic community (Visser and Both, 2005).

4.4.1.1. Phenological

Changes in phenology are occurring in many species and locations (Section 4.3.2.1). Further evidence since AR4 shows how this can be an adaptation to climate change, but also the limits to phenological adaptation. An organism's phenology is typically highly adapted to the climate seasonality of the environment in which it evolved. Species unable to adjust their phenological behaviour will be negatively affected, particularly in highly seasonal habitats (Both *et al.*, 2010).

Moreover, the phenology of any species also needs to be keyed to the phenology of other species with which it interacts, such as competitors, food species and pollinators. Systematic cross-taxa studies indicate different rates of phenological change for different species and trophic levels (Parmesan, 2007; Cook *et al.*, 2008; Thackeray *et al.*, 2010). If adaptation is insufficiently rapid or coordinated between interdependent species, disruption of ecological features such as trophic cascades, competitive hierarchies, and species coexistence is inferred to result (Nakazawa and Doi, 2012). Lack of coordination can occur if one of the species is cued to environmental signals that are not affected by climate change, such as day length (Parmesan, 2006). Increasing temperatures may either bring species more into or out of synchrony, depending on their respective starting positions (Singer and Parmesan, 2010), although evidence is more towards a loss of synchrony (Thackeray *et al.*, 2010).

Changes in interspecific interactions, such as predator-prey or interspecific competition for food, stemming from changes in phenological characteristics and breakdown in synchrony between species have been observed. For example, bird breeding is most effective when synchronized with the availability of food, so changes in the phenology of food supplies can exert a selective pressure on birds. In a study of 100 European migratory bird species, those that advanced their arrival date showed stable or increasing populations between 1990 and 2000, while those that did not adjust their arrival date on average showed declining populations (Møller *et al.*, 2008). In a comparison of nine Dutch populations of the migratory pied flycatcher (*Ficedula hypoleuca*) between 1987 and 2003, populations declined by 90% in areas where food peaked early in the season and the arrival of the birds was mis-timed, but not in areas with a later food peak which could still be exploited by early-breeding birds (Both *et al.*, 2006). However, compensating processes can exist: for example, in a 4-decade study of great tits (*Parus major*), breeding populations were buffered against phenological mismatch due to relaxed competition between individual fledglings (Reed *et al.*, 2013). Between 1970 and 1990, changes in migration date did not predict changes in population (Møller *et al.*, 2008).

Bird breeding can also be affected by phenological shifts in competing species and predators. Between 1953 and 2005 in south-western Finland, the onset of breeding of the resident great tit *Parus major* and the migratory pied flycatcher (*Ficedula hypoleuca*) became closer to each other, increasing competition between them (Ahola *et al.*, 2007). The edible dormouse (*Glis glis*), a nest predator, advanced its hibernation termination by -8 days per decade in the Czech Republic between 1980 and 2005 due to increasing annual spring air temperatures, leading to increased nest predation in three out of four bird surveyed species (Adamik and Kral, 2008).

Plant-insect interactions have also been observed to change. In Illinois, USA, the pattern of which plants were pollinated by which bees were altered by differing rates of phenological shifts and landscape changes over 120 years, with 50% of bee species becoming locally extinct (Burkle *et al.*, 2013). Increasing asynchrony of the winter moth (*Operophtera brumata*) and its feeding host oak tree (*Quercus robur*) in the Netherlands was linked to increasing spring temperatures but unchanging winter temperatures (van Asch and Visser, 2007). Warmer temperatures shorten the development period of European pine sawfly larvae (*Neodiprion sertifer* Geoffr.), reducing the risk of predation and potentially increasing the risk of insect outbreaks, but interactions with other factors including day length and food quality may complicate this prediction (Kollberg *et al.*, 2013). In North America, the spruce budworm (*Choristaneura fumiferana*) lays eggs with a wide range of emergence timings, so the population as a whole is less sensitive to changing phenology of host trees (Volney and Fleming, 2007).

The environmental cues for phenological events are complex and multi-layered (Körner and Basler, 2010; Singer and Parmesan, 2010). For instance, many late-succession temperate trees require a chilling period in winter, followed by a threshold in day length, and only then are sensitive to temperature. As a result, simple projections of current phenological trends may be misleading, since the relative importance of cues can change (Cook *et al.*, 2012b). The effects are complex and sometimes apparently counterintuitive, such as the increased sensitivity of flowering in high-altitude perennial herbs in the Rocky Mountains to frost, since plants begin flowering earlier as a result of earlier snowmelt (Inouye, 2008).

It has been suggested that shorter generation times give greater opportunity for autonomous adaptation through natural selection (Rosenheim and Tabashnik, 1991; Bertaux *et al.*, 2004), but a standardized assessment of 25,532 rates of phenological change for 726 UK taxa indicated that generation time only had limited influence on adaptation rates (Thackeray *et al.*, 2010).

There is *high confidence* [*much evidence, medium agreement*] that climate change-induced phenological shifts will continue to alter the interactions between species in regions with a marked seasonal cycle.

4.4.1.2. Evolutionary and Genetic

Since AR4 there has been substantial progress in defining the concepts and tools necessary for documenting and predicting evolutionary and genetic responses to recent and future climate change, often referred to as "rapid evolution". Evolution can occur through many mechanisms, including selection of existing genes or genotypes within populations, hybridization, mutation and selection of new adaptive genes and perhaps even through epigenetics (Chevin *et al.*, 2010; Chown *et al.*, 2010; Lavergne *et al.*, 2010; Paun *et al.*, 2010; Hoffmann and Sgro, 2011; Anderson *et al.*, 2012a; Donnelly *et al.*, 2012; Franks and Hoffmann, 2012; Hegarty, 2012; Merilä, 2012; Bell, 2013; Zhang *et al.*, 2013). Mechanisms such as selection of existing genes and genotypes, hybridization and epigenetics can lead to adaptation in very few generations, while others, notably mutation and selection of new genes, typically take many tens of generations. This means that species with very fast life cycles, e.g., bacteria, should in general have greater capacity to respond to climate change than species with long life cycles, such as large mammals and trees. There is a paucity of observational or experimental data that can be used for detection and attribution of recent climate effects on evolution.

Observed evolutionary and genetic responses to rapid changes in climate - There is a small but growing body of observations supporting the AR4 assessment that some species may have adapted to recent climate warming or to climatic extremes through genetic responses (e.g., plants: Franks and Weis, 2008; Hill *et al.*, 2011; Anderson *et al.*, 2012b; vertebrates: Ozgul *et al.*, 2010; Phillimore *et al.*, 2010; Husby *et al.*, 2011; Karell *et al.*, 2011; insects: Buckley *et al.*, 2012; van Asch *et al.*, 2012). Karell *et al.* (2011) found increasing numbers of brown genotypes of the tawny owl (*Strix aluco*) in Finland over the course of the last 28 years and attributed it to fewer snow-rich winters, which creates strong selection pressure against the white genotype. Earlier spawning by the common frog (*Rana temporaria*) in Britain could be attributed largely to local genetic adaptation to increasing spring temperatures (Phillimore *et al.*, 2010). Using a combination of models and observations, Husby *et al.* (2011) have built a case for detection and attribution of genetic adaptation in an insectivorous bird, and in an herbivorous insect that has tracked warming-related changes in the budburst timing of its host tree (van Asch *et al.*, 2012). In contrast, many species appear to be maladapted to changing climates, in part because factors such as limited existing genetic variation, weak heritability of adaptive traits or conflicting constraints on adaptation create low potential for rapid evolution (Knudsen *et al.*, 2011; Ketola *et al.*, 2012; Mihoub *et al.*, 2012; Merilä, 2012). Most studies of rapid evolution suffer from methodological weaknesses, making it difficult to clearly demonstrate a genetic basis underlying observed phenotypic responses to environmental change (Gienapp *et al.*, 2008; Franks and Hoffmann, 2012; Hansen *et al.*, 2012; Merilä, 2012). Rapid advances in quantitative genetics, genomics and phylogenetics, combined with recent progress on conceptual frameworks, will substantially improve the detection and attribution of genetic responses to changing climate over the next few years (Davis *et al.*, 2010; Salamin *et al.*, 2010; Hoffmann and Sgro, 2011). In sum, there are few observational studies of rapid evolution and difficulties in detection and attribution, so there is only *medium confidence* that some species have responded to recent changes in climate through genetic adaptations, and insufficient evidence to determine if this is a widespread phenomenon (thus *low confidence* for detection and attribution across all species; Figure 4-4).

The ability of species to adapt to new environmental conditions through rapid evolutionary processes can also be inferred from the degree to which environmental niches are conserved when environment is changed. There is evidence that environmental niches are conserved for some species under some conditions (plants: Petitpierre *et al.*, 2012; birds: Monahan and Tingley, 2012; review: Peterson *et al.*, 2011), but also evidence suggesting that environmental niches can evolve over time scales of several decades following changes in climate (Broennimann *et al.*, 2007; Angetter *et al.*, 2011; Konarzewski *et al.*, 2012; Leal and Gunderson, 2012; Lavergne *et al.*, 2013). The paleontological record provides insight into evolutionary responses in the face of natural climate variation. In general, environmental niches appear to be broadly conserved through time although there is insufficient data to determine the extent to which genetic adaptation has attenuated range shifts and changes in population size (Peterson *et al.*, 2011; Willis and MacDonald, 2011). Phylogeographic reconstructions of past species distributions suggest that hybridization may have helped avoid extinctions during cycles of glaciation and could also play a key role in future adaptation (Soliani *et al.*, 2012; Hegarty, 2012). There is new evidence that epigenetic mechanisms, such as DNA methylation, could allow very rapid adaptation to climate (Paun *et al.*, 2010; Zhang *et al.*, 2013).

Mechanisms mediating rapid evolutionary response to future climate change - Studies of genetic variability across species ranges, and models that couple gene flow with spatially-explicit population dynamics, suggest counterintuitive responses to climate change. Too much or too little gene flow to populations at range margins can create fragile, maladapted populations, which is in contrast to the current wisdom that populations at the range margins may be best adapted to global warming (Bridle *et al.*, 2010; Hill *et al.*, 2011). Conversely, there is evidence from experiments, models and observations that populations in the centre of species ranges may in some cases be more sensitive to environmental change than those at range boundaries (Bell and Gonzalez, 2009). Generalization is complicated by the interactions between local adaptation, gene flow, population dynamics and species interactions (Bridle *et al.*, 2010; Norberg *et al.*, 2012).

Substantial progress has been made since AR4 in developing models for exploring whether genetic adaptation is fast enough to track climate change. Models of long-lived tree species suggest that existing genetic variation may be sufficient to slightly attenuate negative impacts of future climate change (Kuparinen *et al.*, 2010; Kremer *et al.*, 2012), which is coherent with observations and experiments (Jump *et al.*, 2006, Jump *et al.*, 2008). However, these studies also indicate that adaptive responses will lag far behind even modest rates of projected climate change, due to the very long generation time of trees. In a species with much shorter generation times, the great tit (*Parus major*), Gienapp *et al.* (2013) found that modelled avian breeding times tracked climate change, only at low to moderate rates of change. For a herbivorous insect with an even faster life cycle, van Asch *et al.*, (2007; 2012) predicted that rapid evolution of the phenological response should have allowed it to track recent warming, which it has. More broadly, models suggest that species with short generation times, (one year or less), potentially have the capacity to genetically adapt to even the most rapid rates of projected climate change given large enough present-day populations, but species with longer generation times or small populations could be at risk of extinction at moderate to high rates of climate change (Walters *et al.*, 2012; Vedder *et al.*, 2013). Recent experimental and theoretical work on “evolutionary rescue” shows that long-term avoidance of extinction through genetic adaptation to hostile environments is possible, but requires large initial genetic variation and population sizes and is accompanied by substantial loss of genetic diversity, reductions in population size and range contractions over many generations before population recovery (Bell, 2013; Schiffers *et al.*, 2013). Model-based projections must be viewed with considerable caution because there are many evolutionary and ecological mechanisms not accounted for in most models that can either speed up or inhibit heritable adaptation to climate change (Cobben *et al.*, 2012; Norberg *et al.*, 2012; Kovach-Orr and Fussmann, 2013). In some cases, accounting for evolutionary processes in models even leads to predictions of greater maladaptation to climate change, resulting in rapid population declines (Hendry and Gonzalez, 2008; Ferriere and Legendre, 2013). Phenotypic plasticity is thought to generally improve the odds of adaptation to climate change. High plasticity in the face of climate change that has low fitness costs can greatly improve the odds of adaptation; however, plasticity with high costs leads to only modest amounts of adaptation (Chevin *et al.*, 2010).

AR4 concluded that "projected rates of climate change are *very likely* to exceed rates of evolutionary adaptation in many species (*high confidence*)" (Fischlin *et al.*, 2007). Work since then provides a similar, but more nuanced view of rapid evolution in the face of future climate change. The lack of adaptation in some species to recent changes in climate, broad support for niche conservatism, and models showing limited adaptive capacity in species with long generation times, all indicate that high rates of climate change (RCP8.5) will exceed the adaptive capacities of many species (*high confidence*). On the other hand, evidence from observations and models also indicates that there is substantial capacity for genetic adaptation to attenuate phenological shifts, population declines and local extinctions in many species, especially for low rates of climate change (RCP2.6) (*high confidence*). Projected adaptation to climate change is frequently characterized by population declines and loss of genetic diversity for many generations (*medium confidence*), thereby increasing species vulnerability to other pressures.

4.4.1.3. Migration of Species

This mode of adaptation has been extensively dealt with in Section 4.3.2.5. It is anticipated that the observed movement of species – individually and collectively – will continue in response to shifting climate patterns. Its effectiveness as an adaptation mechanism is constrained by three factors. First, the rate of migration for many species, in many regions of the world, is slower than the rate of movement of the climate envelope (see Figure 4-5). Second, the ecosystem interactions can only remain intact if all parts of the ecosystem migrate simultaneously and at the same rate. Thirdly, the contemporary landscape and inland water systems contain many barriers to migration, in the form of habitat fragmentation, roads, human settlements and dams. Mountain ecosystems are less constrained by these factors than flat-land ecosystems, but have additional impediments for species already close to the top of the mountain.

4.4.2. Human-Assisted Adaptation

Human-assisted adaptation means a deliberate, intervention with the intent of increasing the capacity of the target organism, ecosystem or social-ecological system to survive and function at an acceptable level in the presence of climate change. It is also known as "planned adaptation" (Smit *et al.*, 2007). This chapter focuses less on the adaptation of people, human communities and infrastructure, since they are the topics of Chapters 8 to 17, and more on non-human organisms and ecosystems, while acknowledging the importance of the human elements within the ecosystem. Intervention in this context means a range of actions, including ensuring the presence of suitable habitat and dispersal pathways; reducing non-climate stressors; physically moving organisms, storing and establishing them in new places. In addition to the other approaches assessed in this section, "Ecosystem-based Adaptation" (see Cross-Chapter Box CC-EA) provides an option that integrates the use of biodiversity and ecosystem services into climate change adaptation strategies in ways that can optimize co-benefits for local communities and carbon management, as well as reduce the risks associated with possible maladaptation. Note that there are risks associated with all forms of human-assisted adaptation (see Section 4.4.4), particularly in the presence of far-from-perfect predictive capabilities (Willis and Bhagwat, 2009).

4.4.2.1. Reduction of Non-Climate Stresses and Restoration of Degraded Ecosystems

The alleviation of other stresses acting on ecosystems is suggested to increase the capacity of ecosystems to survive, and adapt to, climate change, since the effects are generally either additive or compounding. Ecosystem restoration is one way of alleviating such stresses while increasing the area available for adaptation (Harris *et al.*, 2006). Building the resilience of at-risk ecosystems by identifying the full set of drivers of change and most important areas and resources for protection is the core of the adaptation strategy for the Arctic (Christie and Sommerkorn, 2012). Protective and restorative actions aimed at increasing resilience can also be cost-effective means as part of an overall adaptation strategy to help people to adapt to the adverse effects of climate change and may have other social, economic and cultural benefits. This is part of “ecosystem-based adaptation” (Colls *et al.*, 2009; Box CC-EA).

4.4.2.2. The Size, Location, and Layout of Protected Areas

Additions to, or reconfigurations of, the protected area estate are commonly suggested as pre-adaptations to projected climate changes (Heller and Zavaleta, 2009). This is because for most protected areas, under plausible scenarios of climate change, a significant fraction of the biota will no longer have a viable population within the present protected area footprint. It is noted that the extant geography of protected areas is far from optimal for biodiversity protection even under the current climate; that most biodiversity exists outside rather in protected areas and this between-protected area matrix is as important; that it is usually cheaper to acquire land proactively in the areas of projected future bioclimatic suitability than to correct the current non-optimality and then later add on areas to deal with climate change as it unfolds (Hannah *et al.*, 2007); and that the existing protected area network will still have utility in future climates, even though it may contain different species (Thomas *et al.*, 2012). Hickler *et al.* (2012) analysed the layout of protected areas in Europe and concluded that under projected 21st century climate change a third to a half of them would potentially be occupied by different vegetation than they currently represent. The new areas that need to be added to the existing protected area network to ensure future representativeness is situation-specific, but some general design rules apply: orientation along climate gradients (e.g., altitudinal gradients) is more effective than orientation across them (Roux *et al.*, 2008); regional scale planning is more effective than treating each local case independently since it is the network of habitats and protected areas that confers resilience rather than any single element (Heller and Zavaleta, 2009); and better integration of protected areas with a biodiversity-hospitable landscape outside is more effective than treating the protected areas as islands (Willis and Bhagwat, 2009). Dunlop *et al.* (2012) assessed the implications of climate change for biodiversity conservation in Australia and found many opportunities to facilitate the natural adaptation of biodiversity, including expanding the network of protected areas and restoring habitat at a large scale.

4.4.2.3. Landscape and Watershed Management

The need to include climate change into the management of vulnerable ecosystems is explicitly included in the strategic goals of the Convention on Biological Diversity. Oliver *et al.* (2012b) developed decision trees based on three scenarios: a) *adversely sensitive*, where areas within the species current geographical range will become climatically unsuitable with a changing climate; b) *climate overlap*, where there are areas that should remain climatically suitable within the species’ range; and c) *new climatic space*, which refers to areas outside of the current range that are projected to become suitable. Heller and Zavaleta (2009) reviewed recommendations in the published literature and argue that the majority of them, such as increase habitat heterogeneity of sites and connectivity of habitats across landscapes, lack sufficient specificity to ensure the persistence of many species and related ecosystem services to ongoing climate change. To date, recommendations are overwhelmingly focused on ecological data, neglecting social science insights. Few resources or capacity exist to guide adaptation planning processes at any scale.

Climate-induced impacts to hydrological and thermal regimes in freshwater systems can be offset through improved management of environmental flow releases from reservoirs (Arthington *et al.*, 2006; Poff *et al.*, 2010; Arthington *et al.*, 2010 and references therein). Protection and restoration of riparian vegetation in small stream systems provide an effective strategy to moderate temperature regimes and offset warming, and protect water quality for downstream ecosystems and water supply areas (Davies, 2010; Capon *et al.*, 2013).

General principles for management adaptations were summarized from a major literature review by West *et al.* (2009). They suggest that in the context of climate change, successful management of natural resources will require cycling between "managing for resilience" and "managing for change". This requires the anticipation of changes that can alter the impacts of grazing, fire, logging, harvesting, recreation, and so on. At the national level, principles to facilitate adaptation include: (1) management at appropriate scales, and not necessarily the scales of convenience or tradition; (2) increased collaboration among agencies; (3) rational approaches for establishing priorities and applying triage; and (4) management with the expectation of ecosystem change, rather than keeping them as they have been. Barriers and opportunities were divided into four categories: (1) legislation and regulations, (2) management policies and procedures, (3) human and financial capital, and (4) information and science.

Steenberg *et al.* (2011) simulated the effect on adaptive capacity of three variables related to timber harvesting: the canopy-opening size of harvests, the age of harvested trees within a stand, and the species composition of harvested trees within a stand. The combination of all three adaptation treatments allowed target species and old forest to remain reasonably well represented without diminishing the timber supply. This minimized the trade-offs between management values and climate adaptation objectives. Manipulation of vegetation composition and stand structure has been proposed as a strategy for offsetting climatic change impacts on wildfires in Canada. Large areas of boreal forests are currently being harvested and there may be opportunities for using planned manipulation of vegetation for management of future wildfire risks. This management option could also provide an additional benefit to the use of assisted species migration since the latter would require introducing non-flammable broadleaves species into forests which are otherwise highly flammable (Girardin *et al.*, 2013b; Terrier *et al.*, 2013). Harvesting practices, like partial cuts that limit the opening of the forest cover created by harvest, will be a key element to maintain diverse forest compositions and age class distributions in boreal forests. Other sound option for decreasing the exposure of silvicultural investments to an increasing fire danger is to use tree species necessitating a shorter rotation (Girardin *et al.*, 2013a).

4.4.2.4. Assisted Migration

Assisted migration has been proposed when fragmentation of habitats limits migration potential or when natural migration rates are outstripped by the pace of climate change (Hoegh-Guldberg *et al.*, 2008; Vitt *et al.*, 2010; Chmura *et al.*, 2011; Loss *et al.*, 2011; Ste-Marie *et al.*, 2011). The options for management can be summarized as: i) try to maintain or improve existing habitat or environment so that species don't have to move (e.g., Yan *et al.*, 2013), ii) maintain or improve migration corridors, including active management to improve survival along the moving margin of the distribution (Lawson *et al.*, 2012), and iii) directly translocate species or genetically distinct populations within a species (Aitken *et al.*, 2008; Hoegh-Guldberg *et al.*, 2008; Rehfeldt and Jaquish, 2010; Loss *et al.*, 2011; Pedlar *et al.*, 2012). There is *low agreement* whether it is better to increase the resilience to climate change of ecosystems as they currently occur, or to enhance the capacity of ecosystems to transform in the face of climate change (Richardson *et al.*, 2009).

There is *high agreement* that maintaining or improving migration corridors or ecological networks is a low-regret strategy, partly because it is also seen as useful in combatting the negative effects of habitat fragmentation on population dynamics (Hole *et al.*, 2011; Jongman *et al.*, 2011). This approach has the benefit of improving the migration potential for large numbers of species and is therefore a more ecosystem-wide approach than assisted migration for individual species. However, observational and modelling studies show that increases in habitat connectivity do not always improve the population dynamics of target species, may decrease species diversity, and may also facilitate the spread of invasive species (Cadotte, 2006; Brisson *et al.*, 2010; Matthiessen *et al.*, 2010).

There is *medium agreement* that the practice of assisted migration of targeted species is a useful adaptation option (Hoegh-Guldberg *et al.*, 2008; Vitt *et al.*, 2009; Willis and Bhagwat, 2009; Loss *et al.*, 2011; Hewitt *et al.*, 2011). The velocity of 21st century climate change and substantial habitat fragmentation in large parts of the world means that many species will be unable to migrate or adapt fast enough to keep pace with climate change (Figure 4-5), posing problems for long-term survival of the species. Some ecologists believe that careful selection of species to be moved would minimize the risk of undesirable impacts on existing communities or ecosystem function (Minteer and Collins, 2010), but others argue that the history of intentional species introductions shows that the outcomes are unpredictable and in many cases have had disastrous impacts (Ricciardi and Simberloff, 2009). The number of species that require assisted migration could easily overwhelm funding capacity (Minteer and Collins, 2010). Decisions regarding which species should be translocated are complex and debatable, given variability among and within species and the ethical issues involved (Aubin *et al.*, 2011; Winder *et al.*, 2011b).

4.4.2.5. Ex Situ Conservation

Conservation of plant and animal genetic resources outside of their natural environment, in gardens, zoos, breeding programmes, seed-banks or gene-banks has been widely advocated as an “insurance” against both climate change and other sources of biodiversity loss and impoverishment (Khoury *et al.*, 2010). There are many examples of existing efforts of this type, some with global scope (e.g., Millennium Seed Bank, Svalbard vault, Frozen Ark, Global Genome Initiative and others; Leishman *et al.*, 2007; Lermen *et al.*, 2009; Rawson *et al.*, 2011). Knowledge of which genetic variants within a species have more potential for adaptation to climate change could help prioritise the material stored (Colautti *et al.*, 2010).

Several issues remain largely unresolved (Li and Pritchard, 2009). The physiological, institutional and economic sustainability of such efforts into the indefinite future is unclear. The fraction of the intra-specific variation that needs to be preserved for future viability and how much genetic bias is introduced by collecting relatively small samples from restricted locations, and then later by the selection pressures inadvertently applied during ex-situ maintenance are unknown. Despite some documented successes, it remains uncertain whether it is always possible to reintroduce species successfully into the wild after generations of *ex-situ* conservation.

4.4.3. Consequences and Costs of Inaction and Benefits of Action

Failure to reduce the magnitude or rate of climate change will plausibly lead to changes (often decreases) in the value of ecosystem services provided, or incur costs in order to maintain or restore the services or adapt to their decline. There are several sources of such costs: administration and assessment, implementation, and opportunity costs, including financial cost. Owing to the number of assumptions made, knowledge gaps and recognized uncertainties, such result should be employed with caution. A systematic review of costs related to ecosystems and climate change by Rodriguez-Labajos (2013), shows that the monetary and non-monetary costs are distributed across all ecosystem service categories. Rodriguez-Labajos (2013) also discusses the potential and limits of monetary cost calculations, and issues of timing, trade-offs and the unequal distribution of costs.

A comprehensive monetary estimate of the effects of climate change on ecosystem service provision is not available. The Millennium Ecosystem Assessment (2005c; 2005d; 2005e) included climate change among the direct drivers of ecosystems change and devoted a chapter to the necessary responses. Building on results of the IPCC, the MA offered some estimated costs of action: complying with the Kyoto protocol for industrial countries would range between 0.2 and 2% of GDP; a modest stabilization target of 450 ppm CO_2 in the atmosphere over the 21st century would range from 0.02 to 0.1% of global-average GDP per year. TEEB (2009) underlined priorities in the ecosystem service-climate change coupling (reduction targets in relation to coral reefs, forest carbon markets and accounting, and ecosystem investment for mitigation), without going in depth into analysis of the cost types involved. The Cost of Policy Inaction (COPI) Project (ten Brink *et al.*, 2008) estimated the monetary costs of not meeting the 2010 biodiversity goals. Their model incorporates climate change, among other pressures, through an impaired quality of land, in terms of species abundance in diverse land-use categories. They conclude that the cumulative losses of welfare due to land-use changes, in terms of loss of ecosystem services, could reach an annual amount of EUR 14 trillion (based on values of 2007) in 2050, which may be equivalent to 7% of projected global GDP for that year. Eliasch (2008) estimates the damage costs to forests as reaching USD 1 trillion a year by 2100. The study used the probabilistic model employed by Stern (2006), which did not value effects on biodiversity or water-related ES.

The studies to date agree on the following points. First, climate change has already caused a reduction in ecosystem services which will become more severe as climate change continues. Second, ecosystem-based strategies to mitigate climate change are cost-effective, although more difficult to implement (i.e., more costly) in intensively managed ecosystems such as farming lands. Third, accurately estimating the monetary costs of reduction in ecosystem services that are not marketed is difficult. The provision of monetized costs tends to sideline the non-monetized political, social, and environmental costs relevant for decision making. Finally, there is a large funding gap between the cost of actions necessary to protect ecosystem services against climate change and the actual resources available.

In addition to direct costs, further costs may result from trade-offs between services: e.g. afforestation for climate mitigation and urban greening for climate adaptation may be costly in terms of water provision (Chisholm, 2010; Jenerette *et al.*, 2011; Pataki *et al.*, 2011). Traditional agriculture preserves soil carbon sinks, supports on-site biodiversity and uses less fossil fuel than high-input agriculture (Martinez-Alier, 2011), but due to the typically lower per hectare yields, may require a larger area to be dedicated to cropland. Leaving aside the contested (Searchinger *et al.*, 2008; Plevin *et al.*, 2010) effectiveness of biofuels as a mitigation strategy, there is evidence of their disruptive effect on food security, land tenure, labour rights and biodiversity in several parts of the world (Obersteiner *et al.*, 2010; Tirado *et al.*, 2010).

4.4.4. Unintended Consequences of Adaptation and Mitigation

Actions taken within the terrestrial and freshwater system domain or in other sectors to mitigate or adapt to climate change can have unintended consequences. Some issues relevant to this section are also found in Section 14.7 and the Working Group III report.

Several of the alternatives to fossil fuel require extensive use of the land surface and thus have a direct impact on terrestrial ecosystems and an indirect impact on inland water systems (Paterson *et al.*, 2008; Turner *et al.*, 2010). As an illustration, the RPC2.6 scenario involves both bioenergy and renewables as major components of the energy mix (Box 4-1; van Vuuren *et al.*, 2011).

Policy shifts in developed countries favour the expansion of large-scale bioenergy production, which places new pressures on terrestrial and freshwater ecosystems (Searchinger *et al.*, 2008; Lapola *et al.*, 2010), either through direct use of land or water or indirectly by displacing food crops, which must then be grown elsewhere. Over the past decade there has been a global trend to reduced rates of forest loss; it is unclear if this will continue in the face of simultaneously rising food and biofuel demand (Wise *et al.*, 2009; Meyfroidt and Lambin, 2011). The EU Renewable Energy Sources Directive is estimated to have only a moderate influence on European forests provided that the price paid by the bioenergy producers remained below 50-60 US$ per m^3 wood (Moiseyev *et al.*, 2011). However, a doubled growth rate for bioenergy until 2030 would have major consequences for the global forest sector, including a reduction of forest stocks in Asia of 2 % to 4% (Martin *et al.*, 2010). By 2100 in RCP2.6, bioenergy crops are projected to occupy approximately 4 million km^2, approximately 7% of global cultivated land projected at the time. Modification of the landscape and the fragmentation of habitats are major influences on extinction risks (Fischer and Lindenmayer, 2007), especially if native vegetation cover is reduced or degraded, human land use is intensive and “natural” areas become disconnected. Hence, additional extensification of cultivated areas for energy crops may contribute to extinction risks. Some bioenergy crops may be invasive species (Raghu *et al.*, 2006).

Abandoned former agricultural land could be used for biomass production (McAlpine *et al.*, 2009). However, such habitats may be core elements in cultural landscapes of high conservation value, with European species-rich grasslands often developed from abandoned croplands (Hejcman *et al.*, 2013).

Damming of river systems for hydropower can cause fragmentation of the inland water habitat with implications for fish species, and monitoring studies indicate that flooding of ecosystems behind the dams can lead to declining populations, e.g., of amphibians (Brandão and Araújo, 2007). Reservoirs can be a sink of CO_2 but also a source of biogenic CO_2 and CH_4 – this issue is discussed in WG III AR5 Section 7.8.1.

Wind turbines can kill birds and bats (e.g., Barclay *et al.*, 2007), and inappropriately-sited wind farms can negatively impact on bird populations (Drewitt and Langston, 2006). Effects can be reduced by careful siting of turbines, for example by avoiding migration routes (Drewitt and Langston, 2006). Estimating mortality rates is complex and difficult (Smallwood, 2007) but techniques are being developed in order to inform siting decisions and impact assessments (Péron *et al.*, 2013). Wind farms in Europe and the USA are estimated to cause between 0.3 and 0.4 wildlife fatalities *per* gigawatt-hour (GWh) of electricity, compared to approximately 5.2 fatalities *per* GWh nuclear and fossil-fuel power stations (Sovacool, 2009; but see Willis *et al.*, 2010c). One study found on-site bird populations to be generally affected more by windfarm construction than subsequent operation, with some populations recovering after construction (Pearce-Higgins *et al.*, 2012).

Large-scale solar farms could impact local biodiversity if poorly sited, but the impact can be reduced with appropriate planning (Tsoutsos *et al.*, 2005). Solar PV installations can decrease local surface albedo, giving a small positive radiative forcing. There are some plausible local circumstances in which this may be a consideration, but in general the climate effect is estimated to be 30times smaller than the avoided radiative forcing arising from substituting fossil fuels with PV (Nemet, 2009).

Relocation or expansion of agricultural areas and settlements as climate change adaptation measures could pose risks of habitat fragmentation and loss similar to those discussed above in the context of mitigation through bio-energy. Assisted migration (see Section 4.4.2.4) may directly conflict with other conservation priorities, for example by facilitating the introduction of invasive species (Maclachlan *et al.*, 2007).

4.5. Emerging Issues and Key Uncertainties

Detecting the presence and location of thresholds in ecosystem response to climate change, and specifically the type of thresholds characterized as tipping points, remains a major source of uncertainty with high potential consequences. In general (Field *et al.*, 2007), negative feedbacks currently dominate the climate-ecosystem interaction. For most ecological processes, increasing magnitude of warming shifts the balance towards positive rather than negative feedbacks (Field *et al.*, 2007). In several regions, such as the boreal ecosystems, positive feedbacks may become dominant, under moderate warming). For positive feedbacks to propagate into ‘runaway’ processes leading to a new ecosystem state, the strength of the feedback has to exceed that of the initial perturbation. This has not as yet been demonstrated for any large-scale, plausible and immanent ecological process; but the risk is non-negligible and the consequences if it did occur would be severe: thus further research is needed.

The issue of biophysical interactions between ecosystem state and the climate, over and above the effects mediated through greenhouse gases, is emerging as significant in many areas. Such effects include those caused by changes in surface reflectivity (albedo) or the partitioning of energy between latent energy and sensible heat.

Uncertainty in predicting the response of terrestrial and freshwater ecosystems to climate and other perturbations, particularly at the local scale, remains a major impediment to determining prudent levels of permissible change. A significant source of this uncertainty stems from the inherent complexity of ecosystems, especially where they are coupled to equally-complex social systems. The high number of interactions can lead to cascading effects (Biggs *et al.*, 2011). Some of this uncertainty can be reduced by better systems understanding, but some will remain irreducible because of the failure of predictive models when faced with certain types of complexity (such as those which lead to mathematical bifurcations – a problem that is well-known in climate science). Probabilistic statements about the range of outcomes are possible in this context, but ecosystem science is as yet mostly unable to conduct such analyses routinely and rigorously. One consequence is the ongoing difficulty in attributing observed changes unequivocally to climate change. More comprehensive monitoring is a key element of the solution.

The consequences for species interactions of differing phenological or movement-based responses to climate change are insufficiently known and may make projections based on individual species models unreliable.

Studies of the combined effects of multiple simultaneous elements of global change, such as the effects of elevated carbon dioxide and rising tropospheric ozone on plant productivity - which has critical consequences for the future sink strength of the biosphere, since they are of similar magnitude but opposite sign – are needed as a supplement to the single-factor experiments. For example, uncertainty on the magnitude of CO_2 fertilization is key for forest responses to climate change, particularly in tropical forests, woodlands and savannas (Cox *et al.*, 2013; Huntingford *et al.*, 2013).

The effects of changes in the frequency or intensity of climate-related extreme events, such as floods, cyclones , heat waves, exceptionally large fires on ecosystem change are probably equal to or greater than shifts in the mean values of climate variables. These effects are insufficiently studied, and in particular, are seldom adequately represented in Earth system models.

Understanding of the *rate* of climate change that can be tracked or adapted to by organisms is as important as understanding the *magnitude* of change they can tolerate. Despite being explicitly required under Article 2 of the UNFCCC, rate studies are currently less developed and more uncertain than magnitude (equilibrium) studies. This includes evidence for the achievable migration rates of a range of species as well as the rate of micro-evolutionary change.

The capacity for, and limits to, ecological and evolutionary adaptive processes are only known in a few cases. The development and testing of human-assisted adaptation strategies for their cost-effectiveness in reducing risk is a prerequisite for their widespread adoption.

The costs of the loss of biodiversity and ecosystem services as a result of climate change is known for only a few cases, or is associated with large uncertainties; as are the costs and benefits of assisting ecosystems and species to adapt to climate change.

Frequently Asked Questions

FAQ 4.1: How do land-use and land-cover changes cause changes in climate? *[to be placed in Section 4.2.4.1]*
Land use change affects the local as well as the global climate. Different forms of land cover and land use can cause warming or cooling and changes in rainfall, depending on where they occur in the world, what the preceding land cover was, and how the land is now managed. Vegetation cover, species composition and land management practices (such as harvesting, burning, fertilizing, grazing or cultivation) influence the emission or absorption of greenhouse gases. The brightness of the land cover affects the fraction of solar radiation that is reflected back into the sky, instead of being absorbed, thus warming the air immediately above the surface. Vegetation and land use patterns also influence water use and evapotranspiration, which alter local climate conditions. Effective land-use strategies can also help to mitigate climate change.

FAQ 4.2: What are the non-greenhouse gas effects of rising carbon dioxide on ecosystems?
[to be placed in Section 4.2.4.4]
Carbon dioxide (CO_2) is an essential building block of the process of photosynthesis. Simply put, plants use sunlight and water to convert CO_2 into energy. Higher CO_2 concentrations enhance photosynthesis and growth (up to a point), and reduce the water used by the plant. This means that water remains longer in the soil or recharges rivers and aquifers. These effects are mostly beneficial; however, high CO_2 also has negative effects, in addition to causing global warming. High CO_2 levels cause the nitrogen content of forest vegetation to decline and can increase their chemical defences, reducing their quality as a source of food for plant-eating animals. Furthermore, rising CO_2 causes ocean waters to become acidic (see FAQ 6.3), and can stimulate more intense algal blooms in lakes and reservoirs.

FAQ 4.3: Will the number of invasive alien species increase due to climate change?
[to be placed in Section 4.2.4.6]
Some invasive plants and insects have already been shown to benefit from climate change and will establish and spread into new regions (where they are ‘aliens’), once they are introduced. The number of newly-arrived species

and the abundance of some already-established alien species will increase because climate change will improve conditions for them. At the same time, increasing movement of people and goods in the modern world, combined with land use changes worldwide, increases the likelihood that alien species are accidentally transported to new locations and become established there. There are many actions which can be taken to reduce, but not eliminate, the risk of alien species invasions, such as the treatment of ballast water in cargo ships and wood products, strict quarantine applied to crop and horticultural products, and embargos on the trade and deliberate introduction of known invader species. Some invasive species will suffer from climate change and are expected to decrease in range and population size in some regions. Generally, increased establishment success and spread will be most visible for those alien species that have characteristics favoured by the changing climate, such as those that are drought tolerant or able to take advantage of higher temperatures.

FAQ 4.4: How does climate change contribute to species extinction? *[to be placed in Section 4.3.2.5]*
There is a consensus that climate change over the coming century will increase the risk of extinction for many species. When a species becomes extinct, a unique and irreplaceable life form is lost. Even local extinctions can impair the healthy functioning of ecosystems.

Under the fastest rates and largest amounts of projected climate change, many species will be unable to move fast enough to track suitable environments, which will greatly reduce their chances of survival. Under the lowest projected rates and amounts of climate change, and with the assistance of effective conservation actions, the large majority of species *will* be able to adapt to new climates, or move to places that improve their chances of survival. Loss of habitat and the presence of barriers to species movement increase the risk of extinctions as a result of climate change.

Climate change may have already contributed to the extinction of a small number of species, such as frogs and toads in Central America, but the role of climate change in these recent extinctions is the subject of considerable debate.

FAQ 4.5: Why does it matter if ecosystems are altered by climate change? *[to be placed in Section 4.3.4]*
Ecosystems provide essential services for all life; food, life-supporting atmospheric conditions, drinkable water, as well as raw materials for basic human needs like clothing and housing. Ecosystems play a critical role in limiting the spread of human and non-human diseases. They have a strong impact on the weather and climate itself, which in turn impacts agriculture, food supplies, socio-economic conditions, floods and physical infrastructure. When ecosystems change, their capacity to supply these services changes as well; for better or worse. Human wellbeing is put at risk, along with the welfare of millions of other species. People have a strong emotional, spiritual and ethical attachment to the ecosystems they know, and the species they contain.

By “ecosystem change”, we mean changes in some or all of the following: the number and types of organisms present; the ecosystem's physical appearance (e.g., tall or short, open or dense vegetation); the functioning of the system and all its interactive parts, including the cycling of nutrients and productivity. Though in the long-term not all ecosystem changes are detrimental to all people or to all species, the faster and further ecosystems change in response to new climatic conditions, the more challenging it is for humans and other species to adapt to the new conditions.

FAQ 4.6: Can ecosystems be managed to help them and people to adapt to climate change?
[to be placed in Section 4.4.2.3]
The ability of human societies adapt to climate change will depend, in large measure, upon the management of terrestrial and inland freshwater ecosystems. A fifth of global human-caused carbon emissions today are absorbed by terrestrial ecosystems; this important carbon *sink* operates largely without human intervention, but could be increased through a concerted effort to reduce forest loss and to restore damaged ecosystems, which also co-benefits the conservation of biodiversity.

The clearing and degradation of forests and peatlands represents a *source* of carbon emissions to the atmosphere which can be reduced though management; for instance, there has been a three-quarters decline in the rate of deforestation in the Brazilian Amazon in the last two decades. Adaptation is also helped through more proactive detection and management of wildfire and pest outbreaks, reduced drainage of peatlands, the creation of species migration corridors and assisted migration.

FAQ 4.7: What are the economic costs of changes in ecosystems due to climate change?
[to be placed in Section 4.4.3]
Climate change will certainly alter the services provided by most ecosystems, and for high degrees of change, the overall impacts are most likely to be negative. In standard economics, the value of services provided by ecosystems are known as externalities, which are usually outside the market price system, difficult to evaluate and often ignored.

A good example is the pollination of plants by bees and birds and other species, a service which may be negatively affected by climate change. Pollination is critical for the food supply as well as for overall environmental health. Its value has been estimated globally at $350 billion for the year 2010 (The range of estimates is 200 – 500 $ billion).

Cross-Chapter Boxes

Box CC-EA. Ecosystem Based Approaches to Adaptation - Emerging Opportunities
[Rebecca Shaw (USA), Jonathan Overpeck (USA), Guy Midgley (South Africa)]

Ecosystem-based adaptation (EBA) integrates the use of biodiversity and ecosystem services into climate change adaptation strategies (e.g., CBD, 2009; Munroe et al., 2011; see Chapters 3, 4, 5, 8, 9, 13, 14, 15, 16, 19, 22, 24, 25, and 27). EBA is implemented through the sustainable management of natural resources and conservation and restoration of ecosystems, to provide and sustain services that facilitate adaptation both to climate variability and change (Colls et al., 2009). It also sets out to take into account the multiple social, economic, and cultural co-benefits for local communities (CBD COP 10 Decision X/33).

EBA can be combined with, or even a substitute for, the use of engineered infrastructure or other technological approaches. Engineered defenses such as dams, sea walls and levees adversely affect biodiversity, potentially resulting in maladaptation due to damage to ecosystem regulating services (Campbell et al., 2009; Munroe et al., 2011). There is some evidence that the restoration and use of ecosystem services may reduce or delay the need for these engineering solutions (CBD, 2009). EBA offers lower risk of maladaptation than engineering solutions in that their application is more flexible and responsive to unanticipated environmental changes. Well-integrated EBA can be more cost effective and sustainable than non-integrated physical engineering approaches (Jones et al., 2012), and may contribute to achieving sustainable development goals (e.g., poverty reduction, sustainable environmental management, and even mitigation objectives), especially when they are integrated with sound ecosystem management approaches. In addition, EBA yields economic, social, and environmental co-benefits in the form of ecosystem goods and services (World Bank, 2009).

EBA is applicable in both developed and developing countries. In developing countries where economies depend more directly on the provision of ecosystem services (Vignola et al., 2009), EBA may be a highly useful approach to reduce risks to climate change impacts and ensure that development proceeds on a pathways that are resilient to climate change (Munang et al., 2013). EBA projects may be developed by enhancing existing initiatives, such as community-based adaptation and natural resource management approaches (e.g., Khan et al., 2012; Midgley et al., 2012; Roberts et al., 2012).

Examples of ecosystem based approaches to adaptation include:

- Sustainable water management, where river basins, aquifers, flood plains, and their associated vegetation are managed or restored to provide resilient water storage and enhanced baseflows, flood regulation services, reduction of erosion/siltation rates, and more ecosystem goods (e.g., Day et al., 2007; Midgley et al., 2012; Opperman et al., 2009)
- Disaster risk reduction through the restoration of coastal habitats (e.g., mangroves, wetlands, and deltas) to provide effective measure against storm-surges, saline intrusion, and coastal erosion (Jonkman et al., 2013)
- Sustainable management of grasslands and rangelands to enhance pastoral livelihoods and increase resilience to drought and flooding
- Establishment of diverse and resilient agricultural systems, and adapting crop and livestock variety mixes to secure food provision; traditional knowledge may contribute in this area through, for example, identifying indigenous crop and livestock genetic diversity, and water conservation techniques

- Management of fire-prone ecosystems to achieve safer fire regimes while ensuring the maintenance of natural processes.

Application of EBA, like other approaches, is not without risk, and risk/benefit assessments will allow better assessment of opportunities offered by the approach. The examples of EBA are too few and too recent to assess either the risks or the benefits comprehensively at this stage. EBA is still a developing concept but is should be considered alongside adaptation options based more on engineering works or social change, and existing and new cases used to build understanding of when and where its use is appropriate.

[INSERT FIGURE EA-1 HERE
Figure EA-1: Adapted from Munang et al. (2013). Ecosystem based adaptation (EBA) uses the capacity of nature to buffer human systems from the adverse impacts of climate change. Without EBA, climate change may cause degradation of ecological processes (central white panel) leading to losses in human well-being. Implementing EBA (outer blue panel) may reduce or offset these adverse impacts resulting in a virtuous cycle that reduces climate-related risks to human communities, and may provide mitigation benefits.]

Box CC-RF. Impact of Climate Change on Freshwater Ecosystems due to Altered River Flow Regimes

[Petra Döll (Germany), Stuart E. Bunn (Australia)]

It is widely acknowledged that the flow regime is a primary determinant of the structure and function of rivers and their associated floodplain wetlands, and flow alteration is considered to be a serious and continuing threat to freshwater ecosystems (Bunn and Arthington, 2002; Poff and Zimmerman, 2010; Poff *et al*., 2010). Most species distribution models do not consider the effect of changing flow regimes (i.e. changes to the frequency, magnitude, duration and/or timing of key flow parameters) or they use precipitation as proxy for river flow (Heino *et al.*, 2009).

There is growing evidence that climate change will significantly alter ecologically important attributes of hydrologic regimes in rivers and wetlands, and exacerbate impacts from human water use in developed river basins (*medium confidence*) (Aldous *et al.*, 2011; Xenopoulos *et al.*, 2005). By the 2050s, climate change is projected to impact river flow characteristics like long-term average discharge, seasonality and statistical high flows (but not statistical low flows) more strongly than dam construction and water withdrawals have done up to around the year 2000 (Figure RF-1; Döll and Zhang, 2010). For one climate scenario (SRES A2 emissions, HadCM3 climate model), 15% of the global land area may be negatively affected, by the 2050s, by a decrease of fish species in the upstream basin of more than 10%, as compared to only 10% of the land area that has already suffered from such decreases due to water withdrawals and dams (Döll and Zhang, 2010). Climate change may exacerbate the negative impacts of dams for freshwater ecosystems but may also provide opportunities for operating dams and power stations to the benefit of riverine ecosystems. This is the case if total runoff increases and, as occurs in Sweden, the annual hydrograph becomes more similar to variation in electricity demand, i.e. with a lower spring flood and increased runoff during winter months (Renofalt *et al.*, 2010).

Because biota are often adapted to a certain level of river flow variability, the projected larger variability of river flows that is due to increased climate variability is *likely* to select for generalist or invasive species (Ficke *et al.*, 2007). The relatively stable habitats of groundwater-fed streams in snow-dominated or glacierized basins may be altered by reduced recharge by meltwater and as a result experience more variable (possibly intermittent) flows (Hannah *et al.*, 2007). A high-impact change of flow variability is a flow regime shift from intermittent to perennial or vice versa. It is projected that until the 2050s, river flow regime shifts may occur on 5-7% of the global land area, mainly in semi-arid areas (Döll and Müller Schmied, 2012; see Table 3-2 in Chapter 3).

In Africa, one third of fish species and one fifth of the endemic fish species occur in eco-regions that may experience a change in discharge or runoff of more than 40% by the 2050s (Thieme *et al.*, 2010). Eco-regions containing over 80% of Africa's freshwater fish species and several outstanding ecological and evolutionary phenomena are *likely* to experience hydrologic conditions substantially different from the present, with alterations in long-term average annual river discharge or runoff of more than 10% due to climate change and water use (Thieme *et al.*, 2010).

Due to increased winter temperatures, freshwater ecosystems in basins with significant snow storage are affected by higher river flows in winter, earlier spring peak flows and possibly reduced summer low flows (Section 3.2.3 in Chapter 3). Strongly increased winter peak flows may lead to a decline in salmonid populations in the Pacific Northwest of the USA of 20-40% by the 2050s (depending on the climate model) due to scouring of the streambed during egg incubation, the relatively pristine high-elevation areas being affected most (Battin *et al.*, 2007). Reductions in summer low flows will increase the competition for water between ecosystems and irrigation water users (Stewart *et al.*, 2005). Ensuring environmental flows through purchasing or leasing water rights and altering reservoir release patterns will be an important adaptation strategy (Palmer *et al.*, 2009).

[INSERT FIGURE RF-1 HERE
Figure RF-1: Impact of climate change relative to the impact of water withdrawals and dams on natural flows for two ecologically relevant river flow characteristics (mean annual river flow and monthly low flow Q_{90}), computed by a global water model (Döll and Zhang, 2010). Monthly Q_{90} was defined as the flow that is exceeded in 9 out 10 months. Impact of climate change is the percent change of flow between 1961-1990 and 2041-2070 according to the emissions scenario A2 as implemented by the global climate model HadCM3. Impact of water withdrawals and

reservoirs is computed by running the model with and without water withdrawals and dams that existed in 2002. Please note that the figure does not reflect spatial differences in the magnitude of change.]

Observations and models suggest that global warming impacts on glacier and snow-fed streams and rivers will pass through two contrasting phases (Burkett *et al.*, 2005; Vuille *et al.*, 2008; Jacobsen *et al.*, 2012). In the first phase, when river discharge is increased due to intensified melting, the overall diversity and abundance of species may increase. However, changes in water temperature and stream-flow may have negative impacts on narrow range endemics (Jacobsen *et al.*, 2012). In the second phase, when snowfields melt early and glaciers have shrunken to the point that late-summer stream flow is reduced, broad negative impacts are foreseen, with species diversity rapidly declining once a critical threshold of roughly 50% glacial cover is crossed (Figure RF-2).

River discharge also influences the response of river temperatures to increases of air temperature. Globally averaged, air temperature increases of 2°C, 4°C and 6°C are estimated to lead to increases of annual mean river temperatures of 1.3°C, 2.6°C and 3.8°C, respectively (van Vliet *et al.*, 2011). Discharge decreases of 20% and 40% are computed to result in additional increases of river water temperature of 0.3° C and 0.8°C on average (van Vliet *et al.*, 2011). Therefore, where rivers will experience drought more frequently in the future, freshwater-dependent biota will suffer not only directly by changed flow conditions but also by drought-induced river temperature increases, as well as by related decreased oxygen and increased pollutant concentrations.

[INSERT FIGURE RF-2 HERE
Figure RF-2: Accumulated loss of regional species richness (gamma diversity) of macroinvertebrates as a function of glacial cover in catchment. Obligate glacial river macroinvertebrates begin to disappear from assemblages when glacial cover in the catchment drops below approximately 50%, and 9-14 species are predicted to be lost with the complete disappearance of glaciers in each region, corresponding to 11, 16 and 38% of the total species richness in the three study regions in Ecuador, Europe and Alaska. Data are derived from multiple river sites from the Ecuadorian Andes and Swiss and Italian Alps, and a temporal study of a river in the Coastal Range Mountains of southeast Alaska over nearly three decades of glacial shrinkage. Each data point represents a river site or date (Alaska), and lines are Lowess fits. Adapted by permission from Macmillan Publishers Ltd: *Nature Climate Change*, Jacobsen *et al.*, 2012, © 2012.]

Box CC-VW. Active Role of Vegetation in Altering Water Flows under Climate Change

[Dieter Gerten (Germany), Richard Betts (UK), Petra Döll (Germany)]

Climate, vegetation and carbon and water cycles are intimately coupled, in particular via the simultaneous transpiration and CO_2 uptake through plant stomata in the process of photosynthesis. Hence, water flows such as runoff and evapotranspiration are affected not only directly by anthropogenic climate change as such (i.e. by changes in climate variables such as temperature and precipitation), but also indirectly by plant responses to increased atmospheric CO_2 concentrations. In addition, effects of climate change (e.g. higher temperature or altered precipitation) on vegetation structure, biomass production and plant distribution have an indirect influence on water flows. Rising CO_2 concentration affects vegetation and associated water flows in two contrasting ways, as suggested by ample evidence from Free Air CO_2 Enrichment (FACE), laboratory and modelling experiments (e.g. Leakey *et al.*, 2009; de Boer *et al.*, 2011; Reddy *et al.*, 2010). On the one hand, a *physiological* effect leads to reduced opening of stomatal apertures, which is associated with lower water flow through the stomata, i.e. lower leaf-level transpiration. On the other hand, a *structural* effect ("fertilization effect") stimulates photosynthesis and biomass production of C3 plants including all tree species, which eventually leads to higher transpiration at regional scales. A key question is to what extent the climate- and CO_2-induced changes in vegetation and transpiration translate into changes in regional and global runoff.

The physiological effect of CO_2 is associated with an increased intrinsic water use efficiency (WUE) of plants, which means that less water is transpired per unit of carbon assimilated. Records of stable carbon isotopes in woody plants (Peñuelas *et al.*, 2011) verify this finding, suggesting an increase in WUE of mature trees by 20.5% between the early 1960s and the early 2000s. Increases since pre-industrial times have also been found for several forest sites (Andreu-Hayles *et al.*, 2011; Gagen *et al.*, 2011; Loader *et al.*, 2011; Nock *et al.*, 2011) and in a temperate semi-natural grassland (Koehler *et al.*, 2010), although in one boreal tree species WUE ceased to increase after 1970 (Gagen *et al.*, 2011). Analysis of long-term whole-ecosystem carbon and water flux measurements from 21 sites in North American temperate and boreal forests corroborates a notable increase in WUE over the two past decades (Keenan *et al.*, 2013). An increase in global WUE over the past century is supported by ecosystem model results (Ito and Inatomi, 2012).

A key influence on the significance of increased WUE for large-scale transpiration is whether vegetation structure and production has remained approximately constant (as assumed in the global modelling study by Gedney *et al.*, 2006) or has increased in some regions due to the structural CO_2 effect (as assumed in models by Piao *et al.*, 2007;

Gerten *et al.*, 2008). While field-based results vary considerably among sites, tree ring studies suggest that tree growth did not increase globally since the 1970s in response to climate and CO_2 change (Peñuelas *et al.*, 2011; Andreu-Hayles *et al.*, 2011). However, basal area measurements at over 150 plots across the tropics suggest that biomass and growth rates in intact tropical forests have increased in recent decades (Lewis *et al.*, 2009). This is also confirmed for 55 temperate forest plots, with a suspected contribution of CO_2 effects (McMahon *et al.*, 2010). Satellite observations analysed in Donohue *et al.* (2013) suggest that an increase in vegetation cover by 11% in warm drylands (1982–2010 period) is attributable to CO_2 fertilization. Owing to the interplay of physiological and structural effects, the net impact of CO_2 increase on global-scale transpiration and runoff remains rather poorly constrained. This is also true because nutrient limitation, often omitted in modelling studies, can suppress the CO_2 fertilization effect (see Rosenthal and Tomeo, 2013).

Therefore, there are conflicting views on whether the direct CO_2 effects on plants already have a significant influence on evapotranspiration and runoff at global scale. AR4 reported work by Gedney *et al.* (2006) which suggested that the physiological CO_2 effect (lower transpiration) contributed to a supposed increase in global runoff seen in reconstructions by Labat *et al.* (2004). However, a more recent analysis based on a more complete dataset (Dai *et al.*, 2009) suggested that river basins with decreasing runoff outnumber basins with increasing runoff, such that a small decline in global runoff is *likely* for the period 1948–2004. Hence, detection of vegetation contributions to changes in water flows critically depends on the availability and quality of hydrometeorological observations (Haddeland *et al.*, 2011; Lorenz and Kunstmann, 2012). Overall, the evidence since AR4 suggests that climatic variations and trends have been the main driver of global runoff change in the past decades; both CO_2 increase and land use change have contributed less (Piao *et al*., 2007; Gerten *et al*., 2008; Alkama *et al.*, 2011; Sterling *et al.*, 2013). Oliveira *et al.* (2011) furthermore pointed to the importance of changes in incident solar radiation and the mediating role of vegetation; according to their global simulations, a higher diffuse radiation fraction during 1960–1990 may have increased evapotranspiration in the tropics by 3% due to higher photosynthesis from shaded leaves.

It is uncertain how vegetation responses to future increases in CO_2 and to climate change will modulate the impacts of climate change on freshwater flows. 21st century continental- and basin-scale runoff is projected by some models to either increase more or decrease less when the physiological CO_2 effect is included in addition to climate change effects (Betts *et al.*, 2007; Murray *et al.,* 2012). This could somewhat ease the increase in water scarcity anticipated in response to future climate change and population growth (Gerten *et al.*, 2011; Wiltshire *et al.*, in press). In absolute terms, the isolated effect of CO_2 has been modelled to increase future global runoff by 4–5% (Gerten *et al.*, 2008) up to 13% (Nugent and Matthews, 2012) compared to the present, depending on the assumed CO_2 trajectory and whether feedbacks of changes in vegetation structure and distribution to the atmosphere are accounted for (they were not in Nugent and Matthews, 2012). In a global model intercomparison study (Davie *et al.*, in press), two out of four models projected stronger increases and, respectively, weaker decreases in runoff when considering CO_2 effects compared to simulations with constant CO_2 concentration (consistent with above findings, though magnitudes differed between the models), but two other models showed the reverse. Thus, the choice of models and the way they represent the coupling between CO_2, stomatal closure and plant growth is a source of uncertainty, as also suggested by Cao *et al.* (2009). Lower transpiration due to rising CO_2 concentration may also affect future regional climate change itself (Boucher *et al.*, 2009) and enhance the contrast between land and ocean surface warming (Joshi *et al.*, 2008). Overall, although physiological and structural effects will influence water flows in many regions, precipitation and temperature effects are *likely* to remain the prime influence on global runoff (Alkama *et al.*, 2010).

An application of a soil-vegetation-atmosphere-transfer model indicates complex responses of groundwater recharge to vegetation-mediated changes in climate, with computed groundwater recharge being always larger than would be expected from just accounting for changes in rainfall (McCallum *et al.*, 2010). Another study found that even if precipitation slightly decreased, groundwater recharge might increase as a net effect of vegetation responses to climate change and CO_2 rise, i.e. increasing WUE and either increasing or decreasing leaf area (Crosbie *et al.*, 2010). Depending on the type of grass in Australia, the same change in climate is suggested to lead to either increasing or decreasing groundwater recharge in this location (Green *et al.*, 2007). For a site in the Netherlands, a biomass decrease was computed for each of eight climate scenarios indicating drier summers and wetter winters (A2 emissions scenario), using a fully coupled vegetation and variably saturated hydrological model. The resulting increase in groundwater recharge up-slope was simulated to lead to higher water tables and an extended habitat for down-slope moisture-adapted vegetation (Brolsma *et al.*, 2010).

Using a large ensemble of climate change projections, Konzmann *et al.* (2013) put hydrological changes into an agricultural perspective and suggested that the net result of physiological and structural CO_2 effects on crop irrigation requirements would be a global reduction (Figure VW-1). Thus, adverse climate change impacts on irrigation requirements and crop yields might be partly buffered as WUE and crop production improve (Fader *et al.*, 2010). However, substantial CO_2-driven improvements will only be realized if proper management abates limitation of plant growth by nutrient availability or other factors.

[INSERT FIGURE VW-1 HERE
Figure VW-1: Percentage change in net irrigation requirements of 11 major crops from 1971–2000 to 2070–2099 on areas currently equipped for irrigation, assuming current management practices. Top: impact of climate change including physiological and structural crop responses to increased atmospheric CO_2 concentration (maximum effect in the absence of co-limitation by nutrients). Bottom: impact of climate change only. Shown is the median change derived from climate change projections by 19 GCMs (based on the SRES A2 emissions scenario) used to force a vegetation and hydrology model. Modified after Konzmann *et al.* (2013).]

Changes in vegetation coverage and structure due to long-term climate change or shorter-term extreme events such as droughts (Anderegg *et al.*, 2013) also affect the partitioning of precipitation into evapotranspiration and runoff, sometimes involving complex feedbacks with the atmosphere such as in the Amazon region (Port *et al.*, 2012; Saatchi *et al.*, 2013). One model in the study by Davie *et al.* (in press) showed regionally diverse climate change effects on vegetation distribution and structure, which had a much weaker effect on global runoff than the structural and physiological CO_2 effects. As water, carbon and vegetation dynamics evolve synchronously and interactively under climate change (Heyder *et al.*, 2011; Gerten *et al.*, in press), it remains a challenge to disentangle the individual effects of climate, CO_2 and land cover change on the water cycle.

Table 4-1: Biome shifts of the 20th century from published field research that examined trends over periods > 30 y for biomes in areas where climate (rather than land-use change or other factors) predominantly influenced vegetation, derived from a systematic analysis of published studies (Gonzalez *et al.*, 2010). Pre-AR4 publications are included to provide a comprehensive review. Shift type: elevational (E), latitudinal (L), examined but not detected (N). The biome abbreviations match those in Figure 4-1. Rate of change in temperature (Temp.) and fractional rate of change in precipitation (Precip.) are derived from linear least squares regression of 1901-2002 data (Mitchell and Jones, 2005; Gonzalez *et al.*, 2010). The table provides general regional climate trends at 50 km spatial resolution because the references do not give uniform site-specific climate data to compare across locations. The regional trends are consistent with local trends reported in each reference. * rate significant at P ≤ 0.05.

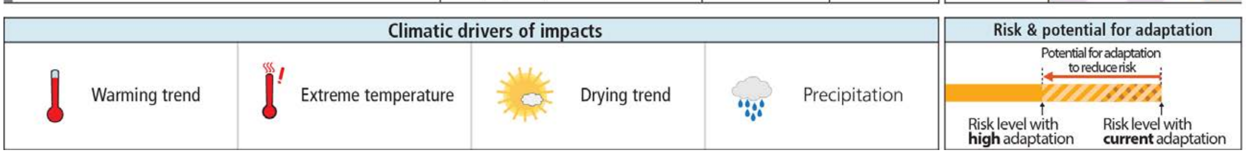
Table 4-2: Summary of drivers and outcomes of LUCC scenarios associated with Representative Concentration Pathways (Hurtt *et al.*, 2011). RCPs are identified with the radiative forcing by 2100 (8.5, 6.0, 4.5 and 2.6 Wm^{-2}) and by the name of the model used to generate the associated land use/cover scenarios (MESSAGE, AIM, GCAM and IMAGE; see Hurtt *et al*. (2011) for further details).

RCP	Model and references	Key assumptions / drivers	Land use / cover outcomes
8.5	MESSAGE, Riahi et al. (2007)	No climate change mitigation actions; radiative forcing still rising at 2100 Strong increase in agricultural resource use driven by the increasing population (rises to 12 billion people by 2100) Yield improvements and intensification assumed to account for most of production increases	Increase in cultivated land by about 305 million hafrom 2000 to 2100 Forest cover declines by 450 million ha from 2000 to 2100 Arable land use in developed countries slightly decreased - all of the net increases occur in developing countries.
6.0	AIM, Fujino *et al*. (2006); Hijioka *et al*. (2008)	Mitigation actions taken late in the century to stabilize radiative forcing at 6 Wm^{-2} after 2100 Population growth and economic growth Increasing food demand drives cropland expansion	Urban land-use increases Cropland area expands Grassland area declines Total forested area extent remains constant
4.5	GCAM, Smith and Wigley (2006); Wise *et al*. (2009)	Mitigation stabilizes radiative forcing at 4.5 Wm^{-2} before 2100 Assumes that global GHG emissions prices are invoked to limit emissions and therefore radiative forcing. Emissions pricing assumes all carbon emissions charged an equal penalty price, so reductions in land-use change carbon emissions available as mitigation Food demand met through crop yield improvements, dietary shifts, production efficiency and international trade.	Preservation of large stocks of terrestrial carbon in forests Overall expansion in forested area Agricultural land declines slightly due to afforestation,
2.6	IMAGE Van Vuuren *et al*., (2007); van Vuuren *et al*. (2006)	Overall trends in land use and land cover mainly determined by demand, trade and production of agricultural products and bio-energy. Expansion of croplands largely due to bioenergy production. Production of animal products met through shift from extensive to more intensive animal husbandry	Much agriculture relocates from high income to low-income regions Increase in bio-energy production, new area for bioenergy crops near current agricultural areas. Pasture largely constant

Table 4-3: Key risks for terrestrial and freshwater ecosystems from climate change and the potential for reducing risk through mitigation and adaptation. Key risks are identified based on assessment of the literature and expert judgments by chapter authors, with evaluation of evidence and agreement in supporting chapter sections. Each key risk is characterized as very low to very high. Risk levels are presented in three timeframes: the present, near-term (here, assessed over 2030-2040), and longer-term (here, assessed over 2080-2100). For the near-term era of committed climate change, projected levels of global mean temperature increase do not diverge substantially across emission scenarios. For the longer-term era of climate options, risk levels are presented for global mean temperature increase of 2°C and 4°C above preindustrial levels. For each timeframe, risk levels are estimated for a continuation of current adaptation and for a hypothetical highly adapted state. Relevant climate variables are indicated by icons. For a given key risk, change in risk level through time and across magnitudes of climate change is illustrated, but because the assessment considers potential impacts on different physical, biological, and human systems, risk levels should not necessarily be used to evaluate relative risk across key risks, sectors, or regions.

Key risk	Adaptation issues and prospects	Climatic drivers	Supporting ch. sections	Timeframe	Risk for current and high adaptation
Reduction in terrestrial carbon sink: Carbon stored in terrestrial Medium high ecosystems is vulnerable to loss back into the atmosphere. Key mechanisms include an increase in fire frequency due to climate change and the sensitivity of ecosystem respiration to rising temperatures (*medium confidence*)	Adaptation prospects include managing land-use (including deforestation), fire and other disturbances and non-climatic stressors.	Warming trend; Extreme temperature; Drying trend	4.2.4 4.3.2 4.3.3	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Very low – Medium – Very high
Boreal tipping point: Arctic ecosystems are vulnerable to abrupt change related to the thawing of permafrost and spread of shrubs in tundra and increase in pests and fires in boreal forests (*medium confidence*)	There are few adaptation options in the Arctic.	Warming trend; Extreme temperature	4.3.3.1.1 Box 4-4	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Very low – Medium – Very high
Amazon tipping point: Moist Amazon forests could change abruptly to less carbon-dense drought and fire-adapted ecosystems (*medium confidence*)	Policy and market measures to reduce deforestation and fire.	Warming trend; Extreme temperature; Drying trend	4.3.3.1.3 Box 4-3	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Very low – Medium – Very high
Tree mortality and forest loss: Tree mortality has been observed to have increased in many places and has been attributed in some cases to direct climate effects and indirect effects due to pests and diseases. The dead trees increase the risk of forest fires (*medium confidence*)	Adaption options include more effective management of fire, pests and pathogens.	Warming trend; Extreme temperature; Drying trend	4.3.3.1 Box 4-2	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Very low – Medium – Very high
Increased risk of species extinction: A large fraction of the species that have been assessed are vulnerable to extinction as a result of climate change, often in interaction with other threats. Species with an intrinsically low dispersal rate, especially when occupying flat landscapes where the projected climate velocity is high, and species in isolated habitats such as mountain tops, islands or small protected areas are especially at risk. Cascading effects through organism interactions, and especially those vulnerable to timing (phenological) changes amplifies the risk (*high confidence*)	Adaptation options include reducing habitat modification, habitat fragmentation, pollution, over-exploitation and invasive species; protected area expansion, assisted dispersal, ex situ conservation.	Warming trend; Extreme temperature; Drying trend	4.3.2.5 4.3.3.3 4.3.2.1 4.4.2	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Very low – Medium – Very high
Invasion by non-native species: Disruptions of species interactions and the increase in physiological stress as a result of being near the edge or outside of the historical climate niche increases the vulnerability of ecosystems to invasion by non-native (alien) species, especially in the presence of increased long-distance dispersal opportunities. In the extreme this can result in biome shifts, with consequent changes in the spectrum of ecosystem services provided (*high confidence*)	Climate is one driver among many. Adaptation options are limited, largely based on reducing other stresses and measures to slow the unintended arrival of aliens. Intensive direct intervention in controlling emergent invasive species is an option, but could be overwhelmed by the rapidly rising number is cases.	Warming trend; Drying trend; Precipitation	4.2.4.6	Present Near-term (2030-2040) Long-term (2080-2100) 2°C 4°C	Very low – Medium – Very high



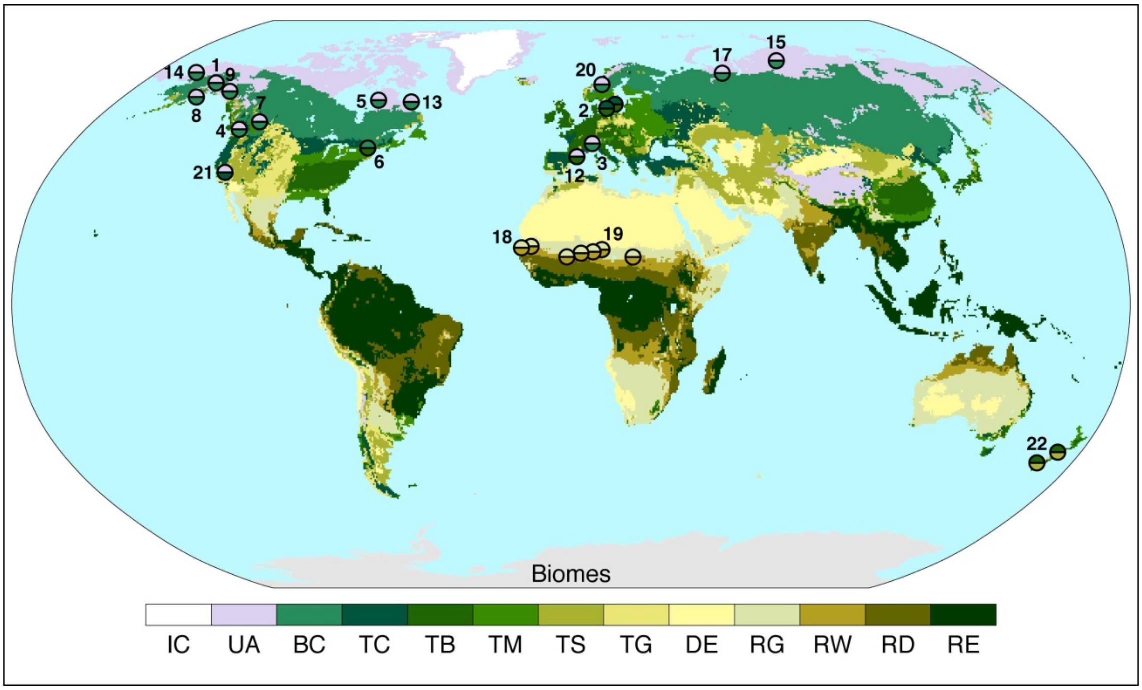


Figure 4-1: Locations of observed biome shifts during the 20th century, listed in Table 4-1, derived from Gonzalez *et al.* (2010). The color of each semi-circle indicates the retracting biome (top for North America, Europe, Asia; bottom for Africa and New Zealand) and the expanding biome (bottom for North America, Europe, Asia; top for Africa and New Zealand), according to published field observations. Biomes, from poles to equator: ice (IC), tundra and alpine (UA), boreal conifer forest (BC), temperate conifer forest (TC), temperate broadleaf forest (TB), temperate mixed forest (TM), temperate shrubland (TS), temperate grassland (TG), desert (DE), tropical grassland (RG), tropical woodland (RW), tropical deciduous broadleaf forest (RD), tropical evergreen broadleaf forest (RE). The background is the potential biome according to the MC1 dynamic global vegetation model under the 1961-1990 climate. **[Illustration to be redrawn to conform to IPCC publication specifications.]**

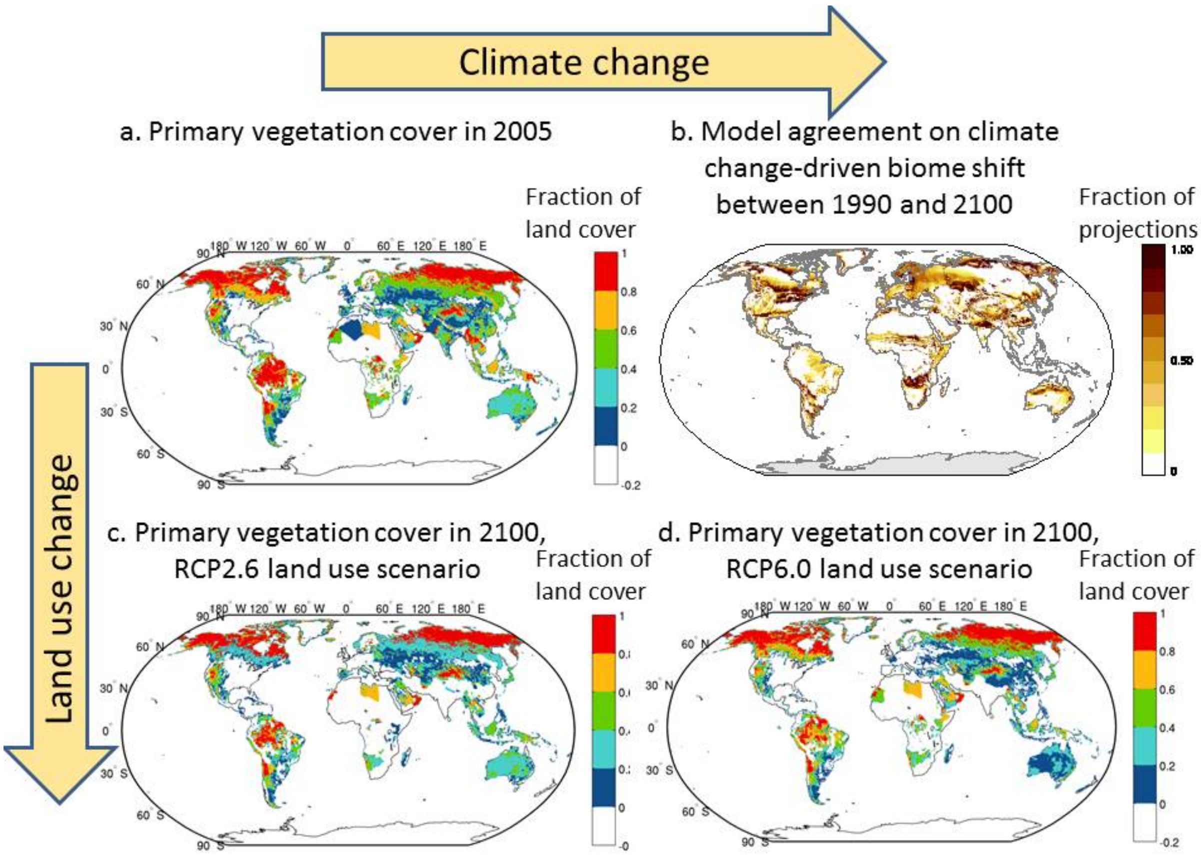

Figure 4-2: Implications of climate change and land use change for biome shifts. (a) Fraction of land covered by primary vegetation in 2005 (Hurtt *et al.*, 2011); (b) Fraction of simulations showing climate change-driven biome shift for any level of global warming between 1990 and 2100, with no direct anthropogenic land use change, using the MC1 vegetation model under 9 CMIP3 climate projections (3 GCMs each forced by the SRES A2, A1B and B1 scenarios; Gonzalez *et al.*, 2010); (c) Fraction of land covered by primary vegetation in 2100 under the RCP2.6 land use scenario with the IMAGE model, with no effect of climate change (Hurtt *et al.*, 2011); (d) Fraction of land covered by primary vegetation in 2100 under the RCP8.5 land use scenario with the MESSAGE model, with no effect of climate change (Hurtt *et al.*, 2011). Comparison of coloured areas in (b) with those in (a) shows where climate- driven biome shifts would occur in current areas of primary vegetation. Comparison of (b) and (d) shows where climate-driven biome shifts would occur in areas of primary vegetation projected under a land use scenario associated with RCP6.0. Comparison of (c) and (a) illustrates a scenario of land use change associated with RCP2.6, in which global climate change is projected to be smaller than that driving the biome shifts in (b) as a result of mitigation measures, some of which involve land use. Further details of the RCP land use / cover scenarios are given in Box 4-1, Figure 4-3 and Table 4-2.
[Illustration to be redrawn to conform to IPCC publication specifications.]

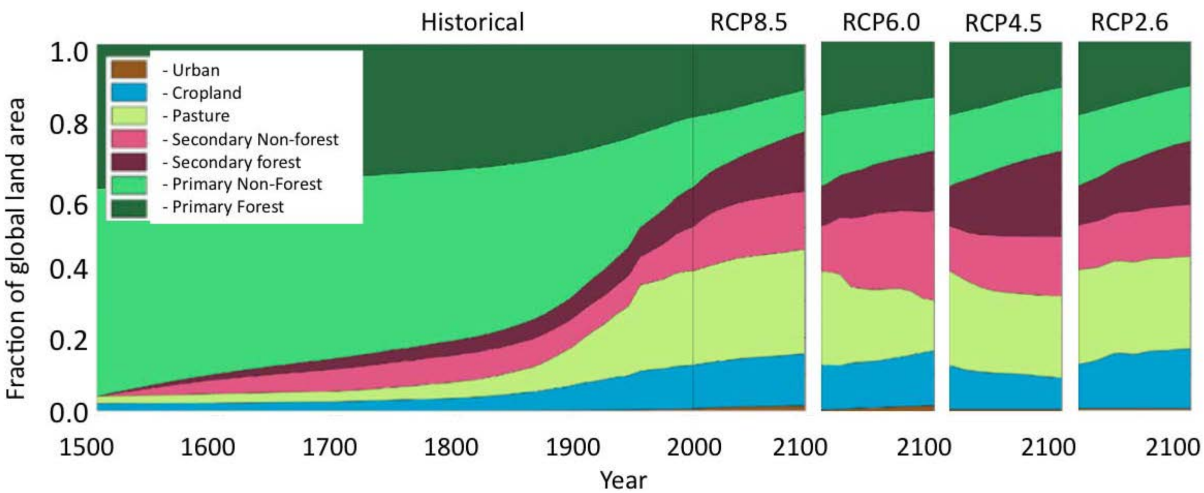

Figure 4-3: Proportion of global land cover occupied by primary and secondary vegetation (forest and non-forest), cropland, pasture and urban land, from satellite data and historical reconstructions up to 2005 (Klein Goldewijk *et al.*, 2010; Klein Goldewijk *et al.*, 2011), and from scenarios associated with the RCPs from 2005 to 2100 (Hurtt *et al.*, 2011)**. [Illustration to be redrawn to conform to IPCC publication specifications.]**

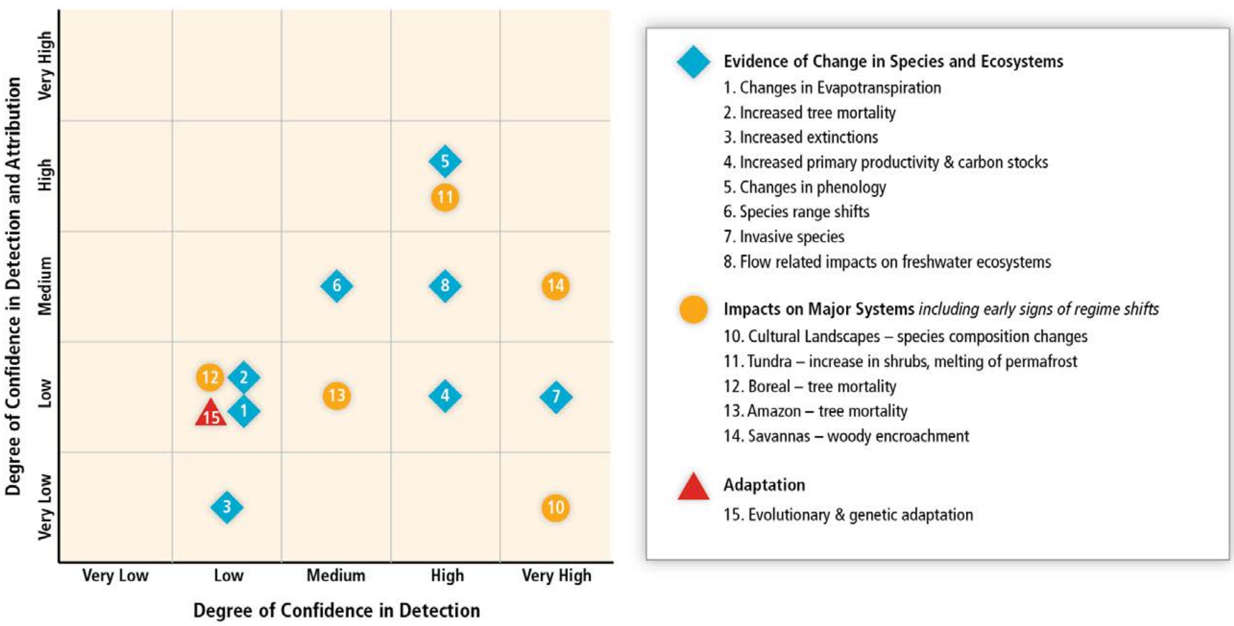

Figure 4-4: Confidence in detection of change and attribution of observed responses of terrestrial ecosystems to climate change. Confidence levels are based on expert judgment of the available literature following the IPCC uncertainty guidance (Mastrandrea *et al.*, 2010), attribution criteria outlined in Chapter 18 and detection criteria defined in the text. The symbols in the figure represent global and cross-taxon assessments; the positioning may be different for specific taxa or regions. The following sections provide the details of the assessments that were used in positioning each of the points Phenology, Section 4.3.2.1; Primary Productivity, Section 4.3.2.2; Biomass and C stocks, Section 4.3.2.3; Evapotranspiration, Section 4.3.2.4; Species distributions, Section 4.3.2.5**;** Global species extinctions, Section 4.3.2.5**;** Invasive and alien species**,** Section 4.2.4.6**;** Tree mortality, Section 4.3.3.1, Box 4-2; Boreal forest regime shift, Section 4.3.3.1.1, Box 4-4; Amazon forest regime shift, Section 4.3.3.1.3, Box 4-3; Tundra regime shift, Section 4.3.3.4, Box 4-4; Woody encroachment, Section 4.3.3.2.2; Cultural landscapes, Section 4.3.3.5.3; Evolutionary and genetic adaptation, Section 4.4.1.2.

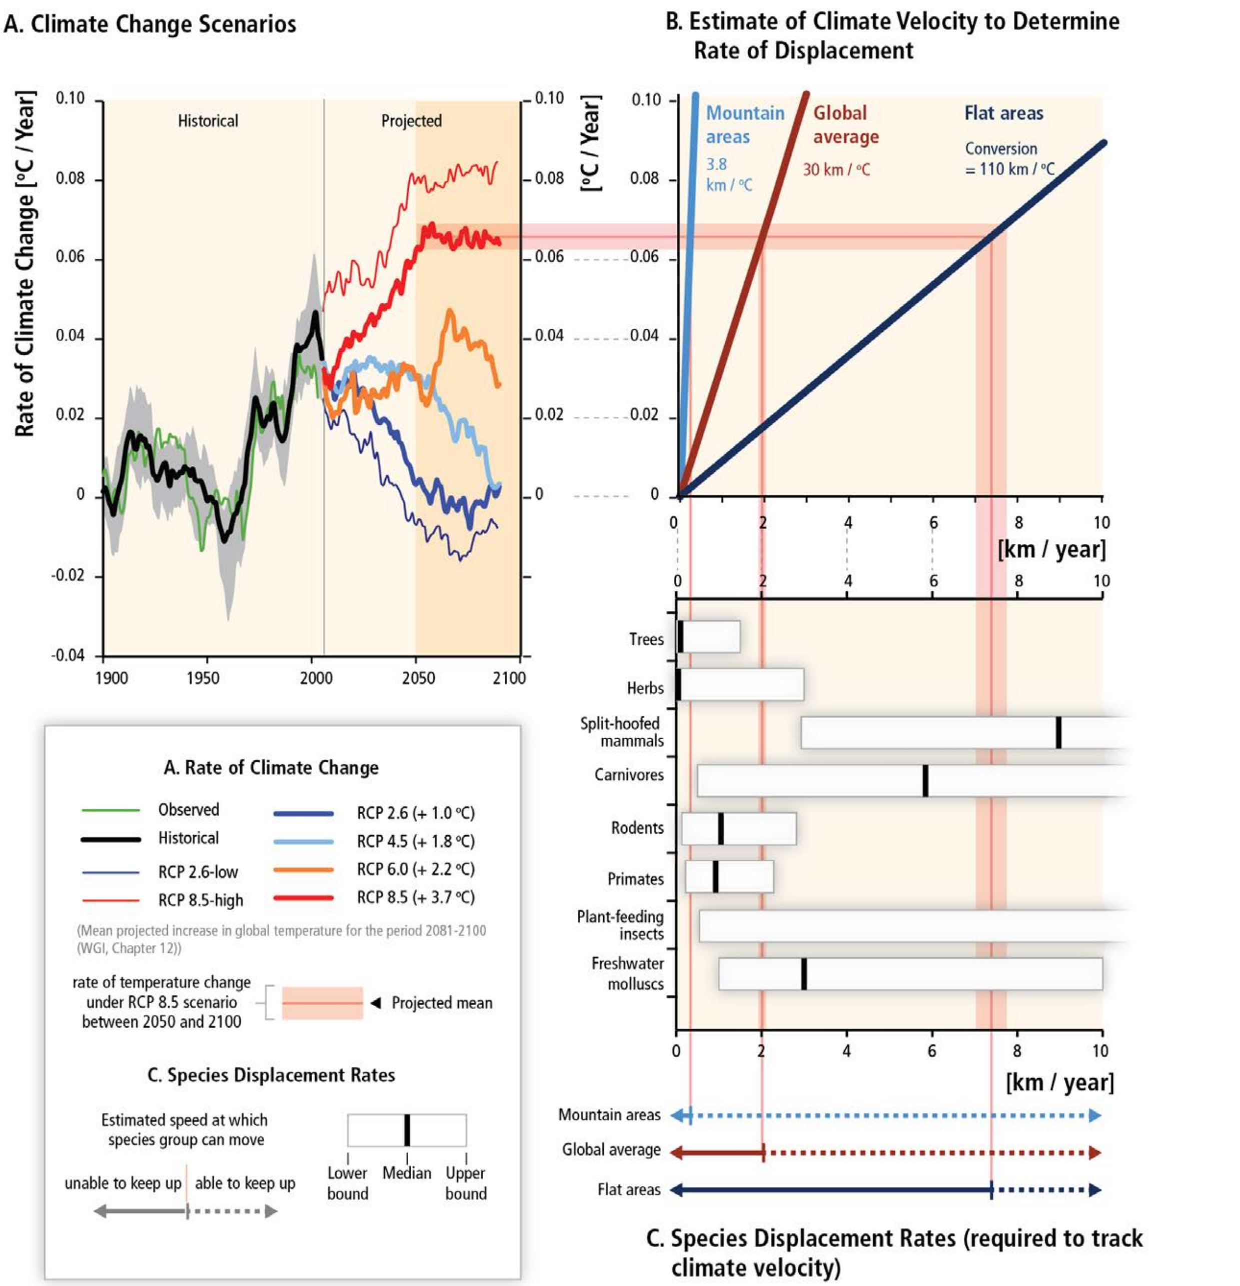

Figure 4-5: (A) Rates of climate change, (B) corresponding climate velocities and (C) rates of displacement of several terrestrial and freshwater species groups in the absence of human intervention. Horizontal and vertical pink bands illustrate the interpretation of this figure. Climate velocities for a given range of rates of climate change are determined by tracing a band from the range of rates in panel A to the points of intersection with the three climate velocity scalars in panel B. Comparisons with species displacement rates are made by tracing vertical bands from the points of intersection on the climate velocity scalars down to the species displacement rates in panel C. Species groups with displacement rates below the band are projected to be unable to track climate in the absence of human intervention. (A) Observed rates of climate change for global land areas are derived from CRUTEM4 climate data reanalysis, all other rates are calculated based on the average of CMIP5 climate model ensembles for the historical period (grey shading indicates model uncertainty) and for the future based on the four RCP emissions scenarios. Data were smoothed using a 20-year sliding window, and rates are means of between 17 and 30 models using one

member per model. Global average temperatures at the end of the 21st century for the four RCP scenarios are from WGI AR5 Chapter 12. (B) Estimates of climate velocity for temperature were synthesized from historical and projected future relationships between rates of temperature change and climate velocity (historical: Burrows *et al.*, 2011; Chen *et al.*, 2011; Dobrowski *et al.*, 2013; projected future: Loarie *et al.*, 2009; Sandel *et al.*, 2011; Feeley and Rehm, 2012). The three scalars are climate velocities that are representative of mountainous areas (left), averaged across global land areas (centre), and large flat regions (right). (C) Rates of displacement are given with an estimate of the median (black bars) and range (boxes = ca. 95% of observations or models for herbaceous plants, trees and plant-feeding insects or median ± 1.5 inter-quartile range for mammals). Displacement rates for herbaceous plants were derived from paleobotanical records, modern plant invasion rates and genetic analyses (Kinlan and Gaines, 2003). Displacement estimates for trees are based on reconstructed rates of tree migration during the Holocene (Clark, 1998; Clark *et al.*, 2003; Kinlan and Gaines, 2003; McLachlan *et al.*, 2005; Nathan, 2006; Pearson, 2006) and modelled tree dispersal and establishment in response to future climate change (Higgins *et al.*, 2003; Iverson *et al.*, 2004; Epstein *et al.*, 2007; Goetz *et al.*, 2011; Nathan *et al.*, 2011; Meier *et al.*, 2012; Sato and Ise, 2012). Displacement rates for mammals were based on modelled dispersal rates of a wide range of mammal species (mean of Schloss *et al.*, 2012 for Western Hemisphere mammals and rates calculated from global assessments of dispersal distance by Santini *et al.*, 2013 and generation length by Pacifici *et al.*, 2013). Displacement rates for phytophagous insects are based on observed dispersal distances and genetic analyses (Peterson and Denno, 1998; Kinlan and Gaines, 2003; Schneider, 2003; Berg *et al.*, 2010; Chen *et al.*, 2011). The estimate of median displacement rate for this group exceeds the highest rates on the axis. These displacement rates do not take into account limitations imposed by host plants. Displacement estimates for freshwater molluscs correspond to the range of passive plus active dispersal rates for upstream movement (Kappes and Haase, 2012).

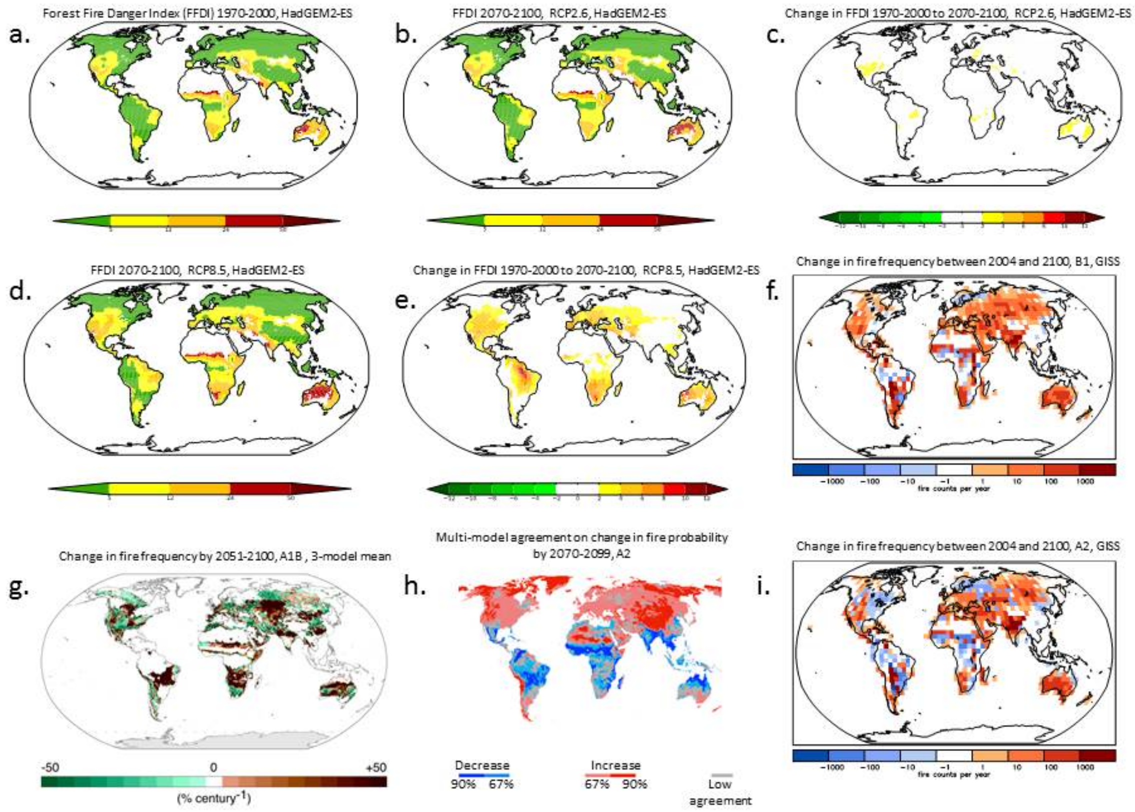

Figure 4-6: Projected changes in meteorological fire danger, fire probability and fire frequency with different methods and climate models. (a)-(e) 30-year annual mean MacArthur Forest Fire Danger Index (FFDI) and change simulated with the HadGEM2-ES Earth System Model, with areas of no vegetation excluded (Betts *et al*., 2013; (a) FFDI 1970-2000; (b) FFDI 2070-2100, RCP2.6; (c) change in FFDI by 2070-2100 relative to 1970-2000, RCP2.6;(d) FFDI 2070-2100; RCP8.5 (e) change in FFDI by 2070-2100 relative to 1970-2000, RCP8.5. (f) Change in fire frequency by 2100 relative to 2004, SRES B1, simulated using climate and land cover projections from the GISS GCM and IMAGE IAM (Pechony and Shindell, 2010). (g) Change in fire frequency by 2051-2100 relative to 1951-2000, SRES A1B, simulated with the MC1 vegetation model driven by 3 GCMs (CSIRO-Mk3.0, HadCM3, MIROC 3.2medres; mean over 3 simulations; Gonzalez et al., 2010). (h) Agreement on changes in fire probability simulated with a statistical model using climate projections from 16 CMIP3 GCMs, SRES A2 (i) Change in fire frequency by 2100 relative to 2004, SRES A2, simulated using climate and land cover projections from the GISS GCM (AR4 version) and IMAGE IAM (Pechony and Shindell, 2010). Changes in FFDI (a)-(e) and fire probability (h) arise entirely from changes in meteorological quantities, whereas changes in fire frequency (f) (g) (i) depend on both meteorological quantities and vegetation.
[Illustration to be redrawn to conform to IPCC publication specifications.]

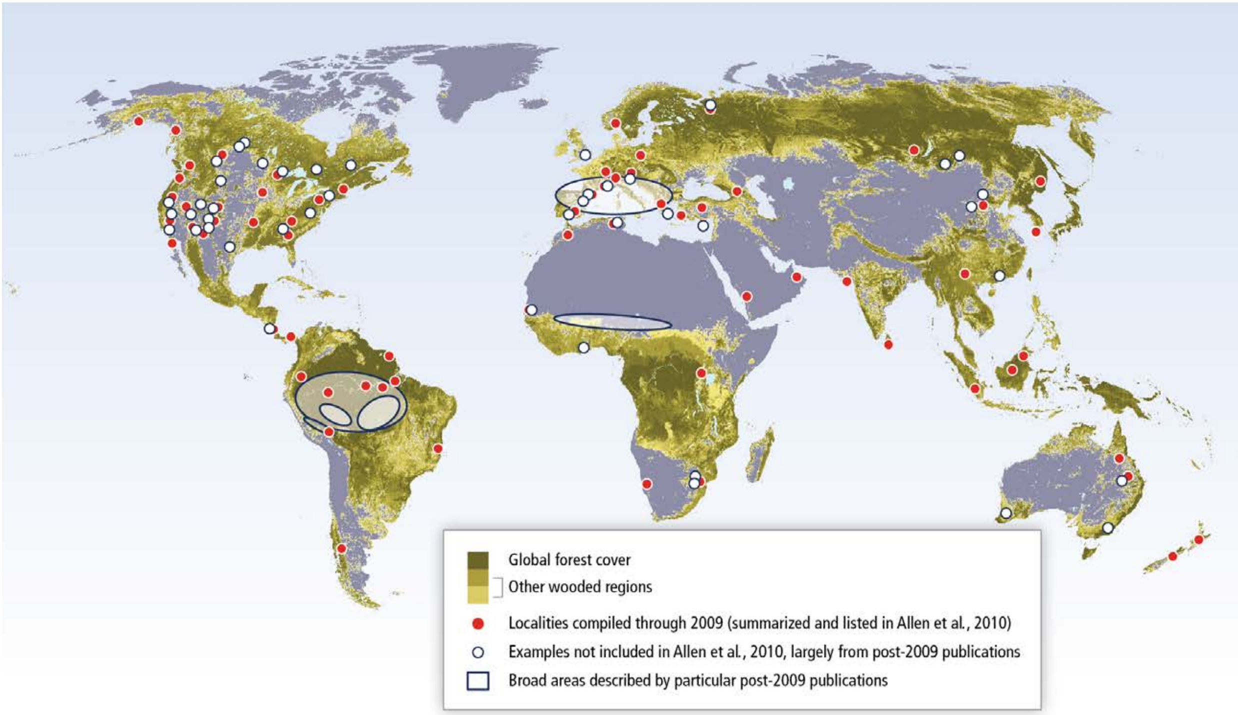

Figure 4-7: Locations of substantial drought- and heat-induced tree mortality around the globe since 1970 (global forest cover and other wooded regions based on FAO, 2005). Studies compiled through 2009 (red dots) are summarized and listed in Allen *et al.* (2010a). Localities and measurement networks not included in Allen *et al.* (2010a), which are largely from post-2009 publications, have been added to this map (white dots and shapes). New locality references by region: Africa – Mehl *et al.*, 2010, van der Linde *et al.*, 2011; Fauset *et al.*, 2012; Gonzalez *et al.*, 2012; Kherchouche *et al.*, 2012; Asia – Dulamsuren *et al.*, 2009; Kharuk *et al.*, 2013; Liu *et al.*, 2013; Zhou *et al.*, 2013; Australasia – Brouwers *et al.*, 2012; Fensham *et al.*, 2012; Keith *et al.*, 2012; Matusick *et al.*, 2012; Brouwers *et al.*, 2013; Matusick *et al.*, 2013; Europe – Innes, 1992; Peterken and Mountford, 1996; Linares *et al.*, 2009; Galiano *et al.*, 2010; Vennetier and Ripert, 2010; Aakala *et al.*, 2011; Carnicer *et al.*, 2011; Linares *et al.*, 2011; Sarris *et al.*, 2011; Marini *et al.*, 2012; Cailleret *et al.*, 2013; Vilà-Cabrera *et al.*, 2013; North America – Fahey, 1998; Minnich, 2007; Klos *et al.*, 2009; Ganey and Vojta, 2011; Michaelian *et al.*, 2011; Peng *et al.*, 2011; DeRose and Long, 2012; Fellows and Goulden, 2012; Kaiser *et al.*, 2012; Millar *et al.*, 2012; Garrity *et al.*, 2013; Kukowski *et al.*, 2013; Williams *et al.*, 2013; Worrall *et al.*, 2013; South America – Enquist and Enquist, 2011; Lewis *et al.*, 2011; Saatchi *et al.*, 2013.

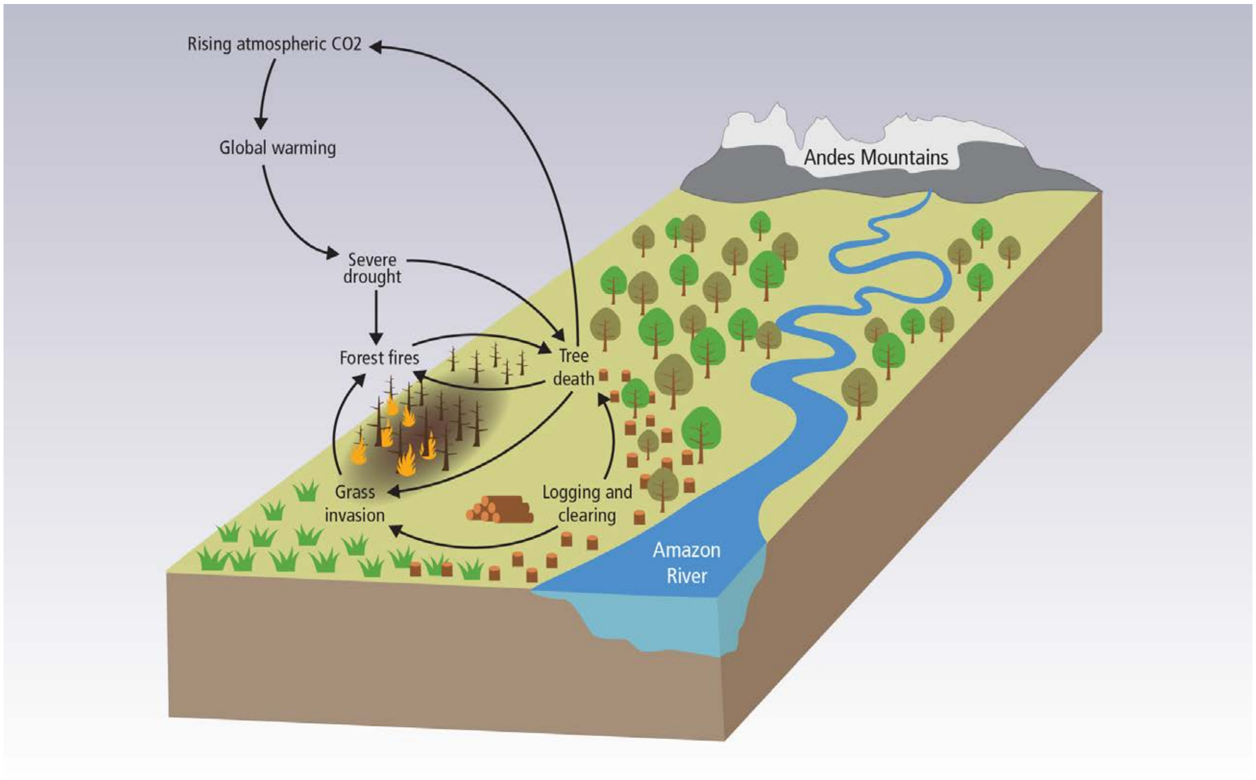

Figure 4-8: The forests of the Amazon Basin are being altered through severe droughts, land use (deforestation, logging), and increased frequencies of forest fire. Some of these processes are self-reinforcing through positive feedbacks, and create the potential for a large-scale tipping point. For example, forest fire kills trees, increasing the likelihood of subsequent burning. This effect is magnified when tree death allows forests to be invaded by flammable grasses. Deforestation provides ignition sources to flammable forests, contributing to this dieback. Climate change contributes to this tipping point by increasing drought severity, reducing rainfall and raising air temperatures, particularly in the eastern Amazon Basin (*medium confidence; medium evidence, medium agreement).*]

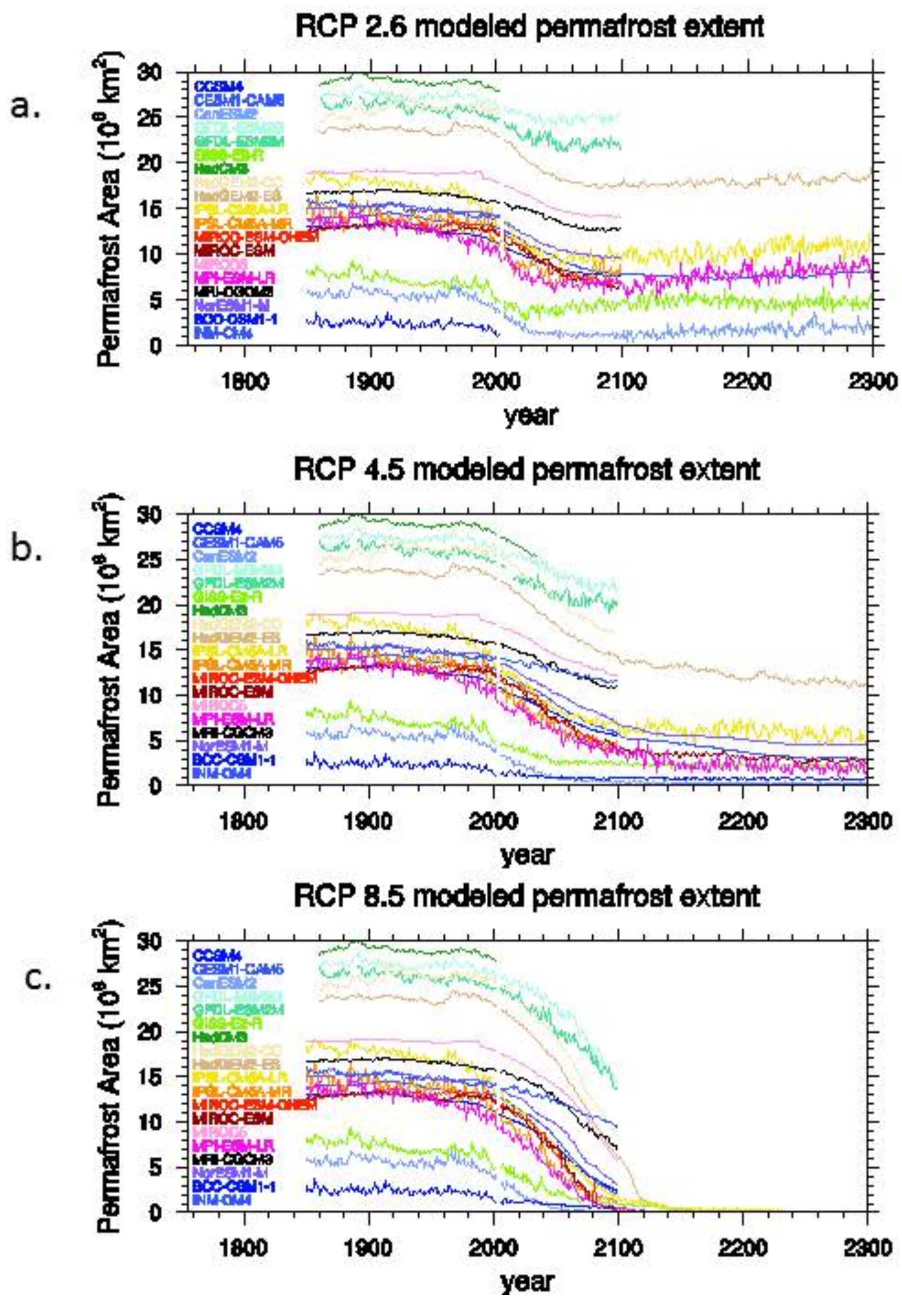

Figure 4-9: CMIP5 multi-model simulated area of Northern Hemisphere permafrost in the upper 3m of soil, from 1850 to 2100 or 2300 depending on extent of individual simulations. Each panel shows historical (1850-2005) and projected (2005 to 2100 or 2300) simulations for (a) RCP2.6, (b) RCP4.5, and (c) RCP8.5. The observed current permafrost extent is 15×10^6 km^2. (Based on Koven *et al.*, 2013, with analysis extended to 2300 following Caesar *et al.*, 2013). **[Illustration to be redrawn to conform to IPCC publication specifications.]**

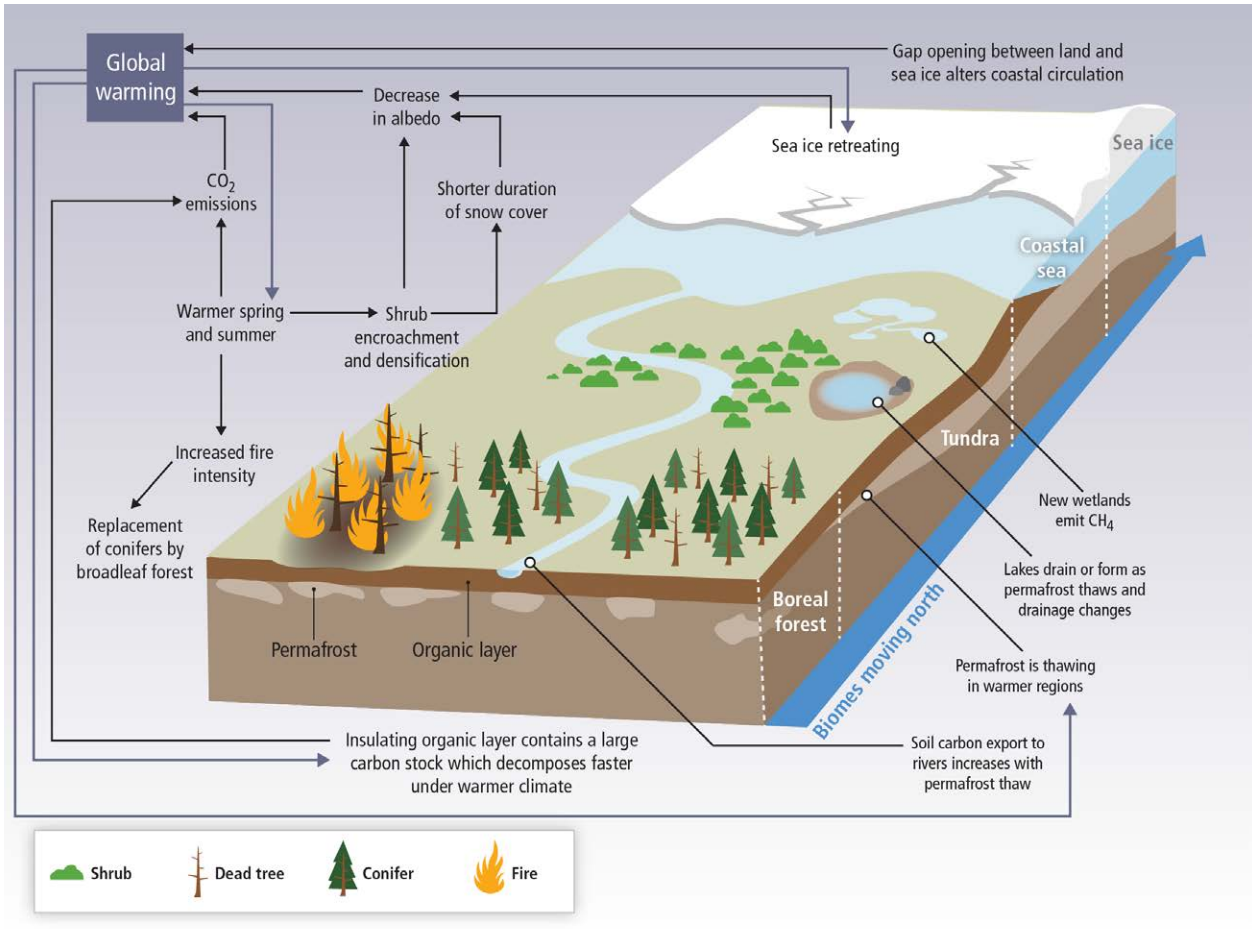

Figure 4-10: Tundra-Boreal Biome Shift. Earth system models predict a northward shift of Arctic vegetation with climate warming, as the boreal biome migrates into what is currently tundra. Observations of shrub expansion in tundra, increased tree growth at the tundra-forest transition, and tree mortality at the southern extent of the boreal forest in recent decades are consistent with model projections. Vegetation changes associated with a biome shift, which is facilitated by intensification of the fire regime, will modify surface energy budgets, and net ecosystem carbon balance, permafrost thawing and methane emissions, with net feedbacks to additional climate change.

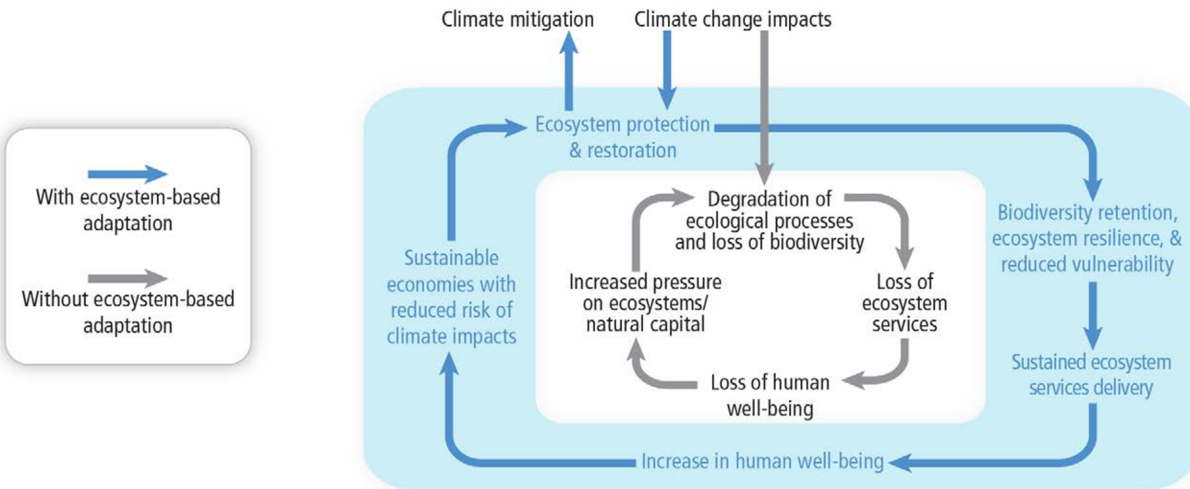

Figure EA-1: Adapted from Munang et al. (2013). Ecosystem based adaptation (EBA) uses the capacity of nature to buffer human systems from the adverse impacts of climate change. Without EBA, climate change may cause degradation of ecological processes (central white panel) leading to losses in human well-being. Implementing EBA (outer blue panel) may reduce or offset these adverse impacts resulting in a virtuous cycle that reduces climate-related risks to human communities, and may provide mitigation benefits.

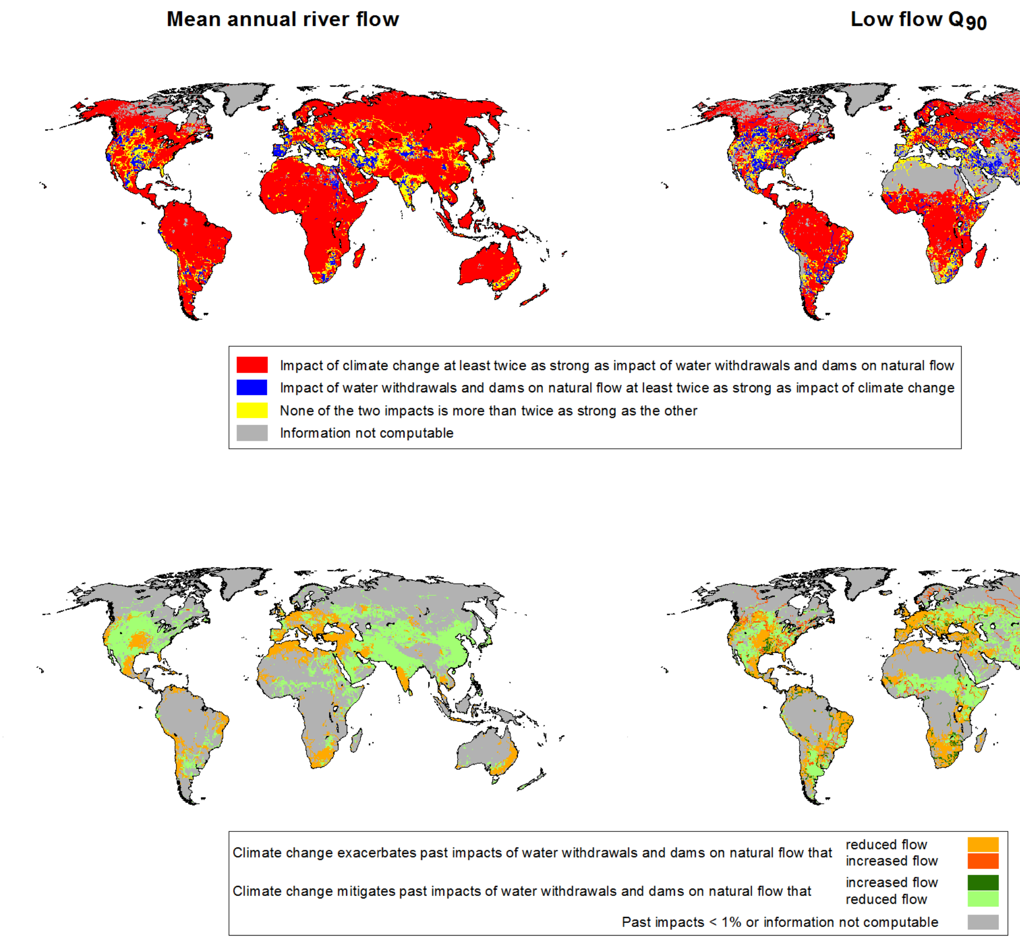

Figure RF-1: Impact of climate change relative to the impact of water withdrawals and dams on natural flows for two ecologically relevant river flow characteristics (mean annual river flow and monthly low flow Q_{90}), computed by a global water model (Döll and Zhang, 2010). Monthly Q_{90} was defined as the flow that is exceeded in 9 out 10 months. Impact of climate change is the percent change of flow between 1961-1990 and 2041-2070 according to the emissions scenario A2 as implemented by the global climate model HadCM3. Impact of water withdrawals and reservoirs is computed by running the model with and without water withdrawals and dams that existed in 2002. Please note that the figure does not reflect spatial differences in the magnitude of change.
[Illustration to be redrawn to conform to IPCC publication specifications.]

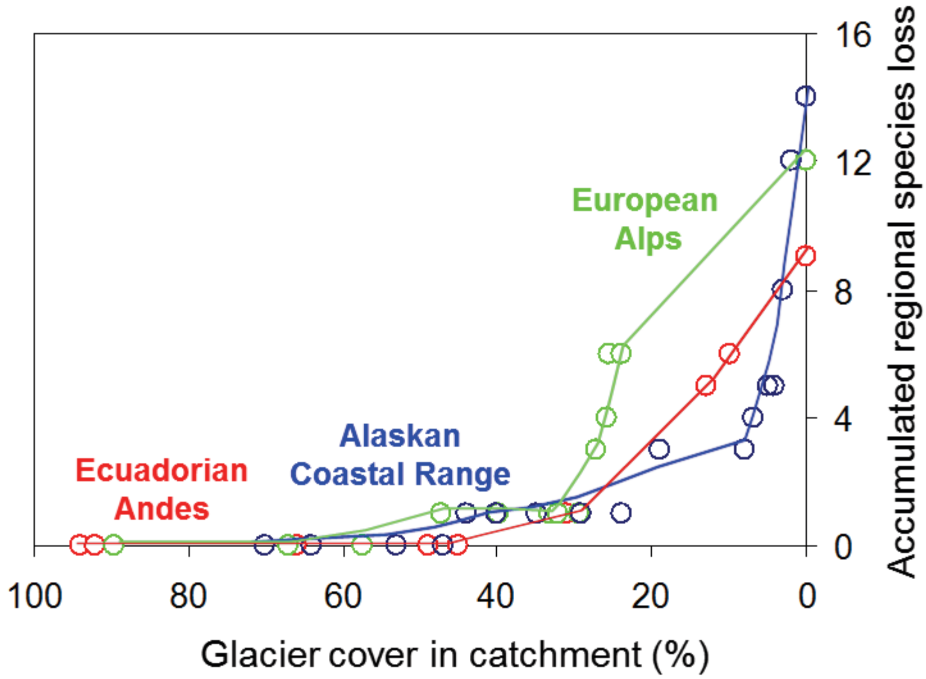

Figure RF-2: Accumulated loss of regional species richness (gamma diversity) of macroinvertebrates as a function of glacial cover in catchment. Obligate glacial river macroinvertebrates begin to disappear from assemblages when glacial cover in the catchment drops below approximately 50%, and 9-14 species are predicted to be lost with the complete disappearance of glaciers in each region, corresponding to 11, 16 and 38% of the total species richness in the three study regions in Ecuador, Europe and Alaska. Data are derived from multiple river sites from the Ecuadorian Andes and Swiss and Italian Alps, and a temporal study of a river in the Coastal Range Mountains of southeast Alaska over nearly three decades of glacial shrinkage. Each data point represents a river site or date (Alaska), and lines are Lowess fits. Adapted by permission from Macmillan Publishers Ltd: *Nature Climate Change*, Jacobsen *et al.*, 2012, © 2012.

Executive Summary

Coastal systems are particularly sensitive to three key drivers related to climate change: sea level, ocean temperature and ocean acidity (*very high confidence*) [5.3.2, 5.3.3.4, 5.3.3.5]. Despite the lack of attribution of observed coastal changes, there is a long-term commitment to experience the impacts of sea level rise because of a delay in its response to temperature [5.5.8] (*high agreement*). In contrast, coral bleaching and species ranges can be attributed to ocean temperature change and ocean acidity [5.4.2.4, 5.4.2.2]. For many other coastal changes, the impacts of climate change are difficult to tease apart from human-related drivers (e.g. land-use change, coastal development, pollution) (*high agreement, robust evidence*).

Coastal systems and low-lying areas will increasingly experience adverse impacts such as submergence, coastal flooding and coastal erosion due to relative sea level rise (*very high confidence*). Beaches, sand dunes and cliffs currently eroding will continue to do so under increasing sea level (*high confidence*) [5.4.2.1, 5.4.2.2]. Large

spatial variations in the projected sea level rise together with local factors means relative sea level rise at the local scale can vary considerably from projected Global Mean Sea Level (GMSL) rise (*very high confidence*) [5.3.2]. The storms related impacts and associated storm surges will be worsened by GMSL rise although uncertainty related to changes in tropical and mid-latitude cyclones at the regional scale will signify that there is *low confidence* in projections of storm surge change [5.3.3.2]. Both relative sea level rise and impacts are also influenced by a variety of local processes unrelated to climate (e.g. subsidence, glacial isostatic adjustment, sediment transport, coastal development) (*very high confidence*).

Acidification and warming of coastal waters will continue with significant negative consequences for coastal ecosystems (*high confidence*). The increase in acidity will be higher in areas where eutrophication or coastal upwellings are an issue. It will have negative impacts for many calcifying organisms (*high confidence*) [5.4.2.2]. Warming and acidification will lead to coral bleaching, mortality and decreased constructional ability (*high confidence)* making coral reefs the most vulnerable marine ecosystem with little scope for adaptation [5.4.2.4, Box CC-OA]. Temperate seagrass and kelp ecosystems will decline with the increased frequency of heat waves and sea temperature extremes as well as through the impact of invasive subtropical species *(high confidence*) (5.4.2.3).

The population and assets exposed to coastal risks as well as human pressures on coastal ecosystems will increase significantly in the coming decades due to population growth, economic development and urbanization (*high confidence*)**.** The exposure of people and assets to coastal risks has been rapidly growing and this trend is expected to continue [5.3.4.1, 5.4.3.1]. Humans have been the primary drivers of changes in coastal aquifers, lagoons, estuaries, deltas and wetlands (*very high confidence*) and are expected to further exacerbate human pressures on coastal ecosystems resulting from excess nutrient input, changes in run-off and reduced sediment delivery (*high confidence*) [5.3.4.2, 5.3.4.3, 5.3.4.4].

For the 21st century, the benefits of protecting against increased coastal flooding and land loss due to submergence and erosion at the global scale are larger than the social and economic costs of inaction (*high agreement, limited evidence***).** Without adaptation, hundreds of millions of people will be affected by coastal flooding and will be displaced due to land loss by year 2100; the majority of those affected are from East, Southeast and South Asia (*high confidence*) [5.3.4.1, 5.4.3.1]. At the same time, protecting against flooding and erosion is considered economically rational for most developed coastlines in many countries under all socio-economic and sea level rise scenarios analyzed, including for the 21st century GSML rise of above 1 m (*high agreement, low evidence*) [5.5.5].

The relative costs of adaptation vary strongly between and within regions and countries for the 21st century (*high confidence***).** Some low-lying developing countries (e.g. Bangladesh, Vietnam) and small island states are expected to face very high impacts and associated annual damage and adaptation costs of several percentage points of GDP [5.5.5]. Developing countries and small island states within the tropics dependent on coastal tourism will be impacted directly not only by future sea level rise and associated extremes but also by coral bleaching and ocean acidification and associated reductions in tourist arrivals **(***high confidence*) [5.4.3.4].

The analysis and implementation of coastal adaptation has progressed more significantly in developed countries than in developing countries towards climate resilient and sustainable coasts (*high confidence***).** Given ample adaptation options, more proactive responses can be made and based on technological, policy related, financial and institutional support. Observed successful adaptations include major projects (e.g. Thames Estuary, Venice Lagoon, Delta Works) and specific practices in both developed countries (e.g. Netherlands, Australia) and developing countries (e.g. Bangladesh) [5.5.4.2]. More countries and communities carry out coastal adaptation measures including those based on integrated coastal zone management, local communities, ecosystems and disaster reduction, and these measures are mainstreamed into relevant strategies and management plans [5.5.4, 5.5.5] (*high confidence*).

5.1. Introduction

This chapter presents an updated picture of the impacts, vulnerability and adaptation of coastal systems and low-lying areas to climate change, with sea level rise perceived as most important risk for the human systems. Unlike the coastal chapter in the previous assessment (Fourth Assessment Report, AR4), materials pertinent to the oceans are not covered here but in two new ocean chapters (Chapters 6 and 30). As in AR4, polar coasts are in another chapter (chapter 28); small islands area also considered separately (chapter 29) and an in depth presentation will not be found herein.

The topics covered in this chapter follow the outline for sectoral chapters approved by the IPCC. An Executive Summary summarizes the key messages with a line of sight to the supporting sections in the chapter.

This chapter comprises six sections with this first section dealing with progress in knowledge from AR4 to AR5 (Fifth Assessment Report), scope of chapter and new developments. Section 2 defines the coastal systems and climate and non-climate drivers. The coastal systems include both natural systems and human systems and this division is generally followed throughout the chapter. The climate and non-climate drivers are assessed in section 3, followed by the impacts, vulnerabilities and risks in section 4. Section 5 deals with adaptation and managing risks. Information gaps, data gaps and research needs are assessed in section 6. There is one box on a specific example and three cross-chapter boxes, distributed within the chapter.

In AR4, the coastal chapter assessed the impact of climate change and a global sea level rise up to 0.59 m in 2090s. The coastal systems were considered to be affected mainly by higher sea levels, increasing temperatures, changes in precipitation, larger storm surges and increased ocean acidity. Human activities had continued to increase their pressure on the coasts with rapid urbanization in coastal areas and growth of megacities with consequences on coastal resources. Regionally, South, Southeast and East Asia, Africa and small islands were identified as most vulnerable. The AR4 chapter offered a range of adaptation measures, many under the ICZM (Integrated Coastal Zone Management) framework that could be carried out in both developed and developing countries, but recognized that the latter would face more challenges. Various issues on increasing the adaptive capacity or increasing the resilience of coastal communities were discussed. The unavoidability of sea level rise in the long term, even with stringent mitigation was noted, with adaptation becoming an urgent issue.

A number of key issues related to the coasts have arisen since AR4. There is now better understanding of the natural systems, their ecosystem functions, their services and benefits to humanity and how they can be affected by climate change. Their linkages landward to the watersheds and seaward to the seas and oceans need to be considered for a more integrated assessment of climate change impacts. The GMSL (global mean sea level) rise is projected to be 0.28-0.98 m by 2100 (Table 5-2) although with regional variations and local factors the local sea level rise can be higher than the projected for the GMSL. This has serious implications for coastal cities, deltas and low-lying states. While higher rates of coastal erosion are generally expected under rising sea levels, the complex inter-relationships between the geomorphological and ecological attributes of the coastal system (Haslett, 2009; Gilman *et al*., 2007) and the relevant climate and oceanic processes need to be better established at regional and local scales. Such complex inter-relationships can be influenced by different methods and responses of coastal management.

Also of concern is ocean acidification. Together with warming, it causes coral reefs to lose their structural integrity with negatively implicating reef communities and shore protection (Sheppard *et al.*, 2005; Manzello *et al.*, 2008; see Boxes CC-OA and CC-CR). Acidification has potential impacts of reduced calcification in shellfish and impacts on commercial aquaculture (Barton *et al.*, 2012). Since AR4, a significant number of new findings regarding the impacts of climate change on human settlements, key coastal systems such as rocky coasts, beaches, estuaries, deltas, salt marshes, mangroves, coral reefs and submerged vegetation have become available and are reviewed in this chapter. However, uncertainties regarding projections of potential impacts on coastal systems remain generally high.

This chapter also provides advances in both vulnerability assessments and the identification of potential adaptation actions, costs, benefits and tradeoffs. A large number of new studies estimate the costs of inaction versus potential adaptation. Coastal adaptation has become more widely used, with a wider range of approaches and frameworks such as integrated coastal management, ecosystem-based adaptation, community-based adaptation and disaster risk reduction and management.

Climate change will interact differently with the variety of human activities and other drivers of change along coastlines of developed and developing countries. For example, on the coastlines of developed countries, changes in weather and climate extremes and sea level rise may impact the demand for housing, recreational facilities and construction of renewable energy infrastructure on the coast (Hadley, 2009) including critical infrastructures such as transportation, ports and naval bases. Along the coasts of developing countries, weather and climate extremes impact on a wide range of economic activities supporting coastal communities and pose an additional risk to many of the fastest-growing low-lying urban areas, such as in Bangladesh and China (McGranahan *et al.*, 2007; Smith, 2011).

5.2. Coastal Systems

Coastal systems and low-lying areas, further referred to as coasts in this assessment, include all areas near mean sea level. Generally, there is no single definition for the coast and the coastal zone/area where the latter emphasizes the area or extent of the coastal ecosystems. In relation to exposure to potential sea level rise, the LECZ (low-elevation coastal zone) has been used in recent years with reference to specific area and population up to 10 m elevation (Vafeidis *et al.*, 2011).

Coastal systems are conceptualized to consist of both natural and human systems (Figure 5-1). The natural systems include distinct coastal features and ecosystems such as rocky coasts, beaches, barriers and sand dunes, estuaries and lagoons, deltas, river mouths, wetlands and coral reefs. These elements help define the seaward and landward boundaries of the coast. In spite of providing a wide variety of regulating, provisioning, supporting and cultural services (MEA, 2005), they have been altered and heavily influenced by human activities, with climate change constituting only one amongst many pressures these systems are facing. The human systems include the built environment (e.g. settlements, water, drainage, as well as transportation infrastructure and networks), human activities (e.g. tourism, aquaculture, fisheries) as well as formal and informal institutions that organize human activities (e.g. policies, laws, customs, norms and culture). The human and natural systems form a tightly coupled social-ecological system (Berkes and Folke, 1998; Hopkins *et al.*, 2012).

[INSERT FIGURE 5-1 HERE
Figure 5-1: Climate, just as anthropogenic or natural changes, affects both climate and human related drivers. Risk on coastal systems is the outcome of integrating drivers and exposure and vulnerability. Adaptation options can be implemented either to modify the drivers or exposure and vulnerability or both.]

5.3. Drivers

5.3.1. Introduction

In AR4, changes in climate drivers (any climate-induced factor that directly or indirectly causes a change), including sea level rise, were projected for different SRES (Special Report on Emissions Scenarios) emissions scenarios (Nakicenovic and Swart, 2000). Consequently, to date, most of the impacts and vulnerability assessments of climate change in coastal areas are based on SRES A2, A1B, B2 and A1F1 scenarios. Since AR4 a new scenario process has been initiated to replace the SRES scenarios with Representative Concentration Pathways (RCPs) and Shared Socio-economic Pathways (SSPs) (Moss *et al.*, 2010). The RCPs are scenarios specifying concentrations, rather than emissions, thereby avoiding differences in concentrations of Long-Lived Greenhouse Gas and aerosol concentrations for the same emissions scenarios that can arise from the use of different models (van Vuuren *et al.*, 2011). For a comparison between RCP and SRES scenarios see WG1, Chapter 1, Box 1.2. In addition, Extended Concentration Pathways (ECPs) have been introduced for the 2100-2300 period (Meinhausen *et al.*, 2009) providing the opportunity to assess the long-term commitment to sea level rise, which is *very likely* to continue beyond 2500 unless global temperature declines (WG1, Chapter 1, 13.5.2).

The SSPs provide representative qualitative story lines (narratives) of world development together with quantitative pathways of key socio-economic variables such as GDP and population. A preliminary list of five SSPs has been proposed (Arnell *et al.*, 2011; O'Neill *et al.*, 2012) and work to further refine it is ongoing (Kriegler *et al.* 2012; Van Vuuren *et al.*, 2012). SSPs do not include assumptions on mitigation policy and are thus independent from RCPs in the sense that the same SSP may lead to different concentration levels and consequently rises in sea level depending on the level of mitigation reached (Arnell *et al.*, 2011; O'Neill *et al.*, 2012). Table 5-1 summarizes the main climate-related drivers for the coastal systems.

[INSERT TABLE 5-1 HERE
Table 5-1: Main climate-related drivers for coastal systems, their trends due to climate change, and their main physical and ecosystem effects.]

5.3.2. Relative Sea Level Rise

Assessments of coastal impacts, vulnerability and adaptation need to consider relative sea level (RSL) rise, which includes climate-induced GMSL rise (5.3.2.1) and regional variations (5.3.2.2) as well as local non-climate related sea level changes (5.3.2.3). Relative sea level rise poses a significant threat to coastal systems and low-lying areas around the globe leading to inundation and erosion of coastlines, contamination of freshwater reserves and food crops (Nicholls, 2010). sea level rise due to thermal expansion as the oceans warm, together with meltwater from glaciers, icecaps and ice sheets of Greenland and Antarctica are the major factors that contribute to relative sea level rise globally. However, regional variations in the rate of rise occur because of ocean circulation patterns and inter-annual and decadal variability (e.g. Zhang and Church, 2012; Ganachaud *et al*., 2013) and glacial isostatic rebound and tectonic movement. Subsidence of coastal land from sediment compaction due to building loads, harbor dredging, changes in sediment supply that cause erosion/accretion, subsurface resource extraction (e.g. groundwater, gas and petroleum; Syvitski *et al.*, 2009), may also contribute to relative sea level rise locally and therefore requires consideration in coastal impact studies. sea level impacts are most pronounced during episodes of extreme sea levels and these are discussed in 5.3.3.

5.3.2.1. Global Mean Sea Level

It is *very likely* that GMSL rose at a mean rate of 1.7 [1.5 to 1.9] mm yr^{-1} between 1900 and 2010 and at a rate 3.2 [2.8 to 3.6] mm yr^{-1} from 1993 to 2010 (WG1, 13.2.2). Ocean thermal expansion and melting of glaciers have been the largest contributors, accounting for over 80% of the GMSL rise over the latter period (WG1, 13.3.1). Future rates of GMSL rise during the 21st century are projected to exceed the observed rate for the period 1971–2010 of 2.0 [1.7 to 2.3] mm yr^{-1} for all RCP scenarios (WG1, Table 13.1). Table 5-2 summarizes the *likely* ranges of 21st century GMSL rise as established by the Working Group 1 (WG1) contribution to this Assessment Report.

From a coastal risk management perspective (Nicholls *et al*., 2013) assessments of impacts, vulnerabilities and adaptation have been using GMSL rise scenarios above the ranges put forward by WG1 reports of AR4 (Meehl *et al*., 2007, Table 10.7) and AR5 (WG1 Table 13.5). The ranges estimated by WG1 of AR4 and AR5 only include those components of GMSL rise that can be quantified using process-based models (i.e. models derived from the laws of physics; WG1 Glossary). The ranges given in AR4 thus explicitly excluded contributions to GMSL rise resulting from changes in ice flows from the ice sheets of Greenland and Antarctica because at that time process-based models were not able to assess this with sufficient confidence (Meehl *et al*., 2007; WG1, 4.4.5). Since then, understanding has increased and the *likely* range of GMSL given in AR5 now includes ice sheet flow contributions. Likely, however, means that there is still a 0-33% probability of GMSL rise beyond this range and coastal risk management needs to consider this. WG1 does not assign probabilities to GMSL rise beyond the *likely* range, because this cannot be done with the available process-based models. WG1, however, assigns *medium confidence* that 21st century GMSL rise does not exceed the *likely* range by several tenths of a meter (WG1, 13.5.1). When using other approaches such as semi-empirical models, evidence from past climates and physical constraints on ice-sheet dynamics GMSL rise upper bounds of up to 2.4m by 2100 have been estimated, but there is *low agreement* on these higher estimates and no consensus on a 21st century upper bound (WG1, 13.5.3). Coastal risk management is thus left to choose an upper bound of GMSL rise to consider based on which level of risk is judged to be acceptable in the specific case. The Dutch Delta Programme, for example, considered a 21st century global mean sea level rise of 1.3m as upper bound.

It is *virtually certain* that sea level rise will continue beyond the 21st Century although projections beyond 2100 are based on fewer and simpler models that include lower resolution coupled climate models for thermal expansion and ice sheet models coupled to climate models to project ice sheet contributions. The basis for the projections are the Extended Concentration Pathways (ECPs) and projections are provided for low, medium and high scenarios which relate to atmospheric GHG concentrations <500 ppm, 500-700 and > 700 ppm respectively (WG1, 13.5.2). Projections of GMSL up to 2500 are also summarized in Table 5-2.

[INSERT TABLE 5-2 HERE
Table 5-2: Projections of global mean sea level rise in meters relative to 1986–2005 are based on ocean thermal expansion calculated from climate models, the contributions from glaciers, Greenland and Antarctica from surface mass balance calculations using climate model temperature projections, the range of the contribution from Greenland and Antarctica due to dynamical processes, and the terrestrial contribution to sea levels, estimated from available studies. For sea levels up to and including 2100, the central values and the 5-95% range are given whereas for projections from 2200 onwards, the range represents the model spread due to the small number of model projections available. Source: WGI AR5 SPM and Sections 12.4.1, 13.5.1, and 13.5.4.]

5.3.2.2. Regional Sea Level

Sea level rise will not be uniform in space and time. Natural modes of climate variability influence sea levels in different regions of the globe and this will affect the rate of rise on interannual and interdecadal time periods. For example in the equatorial Pacific, sea levels can vary from the global mean by up to 40 cm due to ENSO (e.g. Walsh *et al*., 2012) and this can strongly influence trends on decadal scales. Regional variations in the rate of sea level rise on the coast can arise from climate and ocean dynamic processes such as changes in winds and air pressure, air-sea heat and freshwater fluxes, ocean currents and their steric properties (Timmermann *et al*., 2010; WG1, FAQ 13.1). Although the vast majority of coastlines are experiencing sea level rise, coastlines near current and former glaciers and ice sheets are experiencing relative sea level fall (Milne *et al*., 2009; WG1, FAQ 13.1). This is because the gravitational attraction of the icesheet reduces as it melts and exerts less pull on the oceans and also because the land tends to rise as the ice melts, the shape of the sea floor changes under the reduced load of the ice sheets and the change in mass distribution alters the Earths rotation (WG1, FAQ 13.1, Gomez *et al*., 2010). In terms of absolute sea level change, approximately 70% of the global coastlines are projected to experience sea level change that is within 20% of the global mean sea level change (WG1, 13.6.5).

5.3.2.3. Local Sea Level

Besides the effect of long-term vertical land movement on regional sea level, relative sea level rise can occur locally due to subsidence or uplifts of coastal plains as well as due to other natural causes. Natural subsidence can occur because of sediment compaction and loading, as in the Mississippi River, and other deltas (Törnqvist *et al*., 2008; Dokka, 2011; Marriner *et al*., 2012). Tectonic movements, both sustained and abrupt, have brought about relative sea level changes. The Great East Japan Earthquake in 2011 caused subsidence of up to 1.2 m of the Pacific coast of northeast Japan (Geospatial Information Authority of Japan, 2011). The Sumatra-Andaman earthquake in 2004 and subsequent earthquakes in 2005 produced vertical deformation ranging from uplift of 3 m to subsidence of 1 m (Briggs *et al.*, 2006). These movements are especially important in coastal zones located near active plate margins.

Anthropogenic causes of relative sea level rise include sediment consolidation from building loads, reduced sediment delivery to the coast and extraction of subsurface resources such as gas, petroleum and groundwater. Subsidence rates may also be sensitive to the rates of oil and gas removal (e.g. Kolker *et al*., 2011). Syvitski *et al*. (2009) estimate that the majority of the world’s largest deltas are currently subsiding at rates that are considerably larger than the current rates of sea level rise because of coastal sediment starvation due to substantial dam building over the 20th century or sediment compaction through natural or anthropogenic activities. Many large cities on deltas and coastal plains have subsided during the last 100 years ~4.4 m in eastern Tokyo, ~3 m in the Po delta, ~2.6 m in Shanghai, and ~1.6 m in Bangkok (Syvitski *et al*., 2009; Teatini *et al*., 2011). Loads from massive buildings and other large structures can also increase sediment compaction and subsidence (Mazzotti *et al.*, 2009). Relative sea level rise can exceed GMSL rise by an order of magnitude, reaching more than 10 cm yr^{-1} and it is estimated that the delta surface area vulnerable to flooding could increase by 50% for 33 deltas around the world under the sea level rise as projected for 2100 by the IPCC AR4 (Syvitski *et al*., 2009).

Clearly large regional variations in the projected sea level rise, together with local factors such as subsidence indicates that relative sea level rise can be much larger than projected GMSL rise and therefore is an important consideration in impact assessments (*very high confidence*).

5.3.3. Climate-Related Drivers

Increasing greenhouse gases in the atmosphere produce changes in the climate system on a range of time scales that impact the coastal physical environment. On shorter time scales, physical coastal impacts such as inundation, erosion and coastal flooding arise from severe storm-induced surges, wave overtopping and rainfall runoff. On longer time scales, wind and wave climate change can cause changes in sediment transport at the coast and associated changes in erosion or accretion. Natural modes of climate variability, which can affect severe storm behavior and wind and wave climate, may also undergo anthropogenic changes in the future. Ocean and atmospheric temperature change can affect species distribution with impacts on coastal biodiversity. CO_2 uptake in the ocean increases ocean acidity and reduces the saturation state of carbonate minerals, essential for shell and skeletal formation in many coastal species. Changes in freshwater input can alter coastal ocean salinity concentrations. Past and future changes to these physical drivers are discussed in this section (see also Table 5-1).

5.3.3.1. Severe Storms

Severe storms such as tropical and extratropical cyclones can generate storm surges over coastal seas. The severity of these depends on the storm track, regional bathymetry, nearshore hydrodynamics and the contribution from waves. Globally there is *low confidence* regarding changes in tropical cyclone activity over the 20th century due to changes in observational capabilities, although it is *virtually certain* that there has been an increase in the frequency and intensity of the strongest tropical cyclones in the North Atlantic since the 1970s (WG1, 2.6). In the future, it is *likely* that the frequency of tropical cyclones globally will either decrease or remain unchanged, but there will be a *likely* increase in global mean tropical cyclone precipitation rates and maximum wind speed (WG1, 14.6).

Extratropical cyclones occur throughout the mid-latitudes of both hemispheres and their development is linked to large-scale circulation patterns. Assessment of changes in these circulation features reveals a widening of the tropical belt, poleward shift of storm tracks and jet streams and contraction of the polar vortex; this leads to the assessment that it is *likely* that, in a zonal mean sense, circulation features have moved poleward (WG, 2.7.5-2.7.8) but there is *low confidence* regarding regional changes in intensity of extratropical cyclones (e.g. Seneviratne *et al*., 2012). With regards to future changes, a small poleward shift is *likely* in the Southern Hemisphere but changes in the Northern Hemisphere are basin specific and of *lower confidence* (WG1, 14.6.3). Globally, it is *unlikely* that the number of extratropical cyclones will fall by more than a few percent due to anthropogenic climate change (*high confidence*; WG1, 14.6.3).

5.3.3.2. Extreme Sea Levels

Extreme sea levels discussed here are those that arise from combinations of factors including astronomical tides, storm surges, wind waves and swell, and interannual variability in sea levels. Storm surges are caused by the falling atmospheric pressures and surface wind stress associated with storms such as tropical and extratropical cyclones and therefore may change if storms are affected by climate change. To date however, observed trends in extreme sea levels are mainly consistent with MSL trends (e.g. Menendez and Woodworth, 2010; Marcos *et al.*, 2009; Haigh *et al.*, 2010, Losada *et al.*, 2013) indicating that Mean Sea Level (MSL) trends rather than changes in weather patterns are responsible.

Assuming that sea level extremes follow a simple extreme value distribution (i.e. a Gumbel distribution), and accounting for the uncertainty in projections of future sea level rise, Hunter (2012) has developed a technique for estimating a sea level allowance, i.e. the minimum height that structures would need to be raised in a future period so that the number of exceedences of that height remains the same as under present climate conditions (Figure 5-2). Such an allowance can be factored into adaptive responses to rising sea levels. It should be noted however that extreme sea level distributions might not follow a simple Gumbel distribution (e.g. Tebaldi *et al.* 2012) due to different factors influencing extreme levels that may not be measured by tide gauges (e.g. Hoeke *et al.*, 2013).

[INSERT FIGURE 5-2 HERE
Figure 5-2: The estimated increase in height (m) that flood protection structures would need to be raised in the 2081-2100 period to preserve the same frequency of exceedences that was experienced for the 1986-2005 period, shown for 182 tide gauge locations and assuming regionally-varying relative sea level rise projections under an RCP4.5 scenario (adapted from Hunter *et al*., 2013).]

Regarding future changes to storm surges, hydrodynamic models forced by climate models have been used in several extratropical regional studies such as the northeast Atlantic (e.g. Debenard and Roed, 2008; Wang *et al*., 2008; Sterl *et al*., 2009) and southern Australia (Colberg and McInnes, 2012). These studies show strong regional variability and sensitivity to the choice of Global Climate Model (GCM) or Regional Climate Model (RCM). The effect of future tropical cyclone changes on storm surges has also been investigated in a number of regions using a range of different methods. These include methods to stochastically generate and/or perturb cyclones within background environmental conditions that represent historical (e.g. Harper *et al*., 2009) and GCM-represented future conditions (e.g. Mousavi *et al*., 2011; Lin *et al*., 2012). Regional studies include Australia's tropical east coast (Harper *et al*., 2009), Louisiana (Smith *et al*., 2010), Gulf of Mexico, (Mousavi *et al*., 2011), India, (Unnikrishnan *et al*., 2011) and New York (Lin *et al*., 2012) and the details of the methods and findings vary considerably between the studies. While some studies indicate for some regions increase to extreme sea levels due to changes in storms, others indicate the opposite. In general, the small number of regional storm surge studies together with the different atmospheric forcing factors and modeling approaches means that there is *low confidence* in projections of storm surges due to changes in storm characteristics. However, observed upward trends in MSL together with projected increases for 2100 and beyond indicate that coastal systems and low-lying areas will increasingly experience extreme sea levels and their adverse impacts (*high confidence*). (see also WGI, 13.7).

5.3.3.3. Winds and Waves

Changes in wind climate affect large-scale wave climate. Winds also influence longshore current regimes and hence upwelling systems (Narayan *et al.*, 2010; Miranda *et al.*, 2012; see also 6.3.3, 6.3.5). Energy dissipation via wave breaking contributes to longshore and cross-shore currents, elevated coastal sea levels through wave set-up and run-up and beach erosion. Changes to wind and wave climate therefore can affect sediment dynamics and shoreline processes (e.g. Aargaard *et al*., 2004; Reguero *et al.*, 2013) and extreme winds and waves are a threat to coastal populations. The coastal impacts of wave climate change are also a function of wave direction and period as well as the coastline itself, which can influence shoaling and refraction. Long period swell, which dominates the wave energy field, poses a significant danger to coastal and offshore structures and shipping (e.g. Semedo *et al.*, 2011) and can causes significant flooding of coastlines with steep shelf margins (Hoeke *et al*., 2013).

There is *low confidence* in trends calculated from measurements of mean and extreme winds and their causes due to the limited length of records and uncertainties associated with different wind measurement techniques (Seneviratne *et al*., 2012). However, there is increasing evidence for a strengthening wind stress field in the Southern Ocean since the early 1980s from atmospheric reanalyses, satellite observations and island station data (WG1, 3.4.5). Positive trends in wave height have been detected in the Northeast Atlantic over the 1958-2002 period based on reanalyses and ship observations and in the Southern Ocean between 1985–2008 based on satellite data (*medium confidence*) (WG1, 3.4.6, see Table 5-2).

Projected changes in mean and extreme winds and waves were assigned *low confidence* (Seneviratne *et al*., 2012) owing to limited studies. Although there has been an increase in studies addressing future wave climate change (Hemer *et al.,* 2013), generally *low confidence* remains in projected wave climate change (except for *medium confidence* over the southern ocean) and this is due to uncertainties in future winds, particularly those associated with storms (see WG1, 13.7).

5.3.3.4. Sea Surface Temperature

Sea surface temperature (SST) has significantly warmed during the past 30 years along more than 70% of the world's coastlines, with highly heterogeneous rates of change both spatially and seasonally (Lima and Wethey, 2012). The average rate is 0.18 ± 0.16°C per decade and the average change in seasonal timing was -3.3 ± 4.4 days per decade. These values are larger than in the global ocean where the average of change is about 0.1°C per decade in the upper 75 m of the ocean during the 1970-2009 period (WG1, Chapter 3) and the seasonal shift is -2.3 days per decade (Lima and Wethey, 2012). Extreme events have also been reported. For example, the record high ocean temperatures along the Western Australian coast during the austral summer of 2010/2011, with nearshore temperatures peaking at about 5 °C above average, were unprecedented (Pearce and Feng, 2013). In summary, positive trends in coastal SST's are seen on the majority of coastlines and the rate of rise along coastlines is higher on average than the oceans (*high confidence*). Based on projected temperature increases there is *high confidence* that positive coastal SST trends will continue.

5.3.3.5. Ocean Acidification

Anthropogenic ocean acidification refers to the changes in the carbonate chemistry primarily due to the uptake of atmospheric CO_2 (Box CC-OA). Seawater pH exhibits a much larger spatial and temporal variability in coastal waters compared to open ocean due to the variable contribution of processes other than CO_2 uptake (Duarte *et a*l., 2013a) such as upwelling intensity (Feely *et al*., 2008; Box CC-UP), deposition of atmospheric nitrogen and sulphur (Doney *et al*., 2007), carbonate chemistry of riverine waters (Salisbury *et al*., 2008; Aufdenkampe *et al*., 2011), as well as inputs of nutrients and organic matter (Borges, 2011; Cai *et al*., 2011). For example, pH (NBS scale) ranges from 6 to 9 in 24 estuaries (Borges and Abril, 2011) and short-term (hours to weeks) changes of up to 0.5 pH units are not unusual in coastal ecosystems (Hofmann *et al.*, 2011).

Few high-quality ocean acidification time series exceed 5 years in the coastal ocean (Wootton *et al*., 2008; Provoost *et al*., 2010; Waldbusser *et al*., 2010). Some exhibit considerable differences compared to open ocean stations illustrating that anthropogenic ocean acidification can be lessened or enhanced by processes such as primary production, respiration and calcification (Borges and Gypens, 2010; Kleypas *et al*., 2011).

Under the IS92a CO_2 emission scenario, the global pH (total scale) of coastal waters has been projected to decrease from about 8.16 in the year 1850 to 7.83 in 2100 (Lerman *et al*., 2011) but with considerable spatial variability. For example, using the same CO_2 emission scenario, Cai *et al.* (2011) projected an overall decline of pH in the Northern Gulf of Mexico of 0.74 over the same period a value which is much greater than that of the open ocean (Box CC-OA).

To summarize, seawater pH exhibits considerable temporal and spatial variability in coastal areas compared to open ocean due to additional natural and human influences (*very high confidence*). Coastal acidification is projected to continue but with large and uncertain regional and local variations (*high confidence*).

5.3.3.6. Freshwater Input

Changes in river runoff arise from changes in climate drivers such as precipitation, complex interactions between changing levels of CO_2, plant physiology and, consequently, evapotranspiration (e.g. Gedney *et al*., 2006; Betts *et al*., 2007) as well as human drivers such as land-use change, water withdrawal, dam building and other engineered modifications to waterways (see more detailed discussion in Chapter 3). An assessment of run-off trends in 925 of the world's largest ocean-reaching rivers, which account for about 73% of global total runoff, indicates that from 1948–2004 statistically significant trends were present in only one third of the top 200 rivers, and of these, two thirds exhibited downward trends and one third upward trends (Dai *et al.*, 2009). While precipitation changes dominate freshwater flows, decreasing trends in river discharges may be further enhanced due to human pressures (Dai *et al.*, 2009; 3.2.3).

Average annual runoff is generally projected to increase at high latitudes and in the wet tropics and to decrease in most dry tropical regions (3.4.5). Shifts to earlier peak flows are also projected in areas affected by snowmelt (Adam *et al*, 2009). However, there are some regions where there is considerable uncertainty in the magnitude and direction of change, specifically south Asia and large parts of South America. Both the patterns of change and the uncertainty are largely driven by projected changes in precipitation.

To summarize, there is *medium confidence (high agreement, limited evidence)* in a net declining trend in freshwater input globally although large regional variability exists. Trends are dominated by precipitation changes although human pressures on water supply may enhance downward trends (*medium confidence*). Uncertainty in future changes in run-off is linked to precipitation uncertainty. Runoff is generally projected to increase in high latitudes with earlier peak flows and in the wet tropics and decrease in other tropical regions however with large uncertainty (*medium confidence*).

5.3.4. Human-Related Drivers

Coastal systems are subject to a wide range of human-related or anthropogenic drivers (e.g. Crain *et al.*, 2009) which interact with climate-related drivers and confound efforts to attribute impacts to climate change. Some of the major terrestrially based human drivers that directly or indirectly cause changes are briefly reviewed below. Related drivers in the marine environment are discussed in 6.4 and 30.6.

5.3.4.1. Socioeconomic Development

Socio-economic development (SED) drives coastal impacts in several ways. SED influences the number of people and the value of assets exposed to coastal hazards. Since AR4, a number of studies have estimated the influence of future sea level rise and associated hazards on coastal population and assets. Although these estimates are subject to uncertainties associated with global elevation and population datasets (Lichter *et al.*, 2011; Mondal and Tatem, 2012), all the studies indicate high and growing exposure of low-lying coastal areas. The Low Elevation Coastal Zone (LECZ) constitutes 2% of the world's land area but contains 10% of world's population (600 million) and 13% of world's urban population (360 million) based on year 2000 estimates (McGranahan *et al.*, 2007). About 65% of the world's cities with populations of over 5 million are located in the LECZ (McGranahan *et al.*, 2007). The global population exposed to the 1-in-100 year extreme sea level (i.e. the sea level that has a 1% chance of being exceeded every year) has increased by 95% from 1970 to 2010 with about 270 million people and 13 trillion US$ worth of assets being exposed to the 1-in-100 year extreme sea level in 2010 (Jongman *et al*., 2012). In 2002, about 1.9 trillion US$ worth of assets below the 1-in-100 year extreme sea level were concentrated in the following 10 port cities: Miami (USA), New York-Newark (USA), New Orleans (USA), Osaka-Kobe (Japan), Tokyo (Japan), Amsterdam (Netherlands), Rotterdam (Netherlands), Nagoya (Japan), Virginia Beach (USA) and Guangzhou (China) (Hanson *et al.*, 2011). Compared to other regions, Asia exhibits the greatest exposure in terms of population and assets (Jongman *et al*. 2012).

For many locations population and assets exposure is growing faster than the national average trends due to coastward migration, coastal industrialization and urbanization (e.g. McGranahan *et al.*, 2007; Smith, 2011; Seto, 2011; Chapter. 8; *high confidence*). Coastal net migration has largely taken place in flood- and cyclone-prone areas, which poses a challenge for adaptation (de Sherbinin *et al.*, 2012). These processes and associated land use changes are driven by a combination of many social, economic, and institutional factors including taxes, subsidies, insurance schemes, aesthetic and recreational attractiveness of the coast and increased mobility (Bagstad *et al.*, 2007; Palmer *et al.*, 2011). In China, the country with the largest exposed population, urbanization and land reclamation are the major drivers of coastal land-use change (Zhu *et al.*, 2012). Although coastal migration is expected to continue in the coming decades, it is difficult to capture this process in global scenarios as the drivers of migration and urbanization are complex and variable (Black *et al.* 2011).

SED also influences the capacity to adapt. Poor people living in urban informal settlements, of which there are about 1 billion worldwide, are particularly vulnerable to weather and climate impacts (Handmer *et al.*, 2012; de Sherbinin *et al.*, 2012). The top five nations classified by population in coastal low-lying areas are developing and newly industrialized countries: Bangladesh, China, Vietnam, India and Indonesia (McGranahan *et al*., 2007; Bollman *et al.*, 2010; Jongman *et al*. 2012). SED and associated land reclamation are also major drivers of the destruction of coastal wetlands, which also makes human settlements more vulnerable since wetlands act as natural buffers reducing wave and storm impacts on the coast (e.g. Crain *et al.*, 2009; Shepard *et al.*, 2011; Duarte et al., 2013b; Arkema *et al.*, 2013). Finally, socio-economic development is expected to further exacerbate a number of human pressures on coastal systems related to nutrient loads, hypoxia and sediment delivery, which will be discussed in the following sub-sections.

5.3.4.2. Nutrients

Increased river nutrient (N, P) loads to coasts in many regions are observed, and simulated by regional and global models (Alexander *et al.*, 2008; Seitzinger *et al.*, 2010). Anthropogenic global loads of dissolved inorganic nutrients (DIN, DIP) are 2-3 times larger than those of natural sources (Seitzinger *et al.*, 2010) causing coastal ecosystem degradation (5.3.4.3, 5.4.2.6). Large variations exist in magnitude and relative sources of nutrient loads. Anthropogenic sources are primarily related to fertilizer use in agriculture and fossil fuel emissions (NOx) (Bouwman *et al.*, 2009; Galloway *et al.*, 2004).

Future trends depend on measures available to optimize nutrient use in crop production and minimize loss to rivers from agriculture (crop, livestock), sewage, and NOx emissions. In scenarios with little emphasis on nutrient management, global nutrient discharge increases (DIN 30%, DIP 55%) between 2000 and 2050 (Seitzinger *et al.*, 2010). With ambitious nutrient management, global DIN loads decrease slightly and DIP increases (35%). Climate change is projected to change water runoff (Chapter 3) that influences river nutrient loads. Studies of climate change effects related to increased watershed nutrient sources are needed. In summary, nutrient loads have increased in many world regions (*high confidence*); future increases will largely depend on nutrient management practices (*medium confidence*).

5.3.4.3. Hypoxia

The presence of excessive nutrients in coastal waters, which causes eutrophication and the subsequent decomposition of organic matter, is the primary cause of decreased oxygen concentration (hypoxia). Globally, upwelling of low oxygen waters (e.g. Grantham *et al.*, 2004) and ocean warming, which decreases the solubility of oxygen in seawater (Shaffer *et al.*, 2009) are secondary drivers but can be locally important. The oxygen decline rate is greater in coastal waters than in the open ocean (Gilbert *et al.*, 2010). Hypoxia poses a serious threat to marine life, which is exacerbated when combined with elevated temperature (Vaquer-Sunyer and Duarte, 2011; 6.3.3). The number of so-called “dead zones” has approximately doubled each decade since 1960 (Diaz and Rosenberg, 2008). Fishery catches from these areas are generally lower than predicted from nutrient loading alone (Breitburg *et al.*, 2009). Although non-climate anthropogenic factors are responsible for virtually all hypoxia in estuaries and inner continental shelves, climate drivers such as ocean warming, altered hydrological cycles and coastal currents shifts and changes in upwellings may interact with eutrophication in the next decades (Rabalais *et al.*, 2010; Meire *et al.*, 2013; *high confidence*).

5.3.4.4. Sediment Delivery

Human activities in drainage basins and coastal plains have impacted the coastal zone by changing the delivery of sediment to the coast. Sediment trapping behind dams, water diversion for irrigation, and sand and gravel mining in river channels all contribute to decrease sediment delivery, whereas soil erosion due to land-use changes help increase it (Syvitski, 2008; Walling, 2006). It is estimated that the global discharge of riverine sediment was 16-–19 Gt yr-1 in the 1950s before widespread dam construction (e.g. Syvitski *et al.*, 2005; Milliman and Farnsworth, 2011) and it has decreased to 12–13 Gt yr-1 (Syvitski and Kettner, 2011). Out of 145 major rivers with mostly more than 25-year record, only 7 showed evidence of an increase in sediment flux while 68 showed significant downward trends (Walling and Fang, 2003). The number of dams has increased continuously and their distribution has expanded globally. As of early 2011, the world has an estimated 16.7 million reservoirs larger than 0.01 ha (Lehner *et al.*, 2011). Globally, 34 rivers with drainage basins of 19 million km2 in total show a 75% reduction in sediment discharge over the past 50 years (Milliman and Farnsworth, 2011). Reservoir trapping of sediments is estimated globally as 3.6 Gt yr-1 to more than 5 Gt yr-1 (Syvitski *et al.*, 2005; Walling, 2012; Milliman and Farnsworth, 2011). Human pressure is the main driver of the observed declining trend in sediment delivery to the coast (*high agreement*).

5.4. Impacts, Vulnerabilities, and Risks

5.4.1. Introduction

This subsection briefly introduces the diverse approaches and methods applied in the literature on coastal impact, vulnerability and risk. The following subsections then assess this literature related to coastal natural systems (5.4.2) and coastal human systems (5.4.3). Much of this literature focuses on relative sea level rise and extreme sea level events as the main drivers. The main biophysical impacts of this driver are increasing flood damage, dry-land loss due to submergence and erosion, wetland loss and change, saltwater intrusion into surface and ground waters and rising water tables and impeded drainage (Table 5-3).

Impacts and risks are assessed using a wide variety of approaches from the local to global scale. *sea level rise exposure approaches* are applied at all scales to assess values exposed to sea level rise (e.g. people, assets, ecosystems or geomorphological units). *Submergence exposure approaches* assess exposure to permanent inundation under a given sea level rise (e.g. Dasgupta *et al.*, 2009; Boateng, 2012) whereas *flood exposure approaches* assess exposure to temporary inundation during a coastal flood event by combining the extreme water level of the flood event with a given level of sea level rise (e.g. Dasgupta *et al.*, 2011; Kebede and Nicholls, 2012).

Indicator-based approaches are also used at all scales to aggregate data on the current state of the coastal systems into vulnerability indices (Gornitz, 1991; Hinkel, 2011), based on either biophysical exposure or hazard variables (e.g. Yin *et al.*, 2012; Bosom and Jimenez, 2011), socioeconomic variables representing a social group's capacity to adapt (e.g. Cinner *et al.*, 2012) or both kinds of variables (e.g. Bjarnadottir *et al.*, 2011; Yoo *et al.*, 2011; Li and Li, 2011).

At local scales (<100 km coastal length), *process-based models* are applied to assess flooding, erosion and wetland impacts. Approaches include assessments of *flood damage* of single extreme water level events using numerical *inundation models* (e.g. Xia *et al.*, 2011; Lewis *et al.*, 2011). Erosion impacts are assessed using either numerical *morphodynamic models* (e.g. Jiménez *et al., 2009;* Ranasinghe *et al., 2012)* or simple geometric profile relationships such as the Bruun Rule (Bruun, 1962). For ecosystem impacts *ecological landscape simulation models* are used to predict habitat change due to sea level rise and other factors (e.g. Costanza *et al.*, 1990).

At regional to global scales, numerical process-based models are not available for assessing the impacts of relative sea level rise and extreme sea level events due to data and computational limits. Global scale assessments of coastal impacts have been conducted with the models FUND (Climate Framework for Uncertainty, Negotiation and Distribution) and DIVA (Dynamic and Interactive Coastal Vulnerability Assessment). FUND is an integrated assessment model with a coastal impact component that includes country-level cost functions for dry land loss, wet land loss, forced migration and dike construction (Tol, 2002). DIVA is a dedicated coastal impact model employing subnational coastal data (Vafeidis *et al*., 2008) and considering additional impacts such as coastal flooding and erosion as well as adaptation in terms of protection via dikes and nourishment (Hinkel and Klein, 2009). DIVA assesses coastal flood risk based on hydrologically connected elevation and extreme water level distributions (Hinkel *et al.*, 2013) and erosion based on a combination of the Bruun Rule and a simplified version of the ASMITA model for tidal basins (Nicholls *et al.*, 2011). The results of these models are discussed in Sections 5.4.3.1 and 5.5.5.

For impacts on natural systems, the key climate-related drivers considered are temperature, ocean acidification and sea level. A variety of approaches are applied including field observations of ecosystem features (e.g. biodiversity, reproduction) and functioning (e.g. calcification, primary production), remote sensing (e.g. extent of coral bleaching, surface area of vegetated habitats) and perturbation experiments in the laboratory and in the field.

[INSERT TABLE 5-3 HERE
Table 5-3: Main impacts of relative sea level rise. Source: Adapted from Nicholls et al., 2010.]

5.4.2. Natural Systems

Coastal ecosystems are experiencing large cumulative impacts related to human activities (Halpern *et al.*, 2008) arising from both land- and ocean-based anthropogenic drivers. Anthropogenic drivers associated with global climate change are distributed widely and are an important component of cumulative impacts experienced by coastal ecosystems. There is no wetland, mangrove, estuary, rocky shore or coral reef which is not exhibiting some degree of impact. Overexploitation and habitat destruction are often the primary causes of historical changes in coastal systems leading to declines in diversity, structure and functioning (Lotze *et al.*, 2006). Furthermore, extreme climate events generate changes to both the mean and the variance of climatic variables over ecological time scales.

5.4.2.1. Beaches, Barriers, and Sand Dunes

Beaches, barriers and sand dunes are about half as common as rocky coasts (Bird, 2000; Davis and FitzGerald, 2004) but often exhibit distinct and seasonal changes. Due to their aesthetic qualities, they are highly valued for recreation and residences.

Observed impacts

Globally beaches and dunes have in general undergone net erosion over the past century or longer (e.g. see Bird, 2000 for an overview). A number of studies have investigated shoreline change by comparing historical maps and imagery, available since about the mid-19th century with more recent maps and imagery to quantify combined climate and non-climate changes. For example, along the U.S. Mid-Atlantic and New England coasts the long-term rate of erosion, based on 21,184 transects equally spaced along more than 1000 km of coast, is 0.5 ± 0.09 m yr^{-1} with 65% of transects showing net erosion (Hapke *et al.*, 2011). A similar study by Webb and Kench (2010) in the central Pacific utilized historical aerial photographs and satellite images to show physical changes in 27 islets located in 4 atolls over a 19 to 61 year period. The analysis highlighted the dynamic nature of sea level rise response in the recent past, with physical changes in shoreline progradation and displacement influencing whether the island area increased (46%), remained stable (46%) or decreased (14%).

Attributing shoreline changes to climate change is still difficult due to the multiple natural and anthropogenic drivers contributing to coastal erosion. For example, rotation of pocket beaches (i.e. where one end of the beach accretes while the other erodes and then the pattern reverses) in southeast Australia is closely related to interannual changes in swell direction (Harley *et al.*, 2010). Additional processes, unrelated to climate change, that contribute to coastal change, include dams capturing fluvial sand (e.g. in Morocco, Chaibi and Sedrati, 2009). Statistically linking sea level rise to observed magnitudes of beach erosion has had some success although the coastal sea level change signal is often small when compared to other processes (e.g. Sallenger *et al*., 2000; Leatherman *et al*., 2000a; 2000b; Zhang *et al*., 2004). A Bayesian network incorporating a variety of factors affecting coastal change including relative sea level rise, has been successful in hindcasting shoreline change, and can be used to evaluate the probability of future shoreline change (Gutierrez *et al*., 2011).

While some coastal systems may be able to undergo landward retreat under rising sea levels, others will experience coastal squeeze, which occurs when an eroding shoreline approaches hard, immobile, structures such as seawalls or resistant natural cliffs. In these instances the beaches will narrow due to the resulting sediment deficit and produce adverse impacts such as habitat destruction, impacting the survivability of a variety of organisms (Jackson and McIlvenny, 2011). With such a manifestation of coastal squeeze, sand dunes will ultimately be removed as the beach erodes and narrows. Extreme storms can erode and completely remove dunes, degrading land elevations and exposing them to inundation and further change if recovery does not occur before the next storm (Plant *et al*., 2010). Even in the absence of hard obstructions, barrier island erosion and narrowing can occur, as a result of rising sea level and recurrent storms, as in the Chandeleur Islands and Isles Dernieres, Louisiana, U.S.A. (Penland *et al*., 2005).

Projected impacts

With projected GMSL rise (see 5.3.3), inundation and erosion may become detectable and progressively important. The impacts will *likely* be first apparent by sea level rise adding to storm surge, making extreme water levels higher and more frequent to attack beaches and dunes (Tebaldi *et al.*, 2012).

The Bruun rule, (a simple rule based on the assumption that to maintain an equilibrium cross-shore profile under rising sea levels, the coastline will move landwards a distance of approximately 100 times the vertical sea level rise; Bruun, 1962), has been used by many researchers to calculate erosion by sea level rise. However there is disagreement about whether the Bruun rule is appropriate (Cooper and Pilkey, 2004; Woodroffe and Murray-Wallace, 2012) and how to calculate the amount of retreat remains controversial (Gutierrez *et al.*, 2011; Ranasinghe *et al.*, 2012). An increase in storm intensity and ocean swell may accelerate erosion of beaches, barriers and dunes although in some places beach response to sea level rise could be more complex than just a simple retreat (Irish *et al.*, 2010).

Coastal squeeze is expected to accelerate with a rising sea level. In many locations, finding sufficient sand to artificially rebuild beaches and dunes will become increasingly difficult and expensive as present supplies near project sites are depleted (*high confidence*). New generation models are emerging to estimate the costs of saving oceanfront homes through beach nourishment relative to the structures cost (McNamara *et al.*, 2011). In the absence of adaptation measures, beaches and sand dunes currently affected by erosion will continue to do so under increasing sea levels (*high confidence*).

5.4.2.2. Rocky Coasts

Rocky coasts with shore platforms form about ¾ of the world's coasts (Jackson and McIIvenny, 2011; Davis and FitzGerald, 2004) and are characterized by very strong environmental gradients, especially in the intertidal zone where challenges are posed by both aquatic and aerial climatic regimes, such as temperature and desiccation.

Observed impacts

Cliffs and platforms are erosional features and any change that increases the efficiency of processes acting on them, such as relative sea level rise, storminess, wave energy and weathering regimes, increases erosion (Naylor *et al.*, 2010). Their responses vary, due to different lithology (e.g. hard rock vs. non-lithified soft rock) and profiles (e.g. plunging cliffs or cliffs with shore platforms). Cliffs and platforms have reduced resilience to climate change impacts; once platforms are lowered or cliffs have retreated, it is difficult to rebuild them (Naylor *et al.*, 2010). On the decadal scale for example, the retreat of soft rock cliffs in East Anglia, UK, has been linked to the NAO phases with high energetics (Brooks and Spencer, 2013).

Changes in the abundance and distribution of rocky shore animals and algae have long been recognized (Hawkins *et al.*, 2008) and perturbation experiments provide information about environmental limits, acclimation and adaptation, particularly to changes in temperature (Somero, 2012). The challenge is to attribute the changes to climate-related drivers, human-related drivers and to natural fluctuations.

The range limits of many intertidal species have shifted by up to 50 km per decade over the past 30 years in the North Pacific and North Atlantic, much faster than most recorded shifts of terrestrial species (Helmuth *et al.*, 2006; Box CC-MB). However, the distribution of some species has not changed in recent decades, which may be due to weak local warming (Rivadeneira and Fernández, 2005) or overriding effects of variables such as timing of low tide, hydrographic features, lack of suitable substrate, poor larval dispersal, and effects of food supply, predation and competition (Helmuth *et al.*, 2002, 2006; Poloczanska *et al.*, 2011).

The dramatic decline of biodiversity in mussel beds of the Californian coast has been attributed to large-scale processes associated with climate-related drivers (59% loss in species richness, 1960s to 2002; Smith *et al.*, 2006) (*high confidence*). Warming reduced predator-free space on rocky shores, leading to a decrease of the vertical extent of mussel beds by 51% in 52 years in the Salish Sea, and to the disappearance of reproductive populations of mussels (Harley, 2011). Unusually high air or water temperature led to mass mortalities, for example, of mussels on the Californian coast (Harley, 2008) and gorgonians in the Northwestern Mediterranean (Garrabou, 2009).

Rocky shores are one of the few ecosystems for which field evidence of the effects of ocean acidification is available. Observational and modeling analysis have shown that the community structure of a site of the NE Pacific shifted from a mussel to an algal-barnacle dominated community between 2000 and 2008 (Wootton *et al.*, 2008), in relation with rapidly declining pH (Wootton and Pfister, 2012).

Projected impacts

Modeled relationships suggest that soft-rock recession rates depends on the relative change in sea level rise while cliff retreat depends both on total elevation change of sea level and on the rate of sea level rise (Ashton *et al.*, 2011). In a modelling study, Trenhaile (2010) found sea level rise to trigger faster rates of cliff recession, especially in coasts that are already retreating fast. Additionally, based on modelling cliff dynamics with contemporary and historic data of soft cliff retreat along Suffolk Coast, UK, rapid retreat is associated with accelerating sea level rise (Brooks and Spencer, 2013). However, coasts currently retreating slowly would experience the largest proportional increase in retreat rates. Increases in storminess have smaller effects on rocky shores (Trenhaile, 2011; Dawson *et al.*, 2009).

Few projections of the effect of climate change on rocky shores have considered the effects of direct and indirect species interactions (Poloczanska *et al.*, 2008; Harley, 2011) and the effects of multiple drivers (Helmuth *et al.* 2006). The abundance and distribution of rocky shore species will continue to change in a warming world (*high confidence*). For example, the long-term consequences of ocean warming on mussel beds of the NE Pacific are both positive (increased growth) and negative (increased susceptibility to stress and of exposure to predation) (Smith *et al.*, 2006; Menge *et al.*, 2008; *medium confidence)*. Extrapolations of ecosystem change based on temperature-focused studies alone are likely to be conservative, as hypoxia (Grantham *et al.*, 2004) or ocean acidification (Feely *et al.*, 2008) are also known to occur in this region.

Observations performed near natural CO_2 vents in the Mediterranean Sea show that diversity, biomass, and trophic complexity of rocky shore communities will decrease at future pH levels (Barry *et al.*, 2011; Kroeker *et al.*, 2011; *high confidence*). An abundant food supply appears to enable mussels of the Baltic Sea to tolerate low pH (Thomsen *et al*., 2010; 2013) at the cost of increased energy expenditure. Model projections that include the interactive effects of ocean warming and acidification suggest that a population of barnacle of the English Channel will become extinct 10 years earlier than it would with warming alone (Findlay *et al.*, 2010; *medium confidence*). Ocean acidification may also exacerbate mass mortality events in the Mediterranean Sea (Rodolfo-Metalpa *et al*., 2011; *limited evidence).*

In summary, rocky shores are among the better-understood coastal ecosystems in terms of potential impacts of climate variability and change. The most prominent effects are range shifts of species in response to ocean warming (*high confidence*) and changes in species distribution and abundance (*high confidence*) mostly in relation to ocean warming and acidification.

5.4.2.3. Wetlands and Seagrass Beds

Vegetated coastal habitats and coastal wetlands (mangrove forests, salt marshes, seagrass meadows and macroalgal beds) extend from the intertidal to the subtidal areas in coastal areas, where they form key ecosystems.

Observed impacts

Vegetated coastal habitats are globally declining globally (Duarte *et al.*, 2005), rendering shorelines more vulnerable to erosion due to increased sea level rise and increased wave action (e.g. Alongi, 2008) and leading to the loss of carbon stored in sediments. Together, the loss of coastal wetlands and seagrass meadows results in the release of 0.04 to 0.28 Pg C annually from organic deposits (Pendleton *et al.*, 2012). Recognition of the important consequences of the losses of these habitats for coastal protection and carbon burial (Duarte *et al*., 2013a), has led to large-scale reforestation efforts in some nations (e.g. Thailand, India, Vietnam).

The response of saltmarshes to sea level rise involves landward migration of salt-marsh vegetation zones, submergence at lower elevations, and drowning of interior marshes. Ocean warming is leading to range shifts in vegetated coastal habitats. The poleward limit of mangrove forests is generally set by the 20 ºC mean winter isotherm (Duke *et al.*, 1998). Accordingly, migration of the isotherm with climate change (Burrows *et al.*, 2011) should lead to a poleward expansion of mangrove forests, as observed in the Gulf of Mexico (Perry and Mendelssohn, 2009; Comeaux *et al.*, 2011; Raabe *et al.* 2012), and New Zealand (Stokes *et al.*, 2010),leading to increased sediment accretion (*medium confidence*).

Seagrass meadows are already under stress due to climate change (*high confidence*), particularly where maximum temperatures already approach their physiological limit. Heat waves lead to widespread seagrass mortality, as documented for *Zostera* species in the Atlantic (Reusch *et al.*, 2005), and *Posidonia* meadows in the Mediterranean Sea (Marbà and Duarte, 2010) and Australia (Rasheed and Unsworth, 2011; *high confidence*). Warming also favors flowering of *P. oceanica* (Diaz-Almela *et al.*, 2007), but the increased recruitment rate is insufficient to compensate for the losses resulting from elevated temperatures (Diaz-Almela *et al.*, 2009).

Kelp forests have been reported to decline in temperate areas in both hemispheres (Johnson *et al.*, 2011, Wernberg *et al.*, 2011a,b, Fernández *et al.*, 2011), a loss involving climate change (*high confidence*). Decline in kelp populations attributed to ocean warming has been reported in southern Australia (Johnson *et al.*, 2011; Wernberg *et al.*, 2011a,b) and the North Coast of Spain (Fernández *et al.*, 2011). The spread of subtropical invasive macroalgal species may be facilitated by climate change, adding to the stresses experienced by temperate seagrass meadows due to ocean warming (*medium evidence, high agreement*).

Projected impacts

Ocean acidification (5.3.3.5; Box CC-OA) is expected to enhance the production of seagrass, macroalgae, salt-marsh plants and mangrove trees through the fertilization effect of CO_2 (Hemminga and Duarte, 2000; Wu *et al.*, 2008;

McKee *et al.*, 2012; *high confidence*). Increased CO_2 concentrations may have already increased seagrass photosynthetic rates by 20% (Hemminga and Duarte, 2000; Hendriks *et al.*, 2010; *limited evidence, high agreement*).

Coupling of downscaled model projections using the SRES A1B scenario in the Western Mediterranean with relationships between mortality rates and maximum seawater temperature led Jordá *et al.* (2012) to conclude that seagrass meadows may become functionally extinct by 2050 to 2060 (*high confidence*). Poleward range shifts in vegetated coastal habitats are expected to continue with climate change (*high confidence*).

Although elevated CO_2 and ocean acidification are expected to increase productivity of vegetated coastal habitats in the future, there is *limited evidence* that elevated CO_2 will increase seagrass survival or resistance to warming (Alexandre *et al.*, 2012; Jordá *et al.*, 2012).

Coastal wetlands and seagrass meadows experience coastal squeeze in urbanized coastlines, with no opportunity to migrate inland with rising sea levels. However, increased CO_2 and warming can stimulate marsh elevation gain, counterbalancing moderate increases in sea level rise rates (Langley *et al.*, 2009; Kirwan and Mudd, 2012). Climate change is expected to increase carbon burial rates on salt-marshes during the first half of the twenty-first century, provided sufficient sediment supply, with carbon–climate feedbacks diminishing over time (Kirwan and Mudd, 2012; *medium confidence*).

In summary, climate change will contribute to the continued decline in the extent of seagrasses and kelps in the temperate zone (*medium confidence*) and the range of seagrasses, mangroves and kelp in the northern hemisphere will expand poleward (*high confidence*). The limited positive impact of warming and increased CO_2 on vegetated ecosystems will be insufficient to compensate the decline of their extent resulting from other human drivers such as land use change (*very high confidence*).

5.4.2.4. Coral Reefs

Coral reefs are shallow-water ecosystems made of calcium carbonate secreted by reef-building corals and algae. They are among the most diverse ecosystems and provide key services to humans (Box CC-CR).

Observed impacts

Mass coral bleaching coincided with positive temperature anomalies over the past 30 years, sometimes followed by mass mortality (Kleypas *et al.*, 2008; *very high confidence*). Over 80% of corals bleached during the 2005 event in the Caribbean and over 40% died (Eakin *et al.*, 2010). Bleaching events and their recovery are variable in time and space: 7% of the reef locations exhibited at least one bleaching between 1985-1994 compared to 38% in the 1995-2004 period, most of which occurred during the 1997-98 El Niño event (Figure 5-3). Recovery from the 1998 global bleaching event was generally slow in the Indian Ocean (about 1% yr^{-1}), absent in the western Atlantic and variable elsewhere (Baker *et al.*, 2008). Warming has caused a poleward range expansion of some corals (Greenstein and Pandolfi, 2008; Yamano *et al.*, 2011; *high confidence)*.

[INSERT FIGURE 5-3 HERE
Figure 5-3: Percent of reef locations (1°x1° grid cells which have at least one reef) that experience no bleaching, at least one mild bleaching event, or at least one severe bleaching event for each decade. Observed bleaching events are summarized from the ReefBase dataset (Kleypas *et al.*, 2008). In the observations, some of the “no bleaching” cells may have experienced bleaching but it was either not observed or not reported. Modeled bleaching events are averages of data from four ensemble runs of the Community Climate System Model version 3 using the SRES A1B CO_2 scenario and the standard degree heating month formula (Teneva *et al.*, 2011). The labels of values ≤ 1% are not shown.]

Persistence of coral reefs depends on the balance between the production and erosion of calcium carbonate and on coral settlement, both of which are affected by ocean acidification (5.3.3.5, Box CC-OA). Experimental data show that ocean acidification generally decreases calcification (Andersson *et al*., 2011; Kroeker *et al.*, 2013) and promotes dissolution of calcium carbonate and bioerosion (Tribollet *et al.*, 2009; Wisshak *et al.*, 2012), leading to poorly cemented reefs (Manzello *et al.*, 2008); it also negatively affects early life history stages which could reduce the number of larval settlers (Albright, 2011).

Coral cover and calcification have decreased in recent decades (e.g., Gardner *et al.*, 2003; De'ath *et al.*, 2009, 2012; Manzello, 2010; Box CC-CR; *very high confidence)* but attribution to climate-related and human-related drivers is difficult. Globally, the primary climate-related driver appears to be ocean warming rather than ocean acidification, cyclonic activity and changes in freshwater input (Cooper *et al.*, 2012; De'ath *et al.*, 2012; *medium confidence)*. sea level rise also controls reef growth but, within the uncertainties of past sea level rise and coral reef growth, most coral reefs seem to have kept pace with the recent sea level rise (Buddemeier and Smith, 1988; Brown *et al*., 2011).

Projected impacts

Coral bleaching and mortality will increase in frequency and magnitude over the next decades (*very high confidence*). Under the A1B CO_2 emission scenario, 99% of the reef locations will experience at least one severe bleaching event between 2090-2099 (Figure 5-3), with *limited evidence* and *low agreement* that coral acclimation and/or adaptation will limit this trend (Logan *et al.*, 2013). The onset of annual bleaching event under RCP 8.5 is delayed by more than two decades in about 23% of reef locations compared to RCP 6.0 (van Hooidonk *et al*., 2013).

Ocean warming and acidification have synergistic effects in several reef-builders (Reynaud *et al.*, 2003; Anthony *et al.*, 2008). They will increase coral mortality, reduce calcification and the strength of calcified organisms, and enhance skeletal dissolution (Manzello *et al.*, 2008; *high confidence*). Reefs will transition from a condition of net accretion to one of net erosion (Andersson and Gledhill, 2013; *high confidence*) and will be more susceptible to breakage. The onset of global dissolution is an atmospheric CO_2 of 560 ppm (Silverman *et al.*, 2009; *medium confidence*) and dissolution will be widespread in 2100 (RCP 8.5 emission scenario, Dove *et al*., 2013; *medium confidence*). The observed poleward range extension will be limited by ocean acidification (Yara *et al*., 2012; Couce *et al.*, 2013) and may be followed by equatorial range retractions (Kiessling *et al.*, 2012).

The maximum rate of vertical accretion has been variable regionally during the last deglaciation (about 20 mm yr^{-1}; Dullo, 2005; Montaggioni *et al.*, 2005) and has not enabled all coral reefs to keep-up with sea level rise. Some reefs kept up, even when the eustatic sea level rise exceeded 40 mm yr^{-1} (Camoin *et al.*, 2012). A number of coral reefs could therefore keep up with the maximum rate of sea level rise of 15.1 mm yr^{-1} projected at the end of the century (WGI, Table 13.5; *medium confidence*) but a lower net accretion than during the Holocene (Perry *et al.*, 2013) and increased turbidity (Storlazzi *et al.*, 2011) will weaken this capability (*very high confidence*)

In summary, ocean warming is the primary cause of mass coral bleaching and mortality (*very high confidence*), which, together with ocean acidification, deteriorates the balance between coral reef construction and erosion (*high confidence*). The magnitude of these effects depends on future rates of warming and acidification (*very high confidence*), with a limited moderating role due to biological acclimation and adaptation (*medium confidence*).

5.4.2.5. Coastal Aquifers

Coastal aquifers are of strategic importance for the water supply of highly populated coastal areas, especially in small islands (29.3).

Observed impacts

Temperature and evaporation rise, precipitation changes and extended droughts affecting aquifer recharge can contribute to saltwater intrusion (3.2.4). Rising sea levels and overwash from waves or storm surge are also relevant, especially in low-lying areas and islands (Terry and Falkland, 2010, White and Falkland, 2010) (29.3).

Aquifers on the coasts of the US have experienced increased levels of salinity largely due to excessive water extraction (Barlow and Reichard, 2010). Natural drivers combined with over-extraction, pollution, mining and erosion compound groundwater supply problems in small islands in the Pacific, Indian and Atlantic Oceans (White *et al.*, 2007; White and Falkland, 2010). This increased usage of groundwater resources globally has, over the last century, led to a reduction in groundwater quality, including increased salinization (*very high confidence*).

Attribution of saline intrusion to incremental sea level rise is still not sufficiently supported (Rozell and Wong, 2010; White and Falkland 2010). In small islands, observed saltwater intrusion due to flooding and overwash under storm events cannot be attributed to climate change (29.3.2; *high agreement)*.

Projected impacts

Available information on projected impacts on coastal aquifers is limited (3.4.6). Rozell and Wong (2010) assessed the impact of rising sea levels on fresh water resources on Shelter Island (USA) for two different combinations of precipitation change and sea level rise. Projected impacts were highly dependent on local conditions. Ferguson and Gleeson (2012) concluded that the direct impact of groundwater extraction in the US has been and will be much more significant than the impact of a 0.59 m sea level rise by the end of the 21st century under a wide range of hydrogeological conditions and population densities.

Saltwater intrusion is generally a very slow process; as a consequence reaching equilibrium may take several centuries limiting the reversibility of the process in the near-term (Webb and Howard, 2011).

Human-induced pressure will continue to be the main driver for aquifer salinization during the next century (*high confidence*). Changing precipitation, increased storminess and sea level rise will exacerbate these problems (*high agreement, limited evidence*).

5.4.2.6. Estuaries and Lagoons

Coastal lagoons are shallow water bodies separated from the ocean by a barrier and connected at least intermittently to the ocean, while estuaries, where fresh and saltwater mix, are the primary conduit for nutrients, particulates and organisms from land to the sea.

Observed impacts

Sediment accumulation in estuaries is high, heterogeneous and habitat-specific and directly affected by human drivers, such as dredging and canalization, and indirectly via habitat loss, changes in sea level, storminess and freshwater and sediment supply by rivers (Syvitski *et al.*, 2005; Swanson and Wilson, 2008). Coastal lagoons are also susceptible to alterations of sediment input and erosional processes driven by changes in sea level, precipitation, and storminess (Pickey and Young, 2009). Droughts, floods and other runoff events, as well as sea level rise impact estuarine circulation, tidal characteristics, suspended matter, and consequently the light climate, and biological communities, in particular in microtidal systems. Climate change and habitat modification (e.g., dams and obstructions) impact fish species such as salmon and eels that pass through estuaries (Lassalle and Rochard 2009).

Enhanced nutrient delivery (5.3.4.3) has resulted in major changes in biogeochemical processes, community structure, metabolic balance, and carbon dioxide exchange (Howarth *et al.* 2011 Canuel *et al.*, 2012; Statham, 2012), including enhanced primary production which has affected coastal fishery yield (Nixon, 1982; Savage *et al.*, 2012). Eutrophication has modified the food-web structure (*high confidence*) and led to more intense and long lasting hypoxia (5.3.4.4), more frequent occurrence of harmful algal blooms (Breitburg *et al.*, 2009; Howarth *et al.*, 2011; *medium confidence)* and to enhanced emission of nitrous oxide (Kroeze *et al.*, 2010; de Bie *et al.*, 2002; *high confidence)*.

In summary, there is very high confidence that humans have impacted lagoons and estuaries.

Projected impacts

The increase of atmospheric carbon dioxide levels will reduce the efflux of CO_2 from estuaries (Borges, 2005; Chen and Borges, 2009; *high confidence*). Its impact on the pH of estuarine and lagoon waters will generally be limited because other drivers are usually more important (5.3.3.4 and Box CC-OA; *high confidence*). For example, freshwater flow in the Scheldt estuary was the main factor controlling pH, directly via a decreased supply of dissolved inorganic carbon and total alkalinity, and, indirectly, via decreased input ammonia loadings and lower rates of nitrification (Hofmann *et al.*, 2009).

Changes in sea level and hydrology could affect lagoons and estuaries in multiple ways. sea level rise will impact sediment redistribution, the partitioning of habitats within estuaries, salinity, tidal range and submergence periods (Anthony *et al.*, 2009; *high confidence*). Lagoons may shrink because landward migration is restricted due to human occupation or extend due to the drowning of marshes (Pilkey and Young, 2009: Anthony *et al.*, 2009; Stutz and Pilkey, 2011). Salinity, primary production, biodiversity, fisheries and aquaculture may be impacted by changes in water discharge, withdrawals and precipitation-evaporation balance (Anthony *et al.*, 2009: Smith *et al.*, 2005; Webster and Harris, 2004; Canu *et al.*, 2010). Altered riverine discharge and warming may lead to enhanced thermal and/or salinity stratification of estuaries and lagoons. This has consequences for biogeochemical processes, organism distribution patterns and frequency and duration of hypoxia (Diaz and Rosenberg, 2008; Rabalais *et al.*, 2009; Hong and Shen, 2012; *medium confidence*). However, stronger winds and droughts may reduce the extent, duration and frequency of estuarine stratification, counteracting the decrease in oxygen concentration (Rabalais *et al.*, 2009; *medium confidence*).

Changes in storm events may also alter the sediment deposition-erosion balance of lagoons and estuaries (Pilkey and Young, 2009), the structure and functioning of biological communities via the transport of communities and/or of their resources, and the underwater light climate (Wetz and Paerl, 2008; Canuel *et al.*, 2012; *medium confidence*). Changes in precipitation extremes and freshwater supply may induce fluctuations in salinity with the associated adverse impacts on biodiversity, benthic macrofauna and ecosystem functions (Pollack *et al.*, 2011; Levinton *et al.*, 2011; Fujii and Raffaelli, 2008; Jeppesen *et al.*, 2007). Warming may directly affect most biological processes and the trophic status of coastal ecosystems, and higher carbon dioxide emission (Canuel *et al.*, 2012; *limited evidence, medium agreement*). Warming may lengthen the duration of phytoplankton production season (Cloern and Jassby, 2008; *medium confidence*).

Any change in the primary production of lagoons might impact fisheries, as primary production and fisheries yield are correlated (Nixon, 1982; *limited evidence, medium agreement*). For example, seawater warming and changes in seasonal patterns of precipitations projected in the Venice lagoon using the SRES A2 CO_2 emission scenario for the period 2071-2100, may lead to a reduction in plankton production, with a decline of habitat suitability for clam growth and aquaculture (Canu *et al.*, 2010).

Finally, projected changes in climate-related drivers such as warming, storms, sea level and run-off will interact with non-climate human drivers (e.g. eutrophication, damming) and will have consequences for ecosystem functioning and services of lagoons and estuaries (*high confidence*).

In summary, the primary drivers of change in lagoons and estuaries are human-related rather than climate-related drivers (*very high confidence*). Future changes in climate-related drivers such as warming, acidification, waves, storms, sea level and run-off will have consequences on the functions and services of ecosystems in lagoons and estuaries (*high confidence*) but the impacts cannot be assessed at the global scale as the key drivers operate at a local to regional scale.

5.4.2.7. Deltas

Characterized by the interplay between rivers, lands and oceans and influenced by a combination of river, tidal and wave processes, deltas are coastal complexes that combine natural systems in diverse habitats (e.g. tidal flats, salt marshes, mangroves, beaches, estuaries, low-lying wetlands) and human systems (e.g. houses, agriculture, aquaculture, industry and transport). They are low-lying coastal landforms formed by riverine sediments in the areas around river mouths, mostly during the last 6000–8000 years of relatively stable sea level and have a population density more than 10 times the world average (Ericson *et al*., 2006; Foufoula-Georgiou *et al*., 2011). As low-lying plains, deltas are highly sensitive to changes in sea level. They are subject to climatic impacts from rivers upstream (e.g. freshwater input) and oceans downstream (e.g. sea level changes, waves) as well as within the deltas themselves. At the same time, they are affected by human activities such as land-use changes, dam construction, irrigation, mining, extraction of subsurface resources and urbanization (Nicholls *et al*., 2007).

Observed impacts

The combined impact of sediment reduction, relative sea level rise, land-use changes in delta and river management on channels and banks has led to the widespread degradation of deltas (*very high confidence*). The changes of sediment delivery from rivers due to dams, irrigation and embankments/dykes create an imbalance in sediment budget in the coastal zones. Degradation of beaches, mangroves, tidal flats, and subaqueous delta fronts along deltaic coasts has been reported in many deltas (e.g. Nile and Ebro, Sanchez-Arcilla *et al*., 1998; Po, Simeoni and Corbau, 2009; Krishna-Godavari, Nageswara Rao *et al*., 2010; Changjiang, Yang *et al*., 2011; Huanghe, Chu *et al*., 1996; *very high confidence*). Deltaic coasts naturally evolve by seaward migration of the shoreline, forming a delta plain. However, decreasing sediment discharge during the last 50 years has decreased the growth of deltaic land, even reversing it in some locations (e.g. Nile, Godavari, Huanghe). Artificial reinforcement of natural levees also has reduced the inter-distributory basin sedimentation in most deltas, resulting in wetland loss.

The major impacts of sea level rise are changes in coastal wetlands, increased coastal flooding, increased coastal erosion, and saltwater intrusion into estuaries and deltas (Mcleod *et al*., 2010), which are exacerbated by increased human-induced drivers (*very high confidence*). Ground subsidence amplifies these hazards in farms and cities on deltaic plains through relative sea level rise (Day and Giosan, 2008; Mazzotti *et al*., 2009). Relative sea level rise due to subsidence has induced wetland loss and shoreline retreat (e.g. the Mississippi delta, Morton *et al*., 2005; Chao Phraya delta, Saito *et al*., 2007; *high confidence*). Episodic events superimpose their effects on these underlying impacts and accelerate land loss (*high confidence*) (e.g., Hurricanes Katrina and Rita in 2005, Barras *et al*., 2008). To forestall submergence and frequent flooding, many delta cities now depend on a substantial infrastructure for flood defense and water management (Nicholls *et al*., 2010).

Deltas are impacted by river floods and oceanic storm surges (*very high confidence*). Tropical cyclones are noteworthy for their damages to deltas, for example, the Mississippi delta by Hurricane Katrina in 2005 (Barras *et al*., 2008), the Irrawaddy delta by Cyclone Nargis in 2008, and the Ganges-Brahmaputra delta by Cyclone Gorky in 1991 and Cyclone Sidr in 2007 (Murray *et al*., 2012) (Box CC-TC). A detailed study of 33 deltas around the world found that 85% of them had experienced severe flooding in the past decade, causing the temporary submergence of 260,000 km2 (Syvitski *et al*., 2009).

Projected impacts

The projected natural impacts on deltas under changing global climate are caused mainly by extreme precipitation induced floods and sea level rise. These will result in increased coastal flooding, decreased wetland areas, increased coastal erosion, and increased salinization of cultivated land and groundwater (McLeod *et al*., 2010; Day *et al*., 2011; Box CC-TC; *high confidence)*. The surface area of flooding in 33 deltas around the world is estimated to increase by 50% under sea level rise estimations as projected for 2100 by the IPCC AR4 (Syvitski *et al*., 2009). Non-climatic drivers (e.g. reduction in sediment delivery, subsidence, and land-use changes) rather than climatic drivers have affected deltas for the last 50 years (Syvitski, 2008; *very high confidence*). Densely populated deltas are particularly vulnerable due to further population growth together with the above-described impacts. The impacts of further sea level rise beyond 2100 show a more complex and enhanced flood risk on deltas (e.g. Katsman *et al*., 2011).

In summary, increased human drivers have been primary causes in changes of deltas (e.g. land-use, subsidence, coastal erosion) for at least for the last 50 years (*very high confidence*). There is *high agreement* that future sea level rise will exacerbate the problems of increased anthropogenic degradation in deltas.

5.4.3. Human Systems

5.4.3.1. Human Settlements

Important direct effects of climate change on coastal settlements include dry land loss due to erosion and submergence, damage of extreme events (such as wind storms, storm surges, floods, heat extremes and droughts) on built environments, effects on health, food and water-borne disease, effects on energy use, effects on water availability and resources and loss of cultural heritage (Hunt and Watkiss, 2010). Since AR4, a large number of regional, national and sub-national scale studies on coastal impacts have been conducted. These are covered in the respective regional chapters. At the global scale, studies have focused either on exposure to sea level rise or extreme water levels or on the physical impacts of flooding, submergence and erosion.

Projected exposure

Coastal flood risks are strongly influenced by the growing exposure of population and assets. The population exposed to the 1 in 100 year coastal flood is projected to increase from about 270 million in 2010 to 350 million in 2050 due to socio-economic development only (UN medium fertility projections) (Jongman *et al.*, 2012). Population growth, economic growth and urbanization will be the most important drivers of increased exposure in densely populated areas (Seto, 2011; Hanson *et al.*, 2011; Chapter 14; *high confidence*). For 136 port cities above one million inhabitants the number of people exposed to a 1-in-100 year extreme sea level is expected to increase from 39 million in 2005 to 59 million by 2070 through 0.5 m GMSL rise alone and to 148 million if socio-economic development (UN medium population projections) is considered on top of this (Hanson *et al.*, 2011). Human-induced subsidence alone is expected to increase the global economic exposure of 136 major port cities by around 14% from 2005 to 2070 although this driver only applies to 36 of the cities (Hanson *et al.*, 2011). Due to socio-economic development Asia is expected to continue to have the largest exposed population and Sub-Saharan Africa the largest increases in exposure (Dasgupta *et al.*, 2009; Vafeidis *et al.*, 2011; Jongman *et al.*, 2012).

Projected impacts and risks

Exposure estimates however give an incomplete picture of coastal risks to human settlements because they do not consider existing or future adaptation measures that protect the exposed population and assets against coastal hazards (Hallegatte *et al*., 2013; Hinkel *et al*., 2013). While the global potential impacts of coastal flood damage and land loss on human settlements in the 21st century are substantial, these impacts can be reduced substantially through coastal protection (*limited evidence, high agreement*). Nicholls *et al.* (2011) estimate that without protection 72 to 187 million people would be displaced due to land loss due to submergence and erosion by 2100 assuming GMSL increases of 0.5 to 2.0 m by 2100. Upgrading coastal defenses and nourishing beaches would reduce these impacts roughly by three orders of magnitude. Hinkel *et al.* (2013) estimate the number of people flooded annually in 2100 to reach 170 to 260 million per year in 2100 without upgrading protection and two orders of magnitude smaller with dike (levee) upgrades, if GMSL rises 0.6 to 1.3 m by 2100. The major driver of increasing risks to human settlements in the next decades is socio-economic development. When upgrading flood defenses to maintain a constant probability of flooding, average annual losses (AAL) in the 136 largest coastal cities are expected to increase 9-fold from 2005 to 2050 due to socio-economic development only another 12% due to subsidence and 2 to 8% due to GMSL rises of 0.2 to 0.4 m (Hallegate *et al*., 2013;Figure 5-4).

[INSERT FIGURE 5-4 HERE
Figure 5-4: The 20 cities where average annual losses (AAL) increase most (in relative terms in 2050 compared with 2005) in the case of optimistic sea level rise, if adaptation maintains only current defense standards or flood probability (PD). Source: Hallegatte *et al*., 2013.]

Despite the delayed response of sea level rise to global warming levels (WG1, 13.5.40) mitigation may limit 21st century impacts of increased coastal flood damage, dry land loss and wetland loss substantially (*limited evidence, medium agreement*) albeit numbers are difficult to compare due to differences in scenarios, baselines and adaptation assumptions. Tol (2007) finds that stabilizing CO_2 concentration at 550 ppm reduces global impacts on wetlands and drylands by about 10% in 2100 compared to a scenario of unmitigated emissions. Hinkel *et al.* (2013) report that stabilizing emissions at 450 ppm-CO_2-eq reduces the average number of people flooded in 2100 by about 30% compared to a baseline where emissions increase to about 25 Gt C-eq in 2100. Arnell *et al.* (2013) find that an emissions pathway peaking in 2016 and declining at 5% per year thereafter reduces flood risk by 58-66% compared to an unmitigated A1B scenario. All three studies only consider the effects of mitigation during the 21st century and assume low or no contribution of ice sheets to GMSL rise. Mitigation is expected to be more effective when considering impacts beyond 2100 and higher contributions of ice sheets (5.5.8).

Global studies confirm AR4 findings that there are substantial regional differences in coastal vulnerability and expected impacts (*high confidence*). Most countries in South, South East and East Asia are particularly vulnerable to sea level rise due to rapid economic growth and coastward migration of people into urban coastal areas together with high rates of anthropogenic subsidence in deltas where many of the densely populated areas are located (Nicholls and Cazenave, 2010). At the same time, economic growth in these countries increases the monetary capacity to adapt (Nicholls *et al.*, 2010). In contrast, while many African countries experience a similar trend in rapid urban coastal growth, the level of economic development is generally lower and consequently the monetary capacity to adapt is smaller (Hinkel *et al.*, 2012; Kebede and Nicholls, 2012).

In summary, while there is *high agreement* on some general findings, only a small fraction of the underlying uncertainty has been explored, which means *evidence is limited*. Gaps remain with respect to impacts of possible large contributions of the ice sheets of Greenland and Antarctica to GMSL rise (WG1, 13.4.3, 13.4.4), regional patterns of climate-induced sea level rise, subsidence and socio-economic change and migration. Many studies rely on few or only a single socio-economic scenario. Few studies consider adaptation and those that do generally ignore the wider range of adaptation measures beyond hard protection options. Integrated studies considering the interactions between a wide range of relative sea level rise impacts (Table 5-3) as well as trade-offs between diverse adaptation options are missing.

5.4.3.2. Industry, Infrastructure, Transport, and Network Industries

Coastal industries, their supporting infrastructure including transport (ports, roads, rail, airports), power and water supply, storm water and sewerage are highly sensitive to a range of extreme weather and climate events including temporary and permanent flooding arising from extreme precipitation, high winds, storm surges and sea level rise (Handmer *et al.* 2012, Horton *et al.* 2010, Hanson and Nicholls, 2012, Aerts *et al*. 2013; *high confidence*). Most industrial facilities, infrastructure and networks are designed for service lives extending over several decades. In fact, many bridges, ports, road and railway lines remain in their original design location for centuries even if the infrastructure on them has been rehabilitated or replaced several times. Besides, certain facilities, such as new nuclear power plants are designed to last even well beyond the twenty-second century (Wilby *et al*. 2011).

Since the need to locate most of these industries and networks in coastal areas will remain and probably increase due to human coastal development (5.4.3.1), considering climate variability and climate change drivers in life cycle assessment of industry, infrastructure, transport and network industries is of utmost importance (*high agreement*).

Observed impacts

Climate impacts on coastal industries and infrastructures vary considerably depending on geographical location, associated weather and climate and specific composition of industries within particular coastal regions (*high confidence*).

Over the last 10 years an extensive number of climate related extreme events (Coumou and Rahmstorf, 2012) have served as an example to evidence impacts on coastal industry, infrastructure, transport and network industry. Severe storms with associated winds, waves, rain, lightning and storm surges have been particularly disruptive to transport and power and water supplies (USCCSP, 2008; Horton *et al*., 2010; Jacob *et al*., 2007; *high confidence*). In such network configurations, flooding of even the smallest component of an intermodal system can result in a much larger system disruption. Even though a transportation terminal may not be affected, the access roads to it could be, thus forcing the terminal to cease or reduce operation. Disruption to port activities in one location can disrupt supply chains, which can have far reaching consequences (Becker *et al*. 2012, Becker *et al*. 2013). Existing experience has also shown that impacts of hurricanes and flooding on underground infrastructure can have long-term effects (Chisolm and Matthews, 2012).

Hurricanes like Katrina (2005), causing US$100 Million of damage to Mississippi's ports Irene (2011) and Sandy (2012), leading to a week-long shut-down of the Port of New York, generating economic damages reaching US$ 50 billion (Becker *et al*. 2012), have shown the critical need to better prepare coastal human settlements and associated network infrastructures and industries for future extreme weather impacts and climate change (Aerts *et al.* 2013; *high agreement*).

Projected impacts

While there is *robust evidence* of the impacts and consequences of extreme events on coastal infrastructure and industrial facilities, there are limited assessments on projected impacts of long-term changes (*high agreement*). Besides, while there is an important amount of grey literature on projected impacts of sea level rise and increasing flooding levels on certain coastal infrastructures (USCCSP, 2008; USACE, 2011; McEvoy and Mullet, 2013), limited peer review information is available.

Vulnerability to flooding of railroads, tunnels, ports, roads and industrial facilities at low-lying areas will be exacerbated by rising sea levels or more frequent or intense storms, causing more frequent and more serious disruption of services and damages under extreme sea levels unless adaptation is enforced (Aerts *et al*, 2013,Wilby *et al.* 2011, Esteban et al. 2012, Esteban et al. 2010; *high agreement*).

Furthermore, sea level rise will reduce the extreme flood return periods and will lower the design critical elevations of infrastructure such as airports, tunnels, coastal protections and ship terminals requiring adaptation (Jacob *et al.*, 2007, Becker *et al*. 2013).

It is estimated that a hypothetical 1 m rise in relative sea level projected for the Gulf Coast region between Alabama and Houston over the next 50-100 years would permanently flood a third of the region's roads as well as putting more than 70% of the region's ports at risk (USCCSP, 2008).

The projected impacts of climate change, considering different possible levels and adaptation, to Alaska's public infrastructure including, but not limited to coastal erosion, inundation and flooding, could add US$3.6-6.1 billion (+10% to 20% above normal wear and tear) from 2006 to 2030 and US$5.6-7.6 billion (+10% to 12%) to 2080 to future costs (Larsen *et al*., 2008).

Hanson *et al*. (2011) presents a first estimate of the exposure of the world's large port cities to coastal flooding due to sea level rise and storm surge in the 2070s. The analysis suggests that the total value of assets exposed in 2005 across all cities considered is estimated to be US$3,000 billion; corresponding to around 5% of global GDP in 2005. By the 2070s, and assuming a homogeneous global sea level rise of 0.5 m, increased extreme water levels up to a 10% and a fixed subsidence rate in susceptible cities with respect to today's values, asset exposure is estimated to increase to approximately 9% of projected global GDP in this period.

Coastal infrastructural instability may result from natural hazards triggered by groundwater-level (GWL) variations resulting from rising sea level. For earthquake-prone coasts, this could be exacerbated by earthquake liquefaction if GWL increases with sea level rise (Yasuhara *et al.*, 2007). Increasing sea levels, surges and waves can also lead to a stability loss of coastal structures (Mori *et al*., 2013, Headland *et al.*, 2011).

Other impacts may arise in coastal industries in high latitudes affected by permafrost thaw causing ground instability and erosion thereby affecting transport safety and the industries that rely on such travel in these regions (e.g., Pearce *et al*., 2010).

5.4.3.3. Fisheries, Aquaculture, and Agriculture

Fisheries and aquaculture and the associated post-harvest activities globally create millions of jobs (Daw *et al.*, 2009; Sumaila *et al*., 2011); and contribute significantly to the dietary animal protein of millions of people and to the world merchandise trade (FAO, 2010 and 2012; Chap 6: 6.4.1.1.). In addition to small-scale fisheries and aquaculture, which are important for the food security and economy of coastal communities (Bell *et al*., 2009), coastal zones also support significant agricultural activities, e.g., rice production in the low-lying deltaic regions of Asia (Wassmann *et al.*, 2009).

Observed impacts

Climate variability and change impact both fishers' livelihoods (Badjeck *et al.*, 2010) and fish production (Barange and Perry, 2009) (6.5.3). In the North Sea, ocean warming over the 1977-2002 period led to relatively increased distribution ranges of some fish species (Hiddink and Hofstede, 2008); and demersal fish assemblage deepened in response to climate change (Dulvy *et al.*, 2008). In southeastern Australia, Last *et al.* (2011) found an increasing abundance of some fish species of warm temperate origin (Ridgeway, 2007) and a decline in abundance for fewer other species. A study (Sherman *et al.* , 2009) of the impact of sea surface temperature changes on the fisheries yields of 63 large marine ecosystems over a 25-year period shows a positive relationship for the Northeast Atlantic large marine ecosystems, due to zooplankton biomass increases (6.5.3). Distributional effects are very important for migratory pelagic fisheries, such as tuna (Chap. 29, Table 29-2). Impacts of climate change on aquaculture (*Mytilus edulis and Salmo salar*) in the UK and Ireland have been difficult to discern from natural environmental variability (Callaway *et al.*, 2012).

Seawater inundation has become a major problem for traditional agriculture in Bangladesh (Rahman *et al.*, 2009), and in low-lying island nations (e.g. Lata and Nunn, 2012). The combination of rice yield reduction induced by climate change and inundation of lands by seawater causes an important reduction in production (Chen *et al.*, 2012).

Projected impacts

Fisheries may be impacted either negatively or positively (Cinner *et al.*, 2012; Meynecke and Lee, 2011; Hare *et al.*, 2010) depending on the latitude, location and climatic factors. Climate change can impact the pattern of marine biodiversity through changes in species' distributions, and may lead to large-scale redistribution of global catch potential depending on regions (Cheung *et al*., 2009; Cheung *et al*., 2010). Narita *et al.* (2012) estimated that the global economic costs of production loss of mollusks due to ocean acidification (5.3.3.5) by the year 2100 could be over 100 billion US$. As a result of increased sea temperatures, the reduction in coral cover and its associated fisheries production is expected to lead in the Caribbean basin to a net revenue loss by 2015 (Trotman *et al.*, 2009). Economic losses in landed catch value and the costs of adapting fisheries resulting from a 2°C global temperature increase by 2050 have been estimated at US$ 10-31 billion globally (Sumaila *et al*., 2011).

For aquaculture, negative impacts of rising ocean temperatures will be felt in the temperate regions whereas positive impacts will be felt in the tropical and subtropical regions (De Silva and Soto, 2009). Changes to the atmosphere–ocean in the Pacific Island countries are *likely* to affect coral reef fisheries by a decrease of 20% by 2050 and coastal aquaculture may be less efficient (Bell *et al.*, 2013).

In summary, changes have occurred to the distribution of fish species (*medium confidence*) with evidence of poleward expansion of temperate species (*high agreement, limited evidence*). Tropical and subtropical aquaculture has not been adversely affected by rising ocean temperatures to date *(high agreement, limited evidence)*. Coastal agriculture has experienced negative impacts (*medium confidence)* due mainly to increased frequency of submersion of agricultural land by saltwater inundation (*high agreement, limited evidence).*

5.4.3.4. Coastal Tourism and Recreation

Coastal tourism is the largest component of the global tourism industry. More than 60% of Europeans opt for beach holidays and beach tourism provides more than 80% of US tourism receipts (UNEP, 2009). More than 100 countries benefit from the recreational value provided by their coral reefs, which contributed US$11.5 billion to global tourism (Burke *et al.*, 2011).

Observed impacts

Observed significant impacts on coastal tourism have occurred from direct impacts of extreme events on tourist infrastructure (e.g. beach resorts, roads), indirect impacts of extreme events (e.g. coastal erosion, coral bleaching) and short-term tourist-adverse perception after the occurrence of extreme events (e.g. flooding, tropical storms, storm surges) (IPCC 2012, 4.3.5.3; Scott *et al*., 2008; Phillips and Jones, 2006). Recent observed climate change impacts on the Great Barrier Reef include coral bleaching in the summers of 1997-98, 2001-02 and 2005-06 and extreme events including floods and cyclones (Tropical cyclones Larry in 2006, Hamish in 2009 and Yasi in 2011). The stakeholders show a high level of concern for climate change and various resilience initiatives have been proposed and developed by the Great Barrier Reef Marine Park Authority (Biggs, 2011; GBRMPA, 2012).

Projected impacts

In order to provide some idea of climate change impacts on coastal destinations, many studies have been carried out on projecting tourism demand, for example, in Europe (Perch-Nielson *et al.*, 2010), the Baltic region (Haller *et al.*, 2011) and beach tourism in the Mediterranean (Moreno and Amelung, 2009a) and in 51 countries worldwide (Perch-Nielson, 2010). The studies provide varying details although it is difficult to draw overarching conclusions on tourism demand for coastal destinations. With increased temperature in mid-latitude countries and coupled with increased storms in tropical areas, tourist flows could decrease from mid-latitude countries to tropical coastal regions with large developing countries and small islands most affected (Perch-Nielson, 2010). The Mediterranean would likewise be affected in summer (Moreno and Amelung, 2009a). In contrast, less is known about the relationship between the impacts of climate change and specific tourist behavior, activities or flows to coastal destinations (Moreno and Amelung, 2009b) (see 10.6.2). Usually tourists do not consider climate variability or climate change in their holidays (Hares *et al.*, 2009) although there are a few studies to show the contrary (Alvarez-Diaz *et al.*, 2010; Cambers, 2009).

As for future impacts on coastal tourism, there is *high confidence* in the impacts of extreme events and sea level rise aggravating coastal erosion. A scenario of 1 m sea level rise by 2100 would be a potential risk to Caribbean tourism

(Scott *et al.*, 2012). The presence of coastal tourism infrastructure will continue to exacerbate beach reduction and coastal ecosystems squeeze under rising sea levels, as exemplified in Martinique (Schleupner, 2008). Carbonate reef structures would degrade under a scenario of at least 2ºC by 2050 to 2100 with serious consequences for tourism destinations in Australia, the Caribbean and other small island nations (Hoegh-Gulberg *et al.*, 2007, see Box CC-CR).

The costs of future climate change impacts on coastal tourism are enormous. For example, in the Caribbean community countries, rebuilding costs of tourist resorts are estimated US$10-US$23.3 billion in 2050. A hypothetical 1-m sea level rise would result in the loss or damage of 21 airports, inundation of land surrounding 35 ports and at least 149 multi-million dollar tourism resorts damaged or lost from erosion to the coastal beach areas (Simpson *et al.*, 2010).

In summary, while coastal tourism can be related to climate change impacts, it is more difficult to relate tourism demand directly to climate change. Coastal tourism continues to be highly vulnerable to weather, climate extremes and rising sea levels with the additional sensitivity to ocean temperature and acidity for the sectors that rely on reef tourism *(high confidence*). Developing countries and small island states within the tropics relying on coastal tourism, are most vulnerable to present and future weather and climate extremes, future sea level rise and the added impacts of coral bleaching and ocean acidification (*high confidence*).

5.4.3.5. Health

The relationship between health of coastal populations and climate change include direct linkages (e.g. floods, droughts, storm surges and extreme temperatures) and indirect linkages (e.g. changes in the transmission of vector, food and water borne infectious diseases and increased salinization of coastal land that affects food production and freshwater supply and ecosystem health). Coastal and particularly informal settlements, concentrate injury risk and death from storm surges and rainfall flooding (Handmer *et al.*, 2012). This section deals with human health in the context of the coastal zone, while Chapter 11 addresses general health issues and 6.4.2.3 deals with health issues associated with ocean changes. Understanding the relationship between climate and health is often confounded by socio-economic factors that influence coastal settlement patterns and the capacity of authorities to respond to health-related issues (Baulcomb, 2011).

Observed impacts

Mortality risk in coastal areas is related to exposure and vulnerability of coastal populations to climate hazards (e.g. Myung and Jang, 2011). A regional analysis of changes in exposure, vulnerability and risk indicates that although exposure to flood and cyclone hazards has increased since 1980, the risk of mortality has generally fallen. The reductions reflect a strengthening of the countries' capacity to respond to disasters (Box 5-1). However, mortality is still rising in the countries with the weakest risk governance capacities (UNISDR, 2011).

Coastal regions face a range of climate-sensitive diseases. Increased saline intrusion is linked to increased hypertension disease (Vineis *et al*., 2011), with greater occurrence in pregnant women living in coastal regions compared to further inland (Khan *et al*., 2008). Increasing temperature, humidity and rainfall can increase vector-borne diseases such as malaria, dengue, leishmaniasis and chikungunya. (Stratten *et al.*, 2008; van Kleef *et al.*, 2010; Pialoux *et al.*, 2007; Kolivras, 2010) and diarrhoea, infectious gastrointestinal disease, rotovirus and salmonella (e.g. Chou *et al.*, 2010; Hashizume *et al.*, 2007, 2008a; Zhang *et al.*, 2007, 2010; Onozuka *et al.*, 2010). The parasitic disease, Schistosomiasis, endemic in many tropical and small island coastal regions, (29.3.3.2) is also sensitive to temperature increase (Mangal *et al.*, 2008). Vibrio outbreaks (e.g. cholera) are sensitive to rainfall and SST (e.g. Koelle *et al*., 2005) and recent increased vibrio outbreaks in the Baltic have been linked to heat waves and low salinity (Baker-Austin *et al*., 2013). Harmful Algal Blooms (HABs) outbreaks (e.g. ciguatera) have been linked to SST variability (e.g. Jaykus *et al.*, 2008; Erdner *et al.*, 2008). However, in general there is *limited evidence* and *low confidence* in how global climate change will impact HABs (6.4.2.3) suggesting the need for increased monitoring

(Hallegraeff, 2010). Nontoxic blooms of high biomass can reduce biodiversity through oxygen depletion and shading (Erdner *et al.*, 2008) with consequences for ecosystem and human nutrition and health.

Projected impacts

Under future climate conditions, expansion of brackish and saline water bodies in coastal areas under projected sea level rise may increase the incidence of vector-borne diseases (Ramasamy and Surendran, 2011), diarrhea and hypertension (Vineis *et al*., 2011). Human responses to climate change may also influence outcomes on health however limited empirical climate-health data increases uncertainties on such projections (Kolstad and Johansson, 2011).

Evidence continues to emerge of the relation between climate and diseases that affect human health in the coastal zone including air and water temperature, rainfall, humidity and coastal salinity. However, the relations are often complex and vary between diseases and even regionally for the same disease. The interplay between climate and human systems with regards to health impacts is poorly understood and this continues to confound reliable projections of health impacts (*high agreement, robust evidence*).

5.4.4. Summary: Detection and Attribution

There is *high confidence* in the attribution to climate change of observed coastal impacts that are sensitive to ocean temperature change, such as coral bleaching and movements in species ranges. However, for many other coastal changes, the impacts of climate change are difficult to tease apart from human related drivers (e.g. land-use change, coastal development, pollution).

Figure 5-5 shows changes of major phenomena observed in coastal systems and low-lying areas. Horizontal and vertical axes indicate the degree of confidence in detection of trends for phenomena, which are elements sensitive to climate change, and the degree of confidence in attribution of phenomena to climate change, respectively. Phenomena with high and *very high degree of confidence* in trend detection are mainly selective in this figure.

The increase of coral bleaching and the shift in range limits of some species distribution are attributed to climate change with *high degree of confidence*. Mass coral bleaching coincided with positive temperature anomalies over the past 30 years. A poleward expansion of mangrove forests and some corals, and shifts of range limits of many intertidal species are also attributed. Vegetated coastal habitats are declining globally. Coral cover and calcification have decreased in recent decades. Elevated temperatures along with ocean acidification reduce the calcification rate of corals. However attribution to climate-related and human-related drivers for decrease calcification is difficult. Its attribution is *medium confidence* because the primary climate-related driver appears to be ocean warming globally. Seagrass meadows are already under stress due to climate change, particularly where maximum temperatures already approach their physiological limit. However the decline of the distribution of mangroves and salt marshes is mainly linked with human activities, e.g. deforestation and reclamation. Therefore the degree of their attribution to climate change is *very low*.

Globally beaches and shorelines have, in general, undergone net erosion over the past century or longer. There is *high confidence* in detection of increased beach erosion globally. However attributing shoreline changes to climate change is still difficult due to the multiple natural and human related drivers contributing to coastal erosion (e.g., subsidence, decreased sediment delivery, land-use change). There is *high confidence* that human pressures, e.g., increased usage of surface-water and groundwater resources for agriculture and coastal settlements, and river-channel deepening, have led to increased saltwater intrusion, and *low confidence* in attribution of saltwater intrusion to climate change.

The population living in coastal lowlands is increasing and more than 270 million people in 2010 are already exposed to flooding by the 1-in-100 year coastal flood. Population growth and land subsidence in coastal lowlands are the major causes; therefore there is *very low attribution* to climate change.

[INSERT FIGURE 5-5 HERE
Figure 5-5: Summary of detection and attribution in coastal areas.]

5.5. Adaptation and Managing Risks

5.5.1. Introduction

Coastal adaptation and risk management refer to a wide range of human activities related to the social and institutional processes of framing the adaptation problem, identifying and appraising adaptation options, implementing options, and monitoring and evaluating outcomes (chapters 2, 14, 15, 16 and 17). The governance of this process is challenging due to the complex, non-linearity dynamics of the coastal socio-ecological systems (Rosenzweig *et al*., 2011) as well as the presence of multiple management goals, competing preferences of stakeholders and social conflicts involved (Hopkins *et al*., 2012). In many instances, coastal adaptation may thus be characterized to be a "wicked problem" (Rittel and Webber, 1973), in the sense that there is often *no clear agreement* about what exactly the adaptation problem is and there is uncertainty and ambiguity as to how improvements might be made (Moser *et al.*, 2012).

Since AR4, the set of adaptation measures considered has been expanded specifically towards ecosystem-based measures (5.5.2); novel approaches for appraising coastal adaptation decisions have been applied (5.5.3.1) and the analysis of adaptation governance and the institutional context in which decisions are taken has progressed (5.5.3.2). Progress has also been made in better integrating adaptation practices within existing policy frameworks (5.5.4.1) as well as in implementing adaptation and identifying good practices (5.5.4.2). A number of studies have also explored the global costs and benefits of coastal adaptation (5.5.5), opportunities, constraints and limits of coastal adaptation (5.5.6), linkages between coastal adaptation and mitigation (5.5.7) and the long-term commitment to coastal adaptation (5.5.8).

5.5.2. Adaptation Measures

A detailed discussion on general adaptation needs and measures can be found in chapter 14. As a first approximation, adaptation measures were classified into: institutional and social measures (14.3.2.1), technological and engineered measures (14.3.2.2) and ecosystem-based adaptation measures (14.3.2.3). In terms of coastal adaptation, most of the existing measures can be included within this classification.

The IPCC classification of coastal adaptation strategies consisting of retreat, accommodation and protection (Nicholls *et al.*, 2007) is now widely used and applied in both developed and developing countries (Boateng, 2010; Linham and Nicholls, 2012). This trilogy of strategies has expanded into broad approaches of retreat, defend and attack (Peel, 2010). Protection aims at advancing or holding existing defense lines by means of different options such as: land claim, beach and dune nourishment, the construction of artificial dunes, hard structures such as seawalls, sea dikes and storm surge barriers or removing invasive and restoring native species. Accommodation is achieved by increasing flexibility, flood proofing, flood-resistant agriculture, flood hazard mapping, the implementation of flood warning systems or replacing armored with living shorelines. Retreat options include allowing wetlands to migrate inland, shoreline setbacks and managed realignment by, for example, breaching coastal defenses allowing the creation of an intertidal habitat. The appropriate measure may depend on several factor requiring a careful decision-making and governance process (5.5.3).

Since AR4, coastal adaptation options have been revised and summarized in several guidebooks (USAID, 2009; EPA, 2009; UNEP, 2010) including best practice examples. Especially relevant has been the growth of Community Based Adaptation (CBA) measures (*robust evidence*). Table 5-4 compiles different examples of CBA measures in countries such as Bangladesh, India or the Philippines.

Ecosystem-based adaptation is increasingly attracting attention (Munroe *et al*., 2011). Adaptation measures based on the protection and restoration of relevant coastal natural systems such as mangroves (Schmitt *et al.*, 2013), oyster reefs (Beck *et al.*, 2011) and salt marshes (Barbier *et al*., 2011) are seen as no- or low-regret options irrespective of the future of climate change (Cheong *et al*., 2013; *high agreement, medium evidence*). Further work is still needed in order to make reliable quantitative estimates and predictions of the capability of some of these ecosystems to reduce wave, storm surge and sea level rise impacts and in order to provide reliable cost-benefit analysis of how they compare to other measures based on traditional engineering approaches.

5.5.3. Adaptation Decision-Making and Governance

Since AR4, progress has been made in understanding coastal adaptation decisions and governance. For a general treatment of adaptation decision-making and governance see Chapters 2 and 15, 17.

5.5.3.1. Decision Analysis

One specific quality of many coastal adaptation decisions is that these involve options with long (i.e. 30 and more years) investment time scales (e.g. land-use planning, flood defenses, construction of housing and transportation infrastructure; 5.5.2). For such decisions, standard methods that rely on probability distribution on outcomes, such as cost-benefit analysis under uncertainty, cannot be applied because of the difficulties, both in theory and practice, to associate probabilities to future levels of greenhouse gas emissions, which determine the level of impacts and outcomes (Lempert and Schlesinger, 2001; Hallegate, 2009; 17.3.6.2).

Alternative approaches that represent uncertainty not through a single probability distribution but through a range of scenarios have thus been applied to long-term coastal adaptation. Robust decision-making (RDM), for example, refers to approaches where options that work well over a wide range of these scenarios are preferred (Lempert and Schlesinger, 2000; Lempert and Collins, 2007). RDM in this sense has been applied to, e.g., the Port of Los Angeles infrastructure (Lempert *et al.*, 2012).

Another set of approaches uses the criterion of flexibility to decide between alternative strategies. Flexible and reversible options are favored over non-flexible and non-reversible ones and decisions are delayed to keep future options open (Hallegate, 2009). The adaptation pathways approach, for example, implements the criterion of flexibility by characterizing alternative strategies in terms of two attributes: i) adaptation tipping points (ATP), which are points beyond which strategies are no longer effective (Kwadijk *et al.*, 2010), and ii) what alternative strategies are available once a tipping point has been reached (Haasnoot *et al.*, 2013). Importantly, the exact time when an ATP is reached does not matter; it is rather the flexibility of having alternative strategies available that is driving the decision. Prominent applications of this approach include the Thames Estuary 2100 Plan (Penning-Roswell *et al.* 2012; Box 5-1), the Dutch Delta Programme (Kabat *et al.*, 2009) and the New York City Panel on Climate Change (Rosenzweig *et al.*, 2011).

_____ START BOX 5-1 HERE _____

Box 5-1. London's Thames Estuary 2100 Plan: Adaptive Management for the Long Term

The Environment Agency in Britain has recently developed the Thames Estuary 2100 plan (TE2100) to manage future flood threat to London (Environment Agency, 2012). The motivation was a fear that due to accelerated climate change induced sea level rise the time could already be too short for replacing the Thames Barrier (completed in 1982) and other measures that protect London, because such major engineering schemes take 25 to 30 years to plan and implement. An adaptive plan that manages risk in an iterative way was adopted based on the adaptation pathway approach (Penning-Rowsell *et al.*, 2012; 5.5.3.1; Figure 5-6). This plan includes maintaining the existing system in the first 25 years, then enhancing the existing defenses in a carefully planned way over the next 25-60 years, including selectively raising defenses and possibly over-rotating the Barrier to raise protection standards. Finally, in the longer term (beyond 2070) there will be the need to plan for more substantial measures if sea level rise accelerates. This might include a new barrier, with even higher protection standards, probably nearer to the sea, or even a coastal barrage. In the meantime the adaptive approach requires careful monitoring of the drivers of risk in the Estuary to ensure that flood management authorities are not taken by surprise and forced into emergency measures.

[INSERT FIGURE 5-6 HERE
Figure 5-6: Adaptation measures and pathways considered in the TE2100 project. The boxes show the measures and the range of sea level rise over which the measures are effective. The blue arrows link to alternative measures that may be applied once a measure is no longer effective. The red lines show the various 21st century sea level rise scenarios used in the analysis including a conservative estimate of about 0.9 m by the UK Department for Environment Food and Rural Affairs (Defra), a high-level scenario of 2.6 m (H+) and an extreme scenario of over 4 meters (H++). The fat green line shows a possible future adaptation pathway that allows for lower-end sea level rises but also for the unlikely event of extreme change.]

_____ END BOX 5-1 HERE _____

5.5.3.2. Institution and Governance Analysis

Decisions are made within a context. Institution and governance analysis comprise a variety of approaches that aim at describing this context as well as at explaining the emergence and performance of institutions and governance structures (GS). Institution analysis is particularly relevant to coastal adaptation, because deciding between options and implementing them is an ongoing process involving complex inter-linkages between public and private decisions at multiple levels of decision-making and in the context of other issues, existing policies, conflicting interests and diverse GS (e.g, Few *et al.*, 2007; Urwin and Jordan, 2008; Hinkel *et al.*, 2009; 2.2.2 and 2.2.3). The non-consideration of this context may hinder or mislead adaptation decisions and implementations as reported by the emerging literature on barriers to adaptation (5.5.5). Institution analysis strives to understand how this context shapes decisions, and insights gained may be employed to craft effective institutions and policies for adaptation.

For coastal adaptation, the effectiveness of existing GS is often hindered due to a lack of horizontal (i.e., within the same level of decision-making) and vertical (i.e. between different levels of decision-making) integration of organizations and policies (*high confidence*). Storbjörk and Hedren (2011), for example, report on a weak vertical administrative interplay in coastal GS in Sweden. In the UK, the effectiveness of local GS of Coastal Partnership is found to be limited because these are poorly integrated with higher-level policies (Stojanovic and Barker, 2008). In the UK, national level coastal recommendations are difficult to translate into local level actions (Few *et al.*, 2007) and in the United States, coastal policies often have ambiguous or contradictory goals (Bagstad *et al.*, 2007). In a number of African cases, coastal policies are found not to take into account longer-term climate change (Bunce *et al.*, 2010).

Governance issues are particularly challenging when considering planned retreat (*medium evidence)*. While managed realignment is on the political agenda in Germany and the UK, the political costs of doing so are high as both the existing GS as well as public opinion are geared towards protection (e.g. Tunstall and Tapsell, 2007), so that short election cycles do not provide incentives for politicians to undertake actions that may produce benefits in the long term (Few *et al.*, 2007; Rupp-Armstrong and Nicholls, 2007). Along the Queensland coast in Australia the option of planned retreat is disappearing because of rapid coastal development and liability laws favoring development. To prevent this, risks and responsibilities would need to be redistributed from the governments to the beneficiaries of this development (Abel *et al.*, 2011).

While institutional factors are decisive in enabling coastal adaptation (*high confidence*), the role of institutions in coastal adaptation is generally under-researched. The majority of studies are descriptive. Institutional analysis striving to understand which GS emerge and are effective depending on both biophysical and social system characteristics as found in the fields of social-ecological systems (Dietz *et al.*, 2003; Folke *et al.*, 2005; Ostrom 2007, 2009) and institutional economics (Hagedorn *et al.*, 2002; Bougherara *et al.*, 2009) are practically non-existent.

5.5.4. Implementation and Practice

Since AR4, more experiences have been gained in coastal adaptation implementation and practice. Generally, adaptation is not carried out stand-alone but in the context of already existing policy and practice frameworks. Section 5.5.4.1 assesses frameworks that are particularly relevant for coastal adaptation and Section 5.5.4.2 assesses the experiences made as well as principles and compiled best practice guidelines.

5.5.4.1. Frameworks

The issues for coastal adaptation are not radically different from issues encountered within integrated coastal zone management (ICZM), which offers an enabling environment for adaptation practice (Celliers *et al*., 2013). ICZM is a long-term, institutionalized and iterative process that promotes the integration of coastal activities, relevant policy makers, practitioners and scientists across coastal sectors, space and organizations with a view to use coastal resources in a sustainable way (Kay and Alder 2005; Christie *et al.*, 2005; Sales, 2009; WG2 Glossary). Considering climate change in this framework does not mean radical changes to ICZM, because ICZM already emphasizes the integration of coastal issues across sectors and policy domains as well as the long-term perspective (e.g., Hofstede, 2008; Falaleeva *et al.*, 2011). The major difference of coastal adaptation from ICZM is coping with greater uncertainty, longer time frames in planning (beyond 30 years), and long-term commitments inherent to climate change (Tobey *et al.* 2010).

So far, however, there is *limited evidence* and *low agreement* on the effectiveness of ICZM alone or combined with climate change adaptation. Even though ICZM has been applied throughout the world for over 40 years, many obstacles to its successful implementation still remain (*high confidence*). Generally, there is a lack of empirical research evaluating ICZM (Stojanovic *et al*., 2004; Stojanovic and Ballinger, 2009). A recent review of ICZM in Europe concluded that the complexity of coastal regulations, demographic deficits, lack of sustainable finance and a failure to involve communities, business and industry hinder its implementation (Shipman and Stojanovic, 2007).

Developing countries in particular struggle to meet the goals of ICZM due to a lack of qualified human resources, a lack of human, legal and institutional capacities (Isager, 2008; González-Riancho *et al*., 2009); difficulties in integrating policy across multiple coastal agencies (Ibrahim and Shaw, 2012; Martinez *et al*., 2011); power (abuse) of the majority political party or political leaders (Tabet and Fanning, 2012; Isager, 2008), the lack of long-term financial commitment of donors (González-Riancho *et al*., 2009; Ibrahim and Shaw, 2012), and a lack of knowledge regarding the coastal system (González-Riancho *et al*., 2009).

Another prominent framework used for coastal adaptation practice is adaptive management (AM), which has been developed as a response to the deep uncertainty characterizing ecosystem management, where it is often impossible to predict outcomes of management interventions. AM thus aims to test management hypothesis by implementing them, monitoring their outcomes and learning from these to refine the management hypothesis to be applied (Holling, 1978; Walters, 1986). There are numerous applications of AM to coastal management (e.g. Walters, 1997; Marchand *et al.*, 2011, Mulder *et al.*, 2011), but there is *limited evidence* of its long-term effectiveness. Limitations of AM are also notable, such as the potential high cost of experimentation and a range of institutional barriers hindering the delivery of flexible management approaches (e.g. McLain and Lee, 1996).

Community-based adaptation (CBA) refers to the generation and implementation of locally-driven adaptation strategies that address both climate change impacts and development deficits for the climate vulnerable poor and aim to strengthen the adaptive capacity of local people to climate and non-climate risk factors (Reid *et al.*, 2009; Nicholls *et al.*, 2007; Ayers and Dodman, 2010; Ayers and Huq, 2013; 14.2.1; 15.4.3.1, 24.4.6.5). CBA is a bottom-up approach to adaptation involving all relevant stakeholders especially local communities (Ayers and Huq, 2009; UNDP, 2010; Riadh et al., 2012) (Table 5-4). As such, CBA approaches have been developed through active participatory processes with local stakeholders (Ayers and Forsyth, 2009), and operated on a learning-by-doing, bottom up, empowerment paradigm (Huq and Reid, 2007; Kates, 2000).

CBA experiences emphasize that it is important to understand a community's unique perceptions of their adaptive capacities in order to identify useful solutions (Parvin *et al.*, 2008; Paul and Routray, 2010; Badjeck *et al.*, 2010) and that scientific and technical information on anticipated coastal climate impacts needs to be translated into a suitable language and format that allows people to be able to participate in adaptation planning (Saroar and Routray, 2010). Furthermore, effective CBA needs to consider measures that cut across sectors and technological, social and institutional processes, as technology by itself is only one component of successful adaptation (Sovacool *et al.*, 2011; Rawlani and Sovacool, 2011; Pelling, 2011).

Efforts are also being made to integrate climate change adaptation into Disaster Risk Reduction (DRR) frameworks (Romieu *et al.*, 2010; Mercer, 2010; Polack, 2010; Gero *et al.*, 2011) and adaptation practice is likely to move forward as climate change adaptation (CCA) converges with disaster risk reduction (ISDR, 2009; Setiadi *et al*., 2010; Tran and Nitivattananon, 2011; Hay, 2012). In Japan, for example, coastal climate change adaptation has been mainstreamed into the framework of Coastal Disaster Management in the aftermath of the 2011 Tohoku Earthquake Tsunami. The priority of upgrading coastal defenses in the face of sea level rise is thereby judged from the potential damage on the assets in predicted inundation areas on the one hand as well as from the age and earthquake resistance of the coastal structures on the other hand (Central Disaster Management Council. 2011; Committee on Adaptation Strategy for Global Warming in the Coastal Zone, 2011). Other important policy and practice frameworks in place in the coastal zone include poverty reduction and development (Mitchell *et al.*, 2010).

[INSERT TABLE 5-4
Table 5-4: Community-based adaptation measures.]

5.5.4.2. Principles, Guidance, and Experiences

Much of the observed adaptation practice deals with the coastal hazards of erosion and flooding (Hanak and Moreno, 2012). In many parts of the world, small island indigenous communities address climate change consequences based on their own traditional knowledge (Percival, 2008; Langton *et al*., 2012; Nakashima *et al*., 2012). Long-term adaptation to sea level rise has been confined to a few major projects such as the Venice Lagoon project, the Thames Estuary 2100 project (Box 5-1) and the Delta Programme, Netherlands (Norman, 2009).

Through the Delta Programme, the Dutch Government has set out far-reaching recommendations on how to keep the country flood-proof over the 21st century taking into account a sea level rise as high as 0.65-1.3 by 2100. These recommendations constitute a paradigm shift from 'fighting' the forces of nature with engineered structures to 'working with nature' and providing 'room for river' instead (Kabat *et al.*, 2009). The recommendations include soft and environmentally friendly solutions such as preserving land from development to accommodate increased river inundation; maintaining coastal protection by beach nourishment; improving the standards of flood protection and putting in place the necessary political-administrative, legal and financial resources (Stive et al., 2011).

From adaptation experiences, good practices (practices that have shown consistently better results and could be used as benchmark) have been derived. For some European cases, for example, McInnes (2006) has collected good practices for coastlines facing coastal erosion, flooding and landslide events. In the California adaptation study that includes coasts, the lessons learnt include using best available science, decision on goals and early actions, locating relevant partners, identification and elimination of regulatory barriers and encouragement of introduction of new state mandates and guidelines (Bedsworth and Hanak, 2010). Boateng (2010) presented 15 case studies from 12 countries of best practice in coastal adaptation to help coastal managers and policy makers.. Bangladesh provides good examples on awareness raising, disaster warning and control, and protective building measures (Martinez *et al.*, 2011). In general, documentation on good adaptation practices for coasts is improving.

In addition, numerous principles have been set forward. In a broad-scale assessment of climate change threats to Australia's coastal ecosystems, seven principles in adaptation were suggested: clearly defined goals by location, thorough understanding of connectivity within and between ecosystems, consideration of non-climatic drivers, involvement of all relevant stakeholders, easily available and shared data, re-thinking of existing policy and planning constraints and adaptation at local/regional scales (Hadwen *et al*., 2011). Based on Oxfam's adaptation programms in South Asia that include coastal communities, additional principles presented include a focus on the poor, vulnerable and marginalized, community or local ownership, flexible and responsive implementation, preparation for future and capacity building at multiple levels (Sterrett *et al*., 2011). An assessment of worldwide case studies indicates the importance of knowledge transfer of good practice methods for scaling up adaptation strategies in and between regions and beyond the national scale (Martinez *et al*., 2011).

Further principles reported include: Information on efficient adaptation options alone (as assessed through DA approaches) may not fully serve the needs of managers and must to be supplemented by financial and technical assistance as well as boundary organizations which serve as an interface between science and practice (Tribbia and Moser, 2008). The adaptation and decision-making processes should be participatory and inclusive, integrating all relevant stakeholders in a way that is culturally appropriate (Milligan *et al*., 2009; Nunn, 2009). The adaptation processes should be set up to foster mutual learning, experimentation and deliberation amongst stakeholder and researchers (Fazey *et al.*, 2010; Kenter *et al.*, 2011). For example, neither scientific climate knowledge alone nor indigenous knowledge alone are considered sufficient for coastal adaptation (Sales, 2009; Dodman and Mitland, 2011; Bormann *et al.*, 2012). Finally, as coastal systems are complex, diverse and dynamic, their governance needs experimentation and learning by doing (Jentoft, 2007).

In summary, a wealth of adaptation activities can now be observed in the coastal zone depending on technology, policy, financial and institutional support, and are supported by documentation on good practices (*very high confidence*). ICZM, with its emphasis on integration, is likely to remain a major framework for coastal adaptation. While there is *high agreement* on adaptation principles, there is to date little systematic review of and hence *limited evidence* on why a given principle or approach is effective in a given context (and not in another), which emphasizing the need for research to better understand this context (5.5.3.2). Some of the literature on adaptation practice needs to be treated with caution, because normative principles that have been established *ex-ante* are not systematically distinguished from *ex-post* evaluations of the experiences carried out. Despite the wealth of coastal adaptation activities, it must, however, be emphasized that meeting the multiple goals of coastal adaptation, improving governance, accounting for the most vulnerable populations and sectors and fully integrating consideration of natural ecosystems is still largely aspirational. Meanwhile, development continues in high-risk coastal areas, coastal ecosystems continue to degrade in many regions, coastal freshwater resources are being overexploited in many highly populated areas, and vulnerability to coastal disasters grows (e.g. Jentoft, 2009; McFadden, 2008; Mercer, 2010; Shipman and Stojanovic, 2007).

5.5.5. Global Adaptation Costs and Benefits

This section reports on studies that provide internally consistent estimates of the direct costs of sea level rise impacts and adaptation at global scales. These studies have used the models FUND and DIVA, which are described in Section 5.4.1. Studies that use computable general equilibrium models and growth models to estimate the indirect and dynamic costs of climate change, including sea level rise are reviewed in Chapter 10.

Generally, cost estimates are difficult to compare across studies due to differences in scenarios used, impacts and adaptation options considered, methodologies applied and baseline conditions assumed. Global adaptation costs have only been assessed for protection via dikes and nourishment. Nicholls et al. (2011) estimate annual adaptation cost in terms of dike construction, dike maintenance and nourishment to be US$ 25-270 billion/year in 2100 under a 0.5-2.0 m GMSL rise for 2005-2100. Anthoff et al. (2010) estimate the net present value of dike construction costs for 2005-2100 to be US$ 80-120 billion for 0.5 m SLR and US$ 900-1,100 billion for a 2m GMSL, respectively

The available global studies show that it is economically rational to protect large parts of the world's coastline during the 21st century against sea level rise impacts of increased coastal flood damage and land loss (Nicholls and Tol, 2006; Anthoff *et al.*, 2010; Hinkel *et al.*, 2013; *high agreement, limited evidence*). For dry land and wet land loss, the FUND model shows that cost-benefit analysis would justify protecting 80% of the exposed coast in all but 15 countries under a GMSL rise of 20-40 cm per century (Nicholls and Tol, 2006). Using the same method, Nicholls *et al.* (2008) show that under extreme GMSL rise of up to 4 m in 2100, this fraction would drop to 30% to 50%. For coastal flooding, an application of DIVA shows that for 21st century GMSL rise scenarios of 60-126 cm, the global costs of protection through dikes (levees) are much lower than the costs of damages avoided through adaptation (Hinkel *et al.*, 2013).

At the same time, costs and benefits of sea level rise impacts and adaptation vary strongly between regions and countries with some developing countries and Small Island States reaching limits of adaption or not being able to bear the costs of impacts and adaptation (*high agreement, limited evidence)* (29.6.2.1). The cost of 1 m of GMSL rise in 2100 (considering land loss due to submergence and protection costs) is projected to be above 1% of national GDP for Micronesia, Palau, the Bahamas and Mozambique (Anthoff *et al.*, 2010). For coastal flooding, annual damage and protection costs are projected to amount to several percentages of the national GDP for small island states such as Kiribati, the Solomon Islands, Vanuatu and Tuvalu under GMSL projections of 0.6-1.3 m by 2100 (Hinkel *et al.*, 2013). Further substantial costs arise, particularly for developing countries due to their current adaptation deficit (i.e. coastal defenses are not adapted to the current climate variability), which is not well understood and requires further analysis (Parry *et al.*, 2009). For example, the adaption deficit of Africa with regards to coastal flooding is estimated at US$ 300 billion (Hinkel *et al.*, 2011) and that of Bangladesh with respect to cyclones at US$ 25 billion (World Bank, 2011).

Several methodological gaps remain. As there are so few studies on the costs and benefits of sea level rise at a global level, uncertainties are largely unknown and the need for further research is great. The socioeconomic drivers, sea level rise scenarios and impacts considered as well as damages and losses valued are incomplete. For example, costs of salinity intrusion, land loss due to increased coastal erosion, cost of forced migration due to permanent inundation, the backwater effect and the impact of sea level rise in combination with other drivers on ecosystems have not been assessed at global scales (5.5.5). Generally for sea level rise impacts, it is difficult to establish a “no adaptation” baseline and the choice of the baseline the associated changes damage costs (Yohe *et al.*, 2011).

Another gap is realted to the fact that global studies have focused on protection via hard structures while many more, potentially cheaper or socially preferable measures are available including “soft” protection, retreat and accommodation measures (5.1). Future work needs to consider trade-offs between all available measures. Hard protection measures, for example, may incur additional costs on adjacent unprotected coasts (Brown *et al.*, 2013) or destroy coastal wetlands through coastal squeeze (5.4.2.3). While the costs of “soft” protection measures such as ecosystem-based adaptation (EBA) are largely unknown (Linham and Nicholls, 2010), these may provide additional benefits in the form of a variety of ecosystem services (Espinosa-Romero *et al.*, 2011; McGinnis and McGinnis, 2011; Pérez *et al.*, 2010; Anthony *et al.*, 2009; Alongi, 2008; Zeitlin *et al.*, 2012; Vignola *et al.*, 2009; IUCN, 2008). Finally, it must be noted that protection also further attracts people and development to the floodplain, which in turn increases the risk of potential catastrophic consequence in the case of defense failure. This is particularly true for many coastal cities such as London, Tokyo, Shanghai, Hamburg and Rotterdam that already rely heavily on coastal defenses (Nicholls *et al.*, 2007).

5.5.6. Adaptation Opportunities, Constraints, and Limits

There is a growing recognition of the potential co-benefits and new opportunities that can be achieved by mainstreaming adaptation with existing local to national goals and priorities (14.3.4). Disaster Risk Reduction (DRR) and adaptation share the common goals of reducing vulnerability against impacts of extreme events while creating strategies that limit risk from hazards (IPCC, 2012). This is especially true in coastal areas where extreme flooding events due to severe storm surges are one of the main sources of hazard. Besides, integrating adaptation with national and local planning can also contribute to build resilience in coastal areas.

Ecosystems-Based Adaptation (EBA) is considered to be an emerging adaptation opportunity (Munroe *et al.* 2011) (16.6, 16 CC-EA). In coastal areas, the conservation or restoration of habitats (e.g. mangroves, wetlands and deltas) can provide effective measures against storm surge, saline intrusion and coastal erosion by using their physical characteristics, biodiversity and the ecosystem services they provide as a means for adaptation (Borsje *et al*., 2011; Cheong *et al*., 2013; Duarte *et al*., 2013b; Jones *et al*., 2012; Cheong et al., 2013; 5.5.7).

Since AR4, a variety of studies have been published prodviding a better understanding of the nature of the constraints and limits to adaptation, both generally [16.3, 16.4] and more specifically in the coastal sector (e.g. Lata and Nunn, 2012; Mozumber *et al.*, 2011; Storbjörk and Hedrén, 2011; Bedsworth and Hannak, 2010; Frazier *et al.*, 2010; Saroar and Routray 2010; Moser *et al.*, 2008; Tribbia and Moser, 2008; Ledoux *et al.*, 2005).

Constraints specific to coastal adaptation are: polarized views in the community regarding the risk of sea level rise and concerns regarding the fairness of retreat schemes in Australia (Ryan *et al.*, 2011); lack of awareness of sea level rise risks and spiritual beliefs in Fiji (Lata and Nunn, 2012); insufficient budget for the development of adaptation policies and other currently pressing issues in the US (Mozumber *et al.*, 2011; Tribbia and Moser, 2008); distinct preferences for retreat options depending on several social and exposure conditions in Bangladesh (Saroar and Routray, 2010); need to provide compensatory habitats under the Habitats Regulations and lack of local public support in the UK (Ledoux *et al.*, 2005). Other relevant constraints include the lack of locally, relevant information, resource tenure and political will, especially critical in developing countries (*high agreement*, *robust evidence*). Besides a gap exists between the useful climate information provided by scientists and the one demanded by decision makers.

Different constraints typically do not act in isolation, but come in interacting bundles (*high agreement, robust evidence*). Therefore it is difficult to predict which constraints matter most in any specific context but instead multiple constraints need to be addressed if adaptation is to move successfully through the different stages of the management process (Moser and Ekstrom, 2010; Storbjörk, 2010; Londsdale *et al.*, 2010; *high agreement, moderate evidence*). Besides, some factors can act as enablers and add to the adaptation capacity, while acting as constraints for others (Burch, 2010; Storbjörk, 2010; *high agreement, moderate evidence*).

Finally, a common concern emerging from the literature reviews (Biesbroek *et al.*, 2010; Ekstrom *et al.*, 2011) is that some critical constraints arise from the interactions across policy domains, existing laws and regulations, and long-term impacts of past decisions and policies (*high agreement, low evidence*).

A limit is reached when adaptation efforts are unable to provide an acceptable level of security from risks to existing objectives and values and prevent the loss of key attributes, components or services of ecosystem (Box 16-1; 16.2, 16.5) and may arise due to most of the constraints described above.

Regarding coastal areas, it is widely recognized that biophysical limitations arise, for example, in small developing island states where adaptation through retreat to increasing impact of sea level rise in conjunction with storm surges and flooding is not an option due to limited high land availability, creating a temporary and eventually permanent human displacement from low-lying areas (Pelling and Uitto, 2001; *high agreement, moderate evidence*). Nicholls *et al.* 2011, show that only a limited number of adaptation options are available for specific coastal areas if sea level exceeds a certain threshold (1 m) at the end of the century.

Regarding natural (unassisted) adaptation, several researchers have examined biophysical limits, e.g., of coastal marshes (Kirwan *et al.*, 2010; Craft *et al.*, 2009; Langley *et al.*, 2009; Mudd *et al.*, 2009). Kirwan *et al.* (2010) found that under certain nonlinear feedbacks among inundation, plant growth, organic matter accretion and sediment deposition coastal wetlands can adapt to conservative rates of sea level rise (A1B) if suspended sediment surpasses a certain threshold. In contrast, even coastal marshes with high sediment supplies, will submerge near the end of the 21st century under scenarios of more rapid sea level rise (e.g., those that include ice sheet melting).

Increased ocean acidification is expected to limit adaptation of coral reefs to climate change (Boxes CC-OA and CC-CR).

5.5.7. Synergies and Tradeoffs between Mitigation and Adaptation

Klein *et al.* (2007, p. 749) defined trade-offs between mitigation and adaptation as the “balancing of adaptation and mitigation when it is not possible to carry out both activities fully at the same time (e.g., due to financial or other constraints)”. Successful adaptive coastal management of climate risks will involve assessing and minimizing potential trade-offs with other non-climate policy goals (e.g., economic development, enhancement of coastal tourism) and interactions between adaptation and mitigation (e.g. Bunce *et al.*, 2010; Barbier *et al.*, 2008; Tol, 2007; Brown *et al.*, 2002).

Adaptation will be the predominant approach to reducing climate risks to coastal communities, populations, resources and activities over the 21st century as large increases in sea level rise cannot be ruled out (WG1, Chapter 13, 13.5.2.) and because of the time lag between emission reductions, temperature changes and impacts on global sea levels (Nicholls *et al.*, 2011; Nicholls *et al.*, 2007, 5.5.7). Still, positive synergies and complementarities between mitigation and adaptation in the coastal sector exist.

Since AR4, a series of studies have pointed out that marine vegetated habitats (seagrasses, saltmarshes, macroalgae or mangroves) contribute to almost 50% of the total organic carbon burial in ocean sediments leading to the so-called Blue Carbon (coastal carbon stocks) strategies (Duarte *et al*. 2013b, McLeod *et al*., 2011, Nellemann *et al*. 2009). These strategies aim at exploring and implementing the necessary mechanisms allowing Blue Carbon to become part of emission and mitigation protocols along with other carbon-binding ecosystems such as rainforests (Nellemann *et al*. 2009).

Besides, marine vegetated habitats provide additional functions including the buffering of impacts against storm surges and waves, soil preservation, raising the seafloor and shelter for fish nursery or habitat protection (Duarte *et al.* 2013b, Alongi, 2002, Kennedy and Björk, 2009). Consequently, restoration or ecosystem engineering of marine vegetated areas can be considered as a good example of positive synergies between adaptation and mitigation in coastal areas (Duarte *et al.* 2013b, Jones, *et al.* 2012, Borsje *et al.* 2011) and should be further explored to be considered as a valid alternative in the portfolio of measures for climate change mitigation and adaptation. Only recently results have been presented on the role of a 1700 ha seagrass restoration in carbon storage in sediments of shallow coastal ecosystems in Virginia (USA). Restored seagrass meadows are expected to accumulate carbon at a rate comparable to ranges measured in natural seagrass meadows within 12 years of seeding, providing an estimated social cost of \$4.10 $ha^{-1}yr^{-1}$ (Greiner *et al.* 2013).

Many coastal zone-based activities and various coastal management strategies involve emissions of greenhouse gases. Reduction or cessation of some of them may have positive implications for both mitigation and adaptation. Limiting offshore oil production may imply a net reduction in GHG emissions depending on what form of energy replaces it, but also a reduced risk of oil spills, a reduction of stresses on the marine/coastal eco-systems and variable socio-economic impacts on human communities and public health (O'Rourke and Connolly, 2003). This may result in reduced vulnerability or increased resilience and consequently could prove positive for adaptation. However, this measure would increase the vulnerability of countries whose economies are highly dependent on oil extraction.

Some coastal adaptation options may have potentially negative implications on mitigation. Relocation of infrastructure and development out of the coastal floodplains (retreat) will imply increase in one-time GHG emissions due to rebuilding of structures and possible increase in low-density urban development and ongoing transportation-related emissions (Biesbroek *et al.* 2010). The building or upgrading of coastal protection structures or ports will also imply an increased energy use and GHG emissions related to construction (e.g. cement production) (Boden *et al.* 2011).

Similarly, actions beneficial for mitigation may result in potential negative impacts for adaptation. A more compact coastal urban design, increasing development in floodplains (Giridharan *et al.* 2007) or the development of marine renewable energy (Boehlert and Gill, 2010), may introduce additional drivers on coastal systems reducing coastal resilience and adaptive capacity.

5.5.8. Long-Term Commitment to Sea Level Rise and Adaptation

In AR4 both WG1 and WG2 highlighted the long-term commitment to sea level rise (Meehl *et al*., 2007; Nicholls *et al*., 2007), which means that sea levels will continue to rise for centuries due to global warming until reaching equilibrium conditions even if climate forcing is stabilized, because there is a delay in the response of sea level rise to global warming [WG1, 13.4.1]. In AR5 WG1 has now assessed GMSL rise until 2500 and this shows that even with aggressive mitigation measures (RCP2.6), sea level continues to rise after 2100 [Table 5-1, WGI, 13.5.1, 13.5.4]. With more moderate (RCP4.5.) and little (RCP8.5) mitigation, larger ongoing increases in sea level are expected lasting for several centuries. Note that the ranges given after 2100 are only model spread and not *likely* ranges. Looking beyond 2500, Levermann *et al*. (2013) project that GMSL will rise on average by about 2.3 m per degree Centigrade of global warming within the next 2000 years. Under present levels of global warming, this means that we have already committed to a long term sea level rise of 1.3 m above current levels (Strauss, 2013). For other climate-related drivers, responses to global warming levels are more immediate. For ocean acidification, for example, pH rise would cease several decades after strict CO_2 emission reductions begin (Bernie *et al.* 2010) [19.7.1].

This long term commitment to sea level rise means that there is also a long-term commitment to sea level rise impacts and adaptation. Few studies have considered this and, from a methodological point of view, it is difficult to look at socio-economic conditions and human responses on such large temporal scales. A limited number of studies have estimated the effects of mitigation on coastal impacts on human settlements and adaptation for the 21st century [5.4.3.1]. These studies show that despite the delayed response of sea level rise to global warming, mitigation can reduce impacts significantly already during the 21st century. These studies also show that for most urban areas, coastal protection is cost-efficient in reducing impacts during the 21st century [5.5.5]. Past and current adaptation practice also confirms this: cities such as Tokyo and Shanghai have protected themselves against local sea level rise of several meters during the 20th century and the Dutch and UK Governments have decided that they can protect urban Netherlands and London against 21st century sea level rise above 1 m [5.5.4]. Not protecting cities such as Amsterdam, Rotterdam and London during the 21st century is not an option. On the other hand, there are coastal areas such as small island states where protecting against several meters of sea level rise in the long-term is not a viable option. Failing to mitigate, thus increasingly commits us to a world where densely populated areas lock into a trajectory of increasingly costly hard defenses and rising residual risks on the one hand and less densely populated areas being abandoned on the other hand. Mitigation thus plays, in the long-term, a very important role in avoiding climate change impacts in coastal areas by reducing the rate of sea level rise and providing more time for long-term strategic adaptation measures to be adopted. However, even if anthropogenic CO_2 emissions were reduced to zero, sea levels would continue to rise for centuries, making adaptation in coastal areas inevitable.

5.6. Information Gaps, Data Gaps, and Research Needs

This chapter has updated knowledge on the impacts of climate change on the coastal systems not in isolation but also from the perspective of overexploitation and degradation that have been responsible for most of the historical changes. There is a better understanding of the varying impacts of weather and climate extremes and long-term sea level rise on human systems.

That sea levels will rise is a confident projection of climate science but uncertainties around the magnitude of future sea level rise remain large. The rates and magnitude of sea level rise are summarized in Table 5-1 but under present levels of global warming, we are already committed to 1.3 m future sea level rise above current levels (5.5.8). However, many sea level rise assessments are not provided at spatial or temporal scales most relevant for decision makers who require information on baseline conditions and projections of change (Kettle, 2012) of relative sea level rise (i.e. including local subsidence) for vulnerability assessment and adaptation planning.

Generally, quantitative predictions of future coastal change remain difficult despite the application of improvements in technology, e.g., aerial photographs, satellite imagery, LiDAR (Sesil *et al.*, 2009; Revell *et al.*, 2011; Pe'eri and Long, 2012) to investigate and characterize large-scale shoreline changes. There is incomplete understanding of coastal changes over the decade and century timescales (Woodroffe and Murray-Wallace, 2012). Shoreline response is more complex than simple submergence because of factors such as sediment supply, mobilization and storage, offshore geology, engineering structures, and wave forcing (Ashton *et al.*, 2011).

The projection of the future impacts of climate change on natural systems is often hampered by the lack of sufficiently detailed data at the required levels of space and time. Although observations have been made on impacts on beaches, rocky coasts, wetlands, coastal aquifers, delta areas or river mouths by multi-drivers of climate and human-induced origin, there is still an incomplete understanding of the relative role played by each of these drivers and, especially of their combined effect. Uncertainties are even higher when it comes to the evaluation of projected impacts.

For coastal ecosystems, more work needs to be done to develop predictive models based on findings from multi-stressor experiments, both in the field and laboratory. Reliable predictions require information on multifactorial experiments performed on communities (preferably in the field), and on time scales of months to years in order to take into consideration the processes of biological acclimation and adaptation.

Although sea level is projected to rise in the future, there are significant gaps in vulnerability assessment of other specific coastal impacts. For example, the modeling of diseases that could affect coastal areas is based mainly on the mean values of climate. Also, despite tourism being one of the most important industries in the coastal areas, not enough is known about tourists' reactions to projected climatic change (Moreno and Amelung, 2009b) or required adaptation measures for port facilities (UNCTAD, 2009).

A wide range of coastal management frameworks and measures is available and used in coastal adaptation to climate change, and the scope for their integration has increased by combining scenarios of climate change and socio-economic conditions and risk assessment (Kirshen *et al.*, 2012). While various adaptation measures are available, at the local level, there remains insufficient information on assessment of adaptation options, particularly in developing countries.

Data and knowledge gaps exist or their reliability is insufficient. Despite the availability of potentially useful climate information, a gap exists between what is useful information for scientists and for decision makers. For example, at the project level engineers may have difficulties to "plug in" climate projections presented by scientists. The proposed actions to improve usability include varying levels of interaction, customization, value-adding, retailing and wholesaling (Lemos *et al.*, 2012) so that data and methods can be more openly-accessible to fellow scientists, users and public (Kleiner, 2011).

Coastal systems are affected by human and climate drivers and there are also complex interactions between the two. In general, certain components of coastal systems are sensitive and attributable to climate drivers while others are not clearly discernible. For example, data is available on the range shift in coastal plant and animal species and the role of higher temperatures on coral bleaching (see CC-CR). However, in many cases in the human systems, the detectable changes can be largely attributed to human drivers (5.3.4). Reducing our knowledge gaps on the understanding of the processes inducing changes would help to respond to them more efficiently.

The economics of coastal adaptation are under researched. More comprehensive assessments of valuation of coastal ecosystem services, adaptation costs and benefits that simultaneously consider both the gradual impact of land loss due to sea level rise and the stochastic impacts of extreme water levels (storm surges, cyclones) are needed, as well as other impacts such as salt water intrusion, wetland loss and change and backwater effects. Assessments should also consider a more comprehensive range of adaptation options and strategies, including "soft" protection, accommodation and retreat options as well as the trade-offs between these.

Governance of coastal adaptation and the role of institutions in the transition towards sustainable coasts are under-researched. While institutional factors are recognized to be decisive in constraining and enabling coastal adaptation, most work remains descriptive. There is a great need for dedicated social science research aimed at understanding institutional change and which institutional arrangements are effective in which socio-economic and biophysical contexts (5.5.3; 5.5.4; Kay, 2012).

Developing a coastal adaptation knowledge network between scientists, policy makers, stakeholders and the general public could be considered a priority area for large coastal areas or regional areas affected by climate change and sea level rise. This is well developed in the USA, European Union, the Mediterranean and Australia but less so in the developing countries, except in certain regions, e.g. Caribbean islands, Pacific Islands.

Future research needs for coastal adaptation are identified by several developments in climate science. Based on Li *et al.* (2011) survey of the foci of climate research in the 21st century, the implications for coasts would be on biodiversity and flooding. Future technological advances may be significant, e.g., new forms of energy and food production, information and communication technology (ICT) for risk monitoring (Zevenhagen *et al*., 2013; Campbell *et al*., 2009; Delta Commission, 2008) and these would be useful for flood risks and food production in deltas and coastal systems (aquaculture).

With recent adverse climatic and environmental events on coasts, adaptation demands different decision regimes (Kiker *et al.*, 2010) but adaptation, mitigation and avoidance measures still require integrating research that includes natural and social sciences (CCSP, 2009). Although many gaps still remain, there is nevertheless a greater foundation of climate change research on coasts across a wide range of fields (Grieneisen and Zhang, 2011) upon which scientists, policymakers and public may find improved solutions for coastal adaptation.

Frequently Asked Questions

FAQ 5.1: How does climate change affect coastal marine ecosystems? *[to be placed in Section 5.4.1]*
The major climate-related drivers on marine coastal ecosystems are sea level rise, ocean warming, and ocean acidification.

Rising sea level impacts marine ecosystems by drowning some plants and animals as well as by inducing changes of parameters such as available light, salinity, and temperature. The impact of sea level is mostly related to the capacity of animals (e.g. corals) and plants (e.g. mangroves) to keep up with the vertical rise of the sea. Mangroves and coastal wetlands can be sensitive to these shifts and could leak some of their stored compounds, adding to the atmospheric supply of these greenhouse gases.

Warmer temperatures have direct impacts on species adjusted to specific and sometimes narrow temperature ranges. They raise the metabolism of species exposed to the higher temperatures and can be fatal to those already living at the upper end of their temperature range. Warmer temperatures cause coral bleaching, which weakens those animals and makes them vulnerable to mortality. The geographical distribution of many species of marine plants and animals shifts towards the poles in response to warmer temperatures.

When atmospheric carbon dioxide is absorbed into the ocean, it reacts to produce carbonic acid, increasing the acidity of seawater and diminishing the amount of a key building block (carbonate) used by marine species like shellfish and corals to make their shells and skeletons. The decreased amount of carbonate makes it harder for many of these 'calcifiers' to make their shells and skeletons, weakening or dissolving them. Ocean acidification has a number of other impacts, many of which are still poorly understood.

FAQ 5.2: How is climate change influencing coastal erosion? *[to be placed in Section 5.4.2]*
Coastal erosion is influenced by many factors; sea level, currents, winds and waves (especially during storms, which add energy to these effects). Erosion of river deltas is also influenced by precipitation patterns inland which change patterns of freshwater input, run-off and sediment delivery from upstream. All of these components of coastal erosion are impacted by climate change.

Based on the simplest model, a rise in mean sea level usually causes the shoreline to recede inland due to coastal erosion. Increasing wave heights can cause coastal sand bars to move away from the shore and out to sea. High storm surges (sea levels raised by storm winds and atmospheric pressure) also tend to move coastal sand offshore. Higher waves and surges increase the probability that coastal sand barriers and dunes will be over-washed or breached. More energetic and/or frequent storms exacerbate all these effects.

Changes in wave direction caused by shifting climate may produce movement of sand and sediment to different places on the shore, changing subsequent patterns of erosion.

FAQ 5.3: How can coastal communities plan for and adapt to the impacts of climate change, in particular sea level rise? *[to be placed in Section 5.5]*
Planning by coastal communities that considers the impacts of climate change reduces the risk of harm from those impacts. In particular, proactive planning reduces the need for reactive response to the damage caused by extreme events. Handling things after the fact can be more expensive and less effective.

An increasing focus of coastal use planning is on precautionary measures, i.e. measures taken even if the cause and effect of climate change is not established scientifically. These measures can include things like enhancing coastal vegetation, protecting coral reefs. For many regions, an important focus of coastal use planning is to use the coast as a natural system to buffer coastal communities from inundation, working with nature rather than against it, as in the Netherlands.

While the details and implementation of such planning take place at local and regional levels, coastal land management is normally supported by legislation at the national level. For many developing countries, planning at the grass roots level does not exist or is not yet feasible.

The approaches available to help coastal communities adapt to the impacts of climate change fall into three general categories:

1) Protection of people, property and infrastructure is a typical first response. This includes 'hard' measures such as building seawalls and other barriers, along with various measures to protect critical infrastructure. 'Soft' protection measures are increasingly favored. These include enhancing coastal vegetation and other coastal management programs to reduce erosion and enhance the coast as a barrier to storm surges.
2) Accommodation is a more adaptive approach involving changes to human activities and infrastructure. These include retrofitting buildings to make them more resistant to the consequences of sea level rise, raising low-lying bridges, or increasing physical shelter capacity to handle needs caused by severe weather. Soft accommodation measures include adjustments to land use planning and insurance programs.
3) Managed retreat involves moving away from the coast and may be the only viable option when nothing else is possible.

Some combination of these three approaches may be appropriate, depending on the physical realities and societal values of a particular coastal community. The choices need to be reviewed and adjusted as circumstances change over time.

Cross-Chapter Boxes

Box CC-CR. Coral Reefs

[Jean-Pierre Gattuso (France), Ove Hoegh-Guldberg (Australia), Hans-Otto Pörtner (Germany)]

Coral reefs are shallow-water ecosystems that consist of reefs made of calcium carbonate which is mostly secreted by reef-building corals and encrusting macroalgae. They occupy less than 0.1% of the ocean floor yet play multiple important roles throughout the tropics, housing high levels of biological diversity as well as providing key ecosystem goods and services such as habitat for fisheries, coastal protection and appealing environments for tourism (Wild *et al*., 2011). About 275 million people live within 30 km of a coral reef (Burke *et al*., 2011) and derive some benefits from the ecosystem services that coral reefs provide (Hoegh-Guldberg, 2011) including provisioning (food, livelihoods, construction material, medicine), regulating (shoreline protection, water quality), supporting (primary production, nutrient cycling) and cultural (religion, tourism) services. This is especially true for the many coastal and small island nations in the world's tropical regions (29.3.3.1).

Coral reefs are one of the most vulnerable marine ecosystems (*high confidence*; 5.4.2.4, 6.3.1, 6.3.2, 6.3.5, 25.6.2, and 30.5) and more than half of the world's reefs are under medium or high risk of degradation (Burke *et al*., 2011). Most human-induced disturbances to coral reefs were local until the early 1980s (e.g., unsustainable coastal development, pollution, nutrient enrichment and overfishing) when disturbances from ocean warming (principally mass coral bleaching and mortality) began to become widespread (Glynn, 1984). Concern about the impact of ocean acidification on coral reefs developed over the same period, primarily over the implications of ocean acidification for the building and maintenance of the calcium carbonate reef framework (Box CC-OA).

[INSERT FIGURE CR-1 HERE
Figure CR-1: A and B: the same coral community before and after a bleaching event in February 2002 at 5 m depth, Halfway Island, Great Barrier Reef. Coral cover at the time of bleaching was 95% bleached almost all of it severely bleached, resulting in mortality of 20.9% (Elvidge *et al*., 2004). Mortality was comparatively low due in part because these coral communities were able to shuffle their symbiont to more thermo-tolerant types (Berkelmans and van Oppen, 2006; Jones *et al*., 2008). C and D: three CO_2 seeps in Milne Bay Province, Papua New Guinea show

that prolonged exposure to high CO_2 is related to fundamental changes in the ecology of coral reefs (Fabricius *et al*., 2011), including reduced coral diversity (-39%), severely reduced structural complexity (-67%), lower density of young corals (-66%) and fewer crustose coralline algae (-85%). At high CO_2 sites (panel D; median pH_T ~7.8), reefs are dominated by massive corals while corals with high morphological complexity are underrepresented compared with control sites (D; median pH ~8.0). Reef development ceases at pH_T values below 7.7. pH_T: pH on the total scale. E: temporal trend in coral cover for the whole Great Barrier Reef over the period 1985–2012 (N, number of reefs, mean ± 2 standard errors; De'ath et al., 2012). F: composite bars indicate the estimated mean coral mortality for each year, and the sub-bars indicate the relative mortality due to crown-of-thorns starfish, cyclones, and bleaching for the whole Great Barrier Reef (De'ath et al., 2012). Photo credit: R. Berkelmans (A and B) and K. Fabricius (C and D).]

A wide range of climatic and non-climatic drivers affect corals and coral reefs and negative impacts have already been observed (5.4.2.4, 6.3.1, 6.3.2, 25.6.2.1, 30.5.3, 30.5.6). Bleaching involves the breakdown and loss of endosymbiotic algae, which live in the coral tissues and play a key role in supplying the coral host with energy (see 6.3.1. for physiological details and 30.5 for a regional analysis). Mass coral bleaching and mortality, triggered by positive temperature anomalies (*high confidence*), is the most widespread and conspicuous impact of climate change (Figure CR-1A and B, Figure 5-3; 5.4.2.4, 6.3.1, 6.3.5, 25.6.2.1, 30.5 and 30.8.2). For example, the level of thermal stress at most of the 47 reef sites where bleaching occurred during 1997-98 was unmatched in the period 1903 to 1999 (Lough, 2000). Ocean acidification reduces biodiversity (Figure CR-1C and D) and the calcification rate of corals (*high confidence*; 5.4.2.4, 6.3.2, 6.3.5) while at the same time increasing the rate of dissolution of the reef framework (*medium confidence*; 5.2.2.4) through stimulation of biological erosion and chemical dissolution. Taken together, these changes will tip the calcium carbonate balance of coral reefs towards net dissolution (*medium confidence*; 5.4.2.4). Ocean warming and acidification have synergistic effects in several reef-builders (5.2.4.2, 6.3.5). Taken together, these changes will erode habitats for reef-based fisheries, increase the exposure of coastlines to waves and storms, as well as degrading environmental features important to industries such as tourism (*high confidence*; 6.4.1.3, 25.6.2, 30.5).

A growing number of studies have reported regional scale changes in coral calcification and mortality that are consistent with the scale and impact of ocean warming and acidification when compared to local factors such as declining water quality and overfishing (Hoegh-Guldberg *et al*., 2007). The abundance of reef building corals is in rapid decline in many Pacific and SE Asian regions (*very high confidence*, 1-2% per year for 1968-2004; Bruno and Selig, 2007). Similarly, the abundance of reef-building corals has decreased by over 80% on many Caribbean reefs (1977 to 2001; Gardner *et al*., 2003), with a dramatic phase shift from corals to seaweeds occurring on Jamaican reefs (Hughes, 1994). Tropical cyclones, coral predators and thermal stress-related coral bleaching and mortality have led to a decline in coral cover on the Great Barrier Reef by about 51% between 1985 and 2012 (Figure CR-1E and F). Although less well documented, benthic invertebrates other than corals are also at risk (Przeslawski *et al*., 2008). Fish biodiversity is threatened by the permanent degradation of coral reefs, including in a marine reserve (Jones *et al*., 2004).

Future impacts of climate-related drivers (ocean warming, acidification, sea level rise as well as more intense tropical cyclones and rainfall events) will exacerbate the impacts of non-climate related drivers (*high confidence*). Even under optimistic assumptions regarding corals being able to rapidly adapt to thermal stress, one-third (9 to 60%, 68% uncertainty range) of the world's coral reefs are projected to be subject to long-term degradation (next few decades) under the RCP3-PD scenario (Frieler *et al*., 2013). Under the RCP4.5 scenario, this fraction increases to two-thirds (30 to 88%, 68% uncertainty range). If present day corals have residual capacity to acclimate and/or adapt, half of the coral reefs may avoid high frequency bleaching through 2100 (*limited evidence, limited agreement*; Logan *et al*., 2013). Evidence of corals adapting rapidly, however, to climate change is missing or equivocal (Hoegh-Guldberg, 2012).

Damage to coral reefs has implications for several key regional services:

- *Resources*: Coral reefs account for 10 to 12% of the fish caught in tropical countries, and 20 to 25% of the fish caught by developing nations (Garcia and Moreno, 2003). Over half (55%) of the 49 island countries considered by Newton *et al*. (2007) are already exploiting their coral reef fisheries in an unsustainable way and the production of coral reef fish in the Pacific is projected to decrease 20% by 2050 under the SRES A2 emissions scenario (Bell *et al*., 2013).

- *Coastal* protection: Coral reefs contribute to protecting the shoreline from the destructive action of storm surges and cyclones (Sheppard *et al*., 2005), sheltering the only habitable land for several island nations, habitats suitable for the establishment and maintenance of mangroves and wetlands, as well as areas for recreational activities. This role is threatened by future sea level rise, the decrease in coral cover, reduced rates of calcification and higher rates of dissolution and bioerosion due to ocean warming and acidification (5.4.2.4, 6.4.1, 30.5).
- *Tourism*: More than 100 countries benefit from the recreational value provided by their coral reefs (Burke *et al*., 2011). For example, the Great Barrier Reef Marine Park attracts about 1.9 million visits each year and generates A$ 5.4 billion to the Australian economy and 54,000 jobs (90% in the tourism sector; Biggs, 2011).

Coral reefs make a modest contribution to the Global Domestic Product but their economic importance can be high at the country and regional scales (Pratchett *et al*., 2008). For example, tourism and fisheries represent 5% of the GDP of South Pacific islands (average for 2001-2011; Laurans *et al*., 2013). At the local scale, these two services provided in 2009-2011 at least 25% of the annual income of villages in Vanuatu and Fiji (Pascal, 2011; Laurans *et al*., 2013).

Isolated reefs can recover from major disturbance, and the benefits of their isolation from chronic anthropogenic pressures can outweigh the costs of limited connectivity (Gilmour *et al*., 2013). Marine protected areas (MPAs) and fisheries management have the potential to increase ecosystem resilience and increase the recovery of coral reefs after climate change impacts such as mass coral bleaching (McLeod *et al*., 2009). Although they are key conservation and management tools, they are unable to protect corals directly from thermal stress (Selig *et al*., 2012) suggesting that they need to be complemented with additional and alternative strategies (Rau *et al*., 2012; Billé *et al*., 2013). While MPA networks are a critical management tool, they should be established considering other forms of resource management (e.g., fishery catch limits and gear restrictions) and integrated ocean and coastal management to control land-based threats such as pollution and sedimentation. There is *medium confidence* that networks of highly protected areas nested within a broader management framework can contribute to preserving coral reefs under increasing human pressure at local and global scales (Salm *et al*. 2006). Locally, controlling the input of nutrients and sediment from land is an important complementary management strategy (Mcleod *et al*., 2009) because nutrient enrichment can increase the susceptibility of corals to bleaching (Wiedenmann *et al*., 2012) and coastal pollutants enriched with fertilizers can increase acidification (Kelly *et al.*, 2011). In the long term, limiting the amount of ocean warming and acidification is central to ensuring the viability of coral reefs and dependent communities (*high confidence*; 5.2.4.4, 30.5).

Box CC-OA. Ocean Acidification

[Jean-Pierre Gattuso (France), Peter Brewer (USA), Ove Hoegh-Guldberg (Australia), Joan A. Kleypas (USA), Hans-Otto Pörtner (Germany), Daniela Schmidt (UK)]

Anthropogenic ocean acidification and global warming share the same primary cause, which is the increase of atmospheric CO_2 (Figure OA-1A; WGI, 2.2.1). Eutrophication, loss of sea ice, upwelling and deposition of atmospheric nitrogen and sulphur all exacerbate ocean acidification locally (5.3.3.6, 6.1.1, 30.3.2.2).

[INSERT FIGURE OA-1 HERE
Figure OA-1: A: Overview of the chemical, biological, socio-economic impacts of ocean acidification and of policy options (adapted from Turley and Gattuso, 2012). B: Multi-model simulated time series of global mean ocean surface pH (on the total scale) from CMIP5 climate model simulations from 1850 to 2100. Projections are shown for emission scenarios RCP2.6 (blue) and RCP8.5 (red) for the multi-model mean (solid lines) and range across the distribution of individual model simulations (shading). Black (grey shading) is the modelled historical evolution using historical reconstructed forcings. The models that are included are those from CMIP5 that simulate the global carbon cycle while being driven by prescribed atmospheric CO_2 concentrations. The number of CMIP5 models to calculate the multi-model mean is indicated for each time period/scenario (WGI AR5 Figure 6.28). C: Effect of near future acidification (seawater pH reduction of 0.5 unit or less) on major response variables estimated using weighted random effects meta-analyses, with the exception of survival which is not weighted (Kroeker et al., 2013). The log-transformed response ratio (LnRR) is the ratio of the mean effect in the acidification treatment to the mean effect in a control group. It indicates which process is most uniformly affected by ocean acidification but large variability exists between species. Significance is determined when the 95% bootstrapped confidence interval does not cross zero. The number of experiments used in the analyses is shown in parentheses. * denotes a statistically significant effect.]

Chemistry and Projections

The fundamental chemistry of ocean acidification is well understood (*robust evidence, high agreement*). Increasing atmospheric concentrations of CO_2 result in an increased flux of CO_2 into a mildly alkaline ocean, resulting in a reduction in pH, carbonate ion concentration, and the capacity of seawater to buffer changes in its chemistry (*very high confidence*). The changing chemistry of the surface layers of the open ocean can be projected at the global scale with high accuracy using projections of atmospheric CO_2 levels (Fig. CC-OA-1B). Observations of changing upper ocean CO_2 chemistry over time support this linkage (WGI Table 3.2 and Figure 3.18; Figures 30.8, 30.9). Projected changes in open ocean, surface water chemistry for year 2100 based on representative concentration pathways (WGI, Figure 6.28) compared to preindustrial values range from a pH change of -0.14 unit with RCP 2.6 (421 ppm CO_2, +1 ºC, 22% reduction of carbonate ion concentration) to a pH change of -0.43 unit with RCP 8.5 (936 ppm CO_2, +3.7 ºC, 56% reduction of carbonate ion concentration). Projections of regional changes, especially in the highly complex coastal systems (5.3.3.6, 30.3.2.2), in polar regions (WGI 6.4.4), and at depth are more difficult but generally follow similar trends.

Biological, Ecological, and Biogeochemical Impacts

Investigations of the effect of ocean acidification on marine organisms and ecosystems have a relatively short history, recently analyzed in several metaanalyses (6.3.2.1, 6.3.5.1). A wide range of sensitivities to projected rates of ocean acidification exists within and across diverse groups of organisms, with a trend for greater sensitivity in early life stages (*high confidence*; 5.4.2.2, 5.4.2.4, 6.3.2). A pattern of positive and negative impacts emerges (*high confidence*; Fig. OA-1C) but key uncertainties remain in our understanding of the impacts on organisms, life histories and ecosystems. Responses can be influenced, often exacerbated by other drivers, such as warming, hypoxia, nutrient concentration, and light availability (*high confidence*; 5.4.2.4, 6.3.5).

Growth and primary production are stimulated in seagrass and some phytoplankton (*high confidence*; 5.4.2.3, 6.3.2.2-3, 30.5.6). Harmful algal blooms could become more frequent (*limited evidence, medium agreement*). Ocean acidification may stimulate nitrogen fixation (*limited evidence, low agreement*; 6.3.2.2). It decreases the rate of calcification of most, but not all, sea-floor calcifiers (*medium agreement, robust evidence*) such as reef-building corals (Box CC-CR), coralline algae, bivalves and gastropods reducing the competitiveness with non-calcifiers (5.4.2.2, 5.4.2.4, 6.3.2.5). Ocean warming and acidification promote higher rates of calcium carbonate dissolution resulting in the net dissolution of carbonate sediments and frameworks and loss of associated habitat (*medium confidence*; 5.4.2.4, 6.3.2.5, 6.3.5.4-5). Some corals and temperate fishes experience disturbances to behavior, navigation and their ability to tell conspecifics from predators (6.3.2.4). However, there is no evidence for these effects to persist on evolutionary timescales in the few groups analyzed (6.3.2).

Some phytoplankton and mollusks displayed adaptation to ocean acidification in long-term experiments (*limited evidence, medium agreement*; 6.3.2.1), indicating that the long-term responses could be less than responses obtained in short-term experiments. However, mass extinctions in Earth history occurred during much slower rates of ocean acidification, combined with other drivers changing, suggesting that evolutionary rates are not fast enough for sensitive animals and plants to adapt to the projected rate of future change (*medium confidence*; 6.1.2).

Projections of ocean acidification effects at ecosystem level are made difficult by the diversity of species-level responses. Differential sensitivities and associated shifts in performance and distribution will change predator-prey relationships and competitive interactions (6.3.2.5, 6.3.5-6), which could impact food webs and higher trophic levels (*limited evidence, high agreement*). Natural analogues at CO_2 vents indicate decreased species diversity, biomass and trophic complexity of communities (Box CC-CR; 5.4.2.3, 6.3.2.5, 30.3.2.2, 30.5). Shifts in community structure have also been documented in regions with rapidly declining pH (5.4.2.2).

Due to an incomplete understanding of species-specific responses and trophic interactions the effect of ocean acidification on global biogeochemical cycles is not well understood (*limited evidence, low agreement*) and represents an important knowledge gap. The additive, synergistic or antagonistic interactions of factors such as temperature, concentrations of oxygen and nutrients, and light are not sufficiently investigated yet.

Risks, Socioeconomic Impacts and Costs

The risks of ocean acidification to marine organisms, ecosystems, and ultimately to human societies, include both the probability that ocean acidification will affect fundamental physiological and ecological processes of organisms (6.3.2.1), and the magnitude of the resulting impacts on ecosystems and the ecosystem services they provide to society (Box 19-2). For example, ocean acidification under RCP4.5 to RCP8.5 will impact formation and maintenance of coral reefs (*high confidence*; Box CC-CR, 5.4.2.4) and the goods and services that they provide such as fisheries, tourism and coastal protection (*limited evidence, high agreement*; Box CC-CR, 6.4.1.1,19.5.2, 27.3.3, 30.5, 30.6). Ocean acidification poses many other potential risks, but these cannot yet be quantitatively assessed due to the small number of studies available, particularly on the magnitude of the ecological and socioeconomic impacts (19.5.2).

Global estimates of observed or projected economic costs of ocean acidification do not exist. The largest uncertainty is how the impacts on lower trophic levels will propagate through the food webs and to top predators. However, there are a number of instructive examples that illustrate the magnitude of potential impacts of ocean acidification. A decrease of the production of commercially-exploited shelled mollusks (6.4.1.1) would result in a reduction of US production of 3 to 13% according to the SRES A1FI emission scenario (*low confidence*). The global cost of production loss of mollusks could be over 100 billion USD by 2100 (*limited evidence, medium agreement*). Models suggest that ocean acidification will generally reduce fish biomass and catch (*low confidence*) and that complex additive, antagonistic and/or synergistic interactions will occur with other environmental (warming) and human (fisheries management) factors (6.4.1.1). The annual economic damage of ocean-acidification-induced coral reef loss by 2100 has been estimated, in 2009, to be 870 and 528 billion USD, respectively for the A1 and B2 SRES emission scenarios (*low confidence*; 6.4.1). Although this number is small compared to global GDP, it can represent a very large GDP loss for the economies of many coastal regions or small islands that rely on the ecological goods and services of coral reefs (25.7.5, 29.3.1.2).

Mitigation and Adaptation

Successful management of the impacts of ocean acidification includes two approaches: mitigation of the source of the problem (i.e. reduce anthropogenic emissions of CO_2), and/or adaptation by reducing the consequences of past and future ocean acidification (6.4.2.1). Mitigation of ocean acidification through reduction of atmospheric CO_2 is the most effective and the least risky method to limit ocean acidification and its impacts (6.4.2.1). Climate geoengineering techniques based on solar radiation management will not abate ocean acidification and could increase it under some circumstances (6.4.2.2). Geoengineering techniques to remove carbon dioxide from the atmosphere could directly address the problem but are very costly and may be limited by the lack of CO_2 storage capacity (6.4.2.2). Additionally, some ocean-based approaches, such as iron fertilization, would only re-locate ocean acidification from the upper ocean to the ocean interior, with potential ramifications on deep-water oxygen levels (6.4.2.2; 30.3.2.3 and 30.5.7). A low-regret approach, with relatively limited effectiveness, is to limit the number and the magnitude of drivers other than CO_2, such as nutrient pollution (6.4.2.1). Mitigation of ocean acidification at the local level could involve the reduction of anthropogenic inputs of nutrients and organic matter in the coastal ocean (5.3.4.2). Some adaptation strategies include drawing water for aquaculture from local watersheds only when pH is in the right range, selecting for less sensitive species or strains, or relocating industries elsewhere (6.4.2.1).

Box CC-TC. Building Long-Term Resilience from Tropical Cyclone Disasters

[Yoshiki Saito (Japan), Kathleen McInnes (Australia)]

Tropical cyclones (also referred to as hurricanes and typhoons in some regions or strength) cause powerful winds, torrential rains, high waves and storm surge, all of which can have major impacts on society and ecosystems. Bangladesh and India account for 86% of mortality from tropical cyclones (Murray et al., 2012), which is mainly due to the rarest and most severe storm categories (i.e. Categories 3, 4, and 5 on the Saffir-Simpson scale).

About 90 tropical cyclones occur globally each year (Seneviratne et al., 2012) although interannual variability is large. Changes in observing techniques particularly after the introduction of satellites in the late 1970s, confounds the assessment of trends in tropical cyclone frequencies and intensities. Therefore, IPCC (2012) "Special Report on Managing the Risks of Extreme Events and Disasters to Advance Climate Change Adaptation (SREX)" concluded that there is *low confidence* that any observed long-term (i.e. 40 years or more) increases in tropical cyclone activity are robust, after accounting for past changes in observing capability (Seneviratne et al., 2012; Chapter 2). There is also *low confidence* in the detection and attribution of century scale trends in tropical cyclones. Future changes to tropical cyclones arising from climate change are *likely* to vary by region. This is because there is *medium confidence* that for certain regions, shorter-term forcing by natural and anthropogenic aerosols has had a measurable effect on tropical cyclones. Tropical cyclone frequency is *likely* to decrease or remain unchanged over the 21st century, while intensity (i.e. maximum wind speed and rainfall rates) is *likely* to increase (AR5 WG1 Ch 14.6). Regionally specific projections have *lower confidence* (see AR5 WG1 Box 14.2).

Longer-term impacts from tropical cyclones include salinisation of coastal soils and water supplies and subsequent food and water security issues from the associated storm surge and waves (Terry and Chui, 2012). However, preparation for extreme tropical cyclone events through improved governance and development to reduce their impacts provides an avenue for building resilience to longer-term changes associated with climate change.

Densely populated Asian deltas are particularly vulnerable to tropical cyclones due to their large population density in expanding urban areas (Nicholls et al., 2007). Extreme cyclones in Asia since 1970 caused over 0.5 million fatalities (Murray et al., 2012) e.g., cyclones Bhola in 1970, Gorky in 1991, Thelma in 1998, Gujarat in 1998, Orissa in 1999, Sidr in 2007, and Nargis in 2008. Tropical cyclone Nargis hit Myanmar on 2 May 2008 and caused over 138,000 fatalities. Several-meter high storm surges widely flooded densely populated coastal areas of the Irrawaddy Delta and surrounding areas (Revenga et al., 2003; Brakenridge et al., 2013). The flooded areas were captured by a NASA MODIS image on 5 May 2008 (see Figure TC-1).

[INSERT FIGURE TC-1 HERE
Figure TC-1: The intersection of inland and storm surge flooding. Red shows May 5, 2008 MODIS mapping of the tropical cyclone Nargis storm surge along the Irrawaddy Delta and to the east, Myanmar. The blue areas to the north were flooded by the river in prior years. Source: Brakenridge et al., 2013.]

Murray et al. (2012) compared the response to cyclone Sidr in Bangladesh in 2007 and Nargis in Myanmar in 2008 and demonstrated how disaster risk reduction methods could be successfully applied to climate change adaptation. Sidr, despite being of similar strength to Nargis, caused far fewer fatalities (3,400 compared to over 138000) and this was attributed to advancement in preparedness and response in Bangladesh through experience in previous cyclones such as Bhola and Gorky. The responses included the construction of multistoried cyclone shelters, improvement of forecasting and warning capacity, establishing a coastal volunteer network, and coastal reforestation of mangroves. The strategies of disaster risk management for tropical cyclones in coastal areas, that create protective measures, anticipate and plan for extreme events, increase the resilience of potentially exposed communities. The integration of activities relating to education, training, and awareness-raising into relevant ongoing processes and practices is important for the long-term success of disaster risk reduction and management (Murray et al., 2012). Birkmann and Teichman (2010) caution that while the combination of risk reduction and climate change adaptation strategies may be desirable, different spatial and temporal scales, norm systems, and knowledge types and sources between the two goals can confound their effective combination.
